Title of the Russian edition:

KURS TEORETICHESKOJ FIZIKI

Russian edition published by:

IZDATELSTVO 'NAUKA', GLAVNAJA REDAKCIJA,

FIZIKO-MATEMATIČESKOJ LITERATURY (MOSKVA, 1969)

FOREWORD

The first Russian edition of 'Theoretical Physics', which appeared in 1962, has been widely used as a textbook.

Numerous comments from colleagues, lecturers and students have been taken into account in preparing this new edition, which is the first one in English and which will also appear as the second Russian edition.

The material has now been divided into 4 volumes covering the following subjects

Volume 1

- Part I Theory of the Electromagnetic Field
- Part II Theory of Relativity

Volume 2

- Part III Statistical Physics
- Part IV Electromagnetic Processes in Matter

Volume 3

- Part V Quantum Mechanics

Volume 4

- Part VI Quantum Statistics and Physical Kinetics

The rapid development of physics and the present wide interest in non-equilibrium and non-stationary processes has compelled us to expand the section on physical kinetics. It has also been transferred to the end of Volume 4 as it is practically impossible to expound this topic without using quantum mechanics.

Part IV — 'Electromagnetic Processes in Matter' — has been substantially revised. Interest in this field has increased recently, mainly in connection with the study of plasmas and plasma-like media, which now have sections devoted to them.

The methods of calculating electrostatic and direct-current fields, and other problems of classical electrodynamics in a medium, are covered very briefly as we have assumed that students will be able to consult the many monographs and handbooks on general physics, electrical- and radio-technology, and the equations of mathematical physics.

As for other modifications and additions, we should draw attention to the introduction of tensor notation, to new ideas in the theories of relativity and electromagnetic fields, the broadening of the introduction to the theory of probability, a brief presentation of the method of correlation functions in statistical physics, the exposition of the thermodynamic theory of ferromagnetism and the theory of propagation of electromagnetic waves in plasma. A number of paragraphs have been rewritten. We have tried to bring the content of the book even closer to the interests of present-day theoretical physics.

The general level of the book has been preserved and it is still intended to form an introduction to theoretical physics. Problems requiring the use of cumbersome or special mathematical apparatus are still excluded, and the most difficult sections are marked by an asterisk. These may be skipped at will, since there is no reference to them in the main text.

In conclusion we would like to express our gratitude to all those who helped us in preparing this book, in particular to A.M. Brodsky, A.M. Golovin, B.M. Grafov, R.R. Dogonadze, V.S. Krylov and especially V.S. Markin and V.V. Tolmachev. I.V. Savelyev discovered a number of misprints which have now been corrected.

L.D. Konkina helped us in editing the manuscript.

We are grateful to the readers and students who used the first Russian edition of the book for sending us their valuable comments which have been taken into account in this edition.

August 1970

FOREWORD TO THE FIRST RUSSIAN EDITION

The continuous development of theoretical physics and the regular expansion of its areas of application create increasing demand for textbooks and manuals.

The rapid development and the complexity of the most recent experimental methods of physical investigation, and the corresponding development and extension of the mathematical apparatus of theoretical physics, have meant that one man usually cannot combine the two methods of investigation. The end of the 19th century and particularly the 20th century therefore saw physicists divided into 'experimentalists' and 'theoreticians', the latter studying physical laws by means of the mathematical methods of theoretical physics.

Obviously, a background in theoretical physics is essential in the education of experimental as well as theoretical physicists.

The experimental and theoretical methods of physical investigation have penetrated into a number of branches of science related to physics (physical chemistry, biophysics, geophysics, astrophysics, and so on) and into technology (metal physics and metallurgical science, thermophysics, electrical technology, radiotechnology, computation, the instrument-making industry etc.). Workers in these branches of science and technology also need a certain minimum knowledge of theoretical physics.

The compilation of a modern textbook on theoretical physics is inevitably associated with certain logical and methodological difficulties. It is impossible at present to divide theoretical physics into classical and quantum parts so that it is also impossible to divide it into separate chapters and sections. For example, the exposition of statistical physics without taking into account the quantum properties of atomic systems is impossible, for it would mean that the general theory remained without practical application. In the theory of electromagnetic processes in matter one has of necessity to make use of the ideas of statistical physics, and so on. It may be that the maximum consistency of composition would be obtained if the book were founded on

quantum mechanics but this is completely inadmissible in a book intended as an introductory treatise. Quantum mechanics requires a certain preparedness and the student must be convinced of the necessity of renouncing obvious classical representations. Compromise solutions, which have justified themselves during many years of teaching theoretical physics at the Moscow Engineering-Physical Institute and Moscow State University, are therefore inevitable.

The following general principles have been applied.

(1) The book is written as an introduction to theoretical physics so that aspects requiring the use of cumbersome or special mathematical apparatus have not been included.

(2) As it is to be used for a systematic study of the subject the course is a unique whole and all material necessary for understanding the later sections is contained in the earlier ones.

(3) It would not be feasible to elucidate experimental facts in addition to problems concerning purely theoretical physics. However, physics is a single science, and an attempt to expound the theoretical aspects without taking experiment into account would be quite wrong. The reader is assumed to have some basic experimental knowledge from university courses in general and atomic physics so that we have confined ourselves to references and, in a few instances, to a schematic description of basic experiments.

(4) The acquaintance assumed with general courses in general and atomic physics has allowed us to rely on a certain (very restricted) knowledge of quantum mechanics in our treatment of statistical physics.

(5) Classical mechanics usually forms a separate course so that this topic has been omitted although detailed reference has been made to handbooks of mechanics.

(6) The book similarly does not cover hydrodynamics, aerodynamics, the theory of heat transfer, or problems related to electrical- and radio-technology.

(7) Detailed reference is made to mathematical manuals. The mathematical apparatus utilized, except in the sections marked by an asterisk, is covered by the usual courses in analysis. In the case of quantum mechanics, however, the mathematical apparatus has been included, since it is of a specific character and is not taught in traditional mathematical courses.

(8) As the book is intended as a systematic course in theoretical physics no attempt has been made to achieve the same level of accessibility in all sections. It is a well-known fact that a student's comprehension and assimilation of difficult material increases as a course progresses, and that this is also true for the associated mathematical apparatus. Moreover, experi-

mental physicists will constantly encounter new problems in quantum mechanics which can only be handled using advanced methods of treatment. The section on quantum mechanics (Part V) therefore deals with some topics having a more advanced character than those in other sections. The analysis of applications of the kinetic equations is similarly treated rather extensively.

The uniqueness of the book's objectives has affected the content of individual sections, so that some topics in modern physics have been included at the expense of more traditional material.

Part I contains the foundations of the theory of the electromagnetic field in a vacuum, based on the system of Maxwell-Lorentz equations. A basic knowledge of electromagnetism is assumed. The focus of attention is the theory of radiation and the motion of charged particles in external fields.

In Part II, devoted to the theory of relativity, a four-dimensional form of representation is adopted which not only corresponds to the spirit of the theory but also predominates in contemporary literature. The problems of dynamics in the theory of relativity are treated in some detail. A number of the most recent applications of the theory of relativity, particularly those related to nuclear physics, are covered here for the first time in a textbook.

Part III is a revised version of Levich's 'Introduction to Statistical Physics' and treats statistical physics and the fundamentals of statistical thermodynamics. Classical thermodynamics would require too much space, and did not seem indispensable.

Part IV contains the theory of electromagnetic processes in matter. Relatively little attention is paid to problems in theoretical electrical- and radio-technology. The phenomenological theory of electric and magnetic properties of matter is analyzed in some detail, and the notion of the physics of the plasma state of matter is given.

In Part V the basic ideas of present-day relativistic quantum mechanics are included as well as the traditional problems of non-relativistic quantum mechanics. Applications to solid-state theory are considered at length.

Part VI contains the essential concepts of physical kinetics, which are not usually presented in a general course on theoretical physics.

The experience of teaching theoretical physics shows that the greatest difficulties are often encountered not in understanding new physical ideas but in the actual mathematical treatments. All mathematical operations have therefore been performed in sufficient detail.

For convenience we have presented a brief derivation of those formulae of

vector analysis which are encountered throughout, as well as the necessary data on Fourier integrals and δ -function theory.

The numbering of formulae and sections starts afresh in each Part and references to appendices have been given Roman numerals.

The author hopes that the readers, after making themselves familiar with the foundations of theoretical physics expounded in this book, will be able to proceed to a more profound study using the many-volume treatise of Landau and Lifshitz. The scientific and educational ideas of their work were of great influence on the author, who is a disciple of Landau.

Parts I–IV and Part VI were written by B.G. Levich. Part V was written by Y.A. Vdovin and V.A. Myamlin under the general scientific guidance of B.G. Levich. Chapter XV * of Part V was written by A.I. Naumov.

The author expresses his gratitude to the colleagues who read the book and the manuscripts, and made a number of valuable remarks: B.M. Grafov, R.R. Dogonadze, V.A. Kiryanov, V.S. Krylov, V.S. Markin, V.P. Smilga, Y.A. Chizmadzhev and Y.I. Yalamov.

The creation of a textbook on theoretical physics sufficiently comprehensive in content and clear in presentation is a very complex task. The author is therefore conscious of the fact that shortcomings and errors will be discovered and would be grateful to receive an account of them which can be taken into consideration in the next edition of the book.

1962

* Chapter 13 of the English edition.

Theoretical Physics: Outline of Vols. 1—4

Volume 1 (for details see p. xv)

Part I Theory of the Electromagnetic Field

- Chapter 1 General theory of the electromagnetic field
- 2 The electrostatic field
 - 3 The quasistationary magnetic field
 - 4 The electromagnetic field of arbitrarily moving charges
 - 5 Radiation theory
 - 6 Electromagnetic field in a vacuum and electromagnetic wave scattering
 - 7 The motion of particles in electromagnetic fields

Part II Theory of Relativity

- Chapter 1 General principles of the theory of relativity
- 2 Relativistic mechanics
 - 3 Relativistic electrodynamics

Appendix I, II and III

Subject index

Volume 2

Part III Statistical Physics

- Chapter 1 The basic concepts of the theory of probability
- 2 The kinetic theory of gases

- 3 Statistical distribution
- 4 Statistical and phenomenological thermodynamics
- 5 Ideal gases
- 6 Systems of interacting particles
- 7 Crystals
- 8 The theory of fluctuations
- 9 Systems with a variable number of particles
- 10 Statistical distributions in quantum statistics and some of their applications

Part IV Electromagnetic Processes in Matter

- Chapter 1 Electromagnetic fields in matter
- 2 Electrostatics
 - 3 Direct electric current and the magnetic properties of matter
 - 4 Quasistationary electromagnetic fields
 - 5 High-frequency fields
 - 6 Matter in the plasma state

Appendix IV

Subject index

Volume 3

Part V Quantum Mechanics

- Chapter 1 The basic concepts of quantum mechanics
- 2 The Schrödinger equation
 - 3 The mathematical apparatus of quantum mechanics
 - 4 Motion in a centrally symmetric field
 - 5 The quasi-classical approximation
 - 6 The matrix form of quantum mechanics
 - 7 Perturbation theory
 - 8 Spin and identity of particles
 - 9 Applications of quantum mechanics to the consideration of the properties of atomic and nuclear systems
 - 10 The theory of diatomic molecules
 - 11 Scattering theory

- 12 The method of second-quantization and radiation theory
- 13 Relativistic quantum mechanics
- 14 Some problems of quantum electrodynamics
- 15 Fundamentals of the theory of elementary particles

Subject index

Volume 4

Part VI Quantum Statistics and Physical Kinetics

- Chapter 1 Quantum statistics
- 2 Physical kinetics
- 3 Kinetic theory of gases and gas-like systems
- 4 Time correlative function method and Onsager's theory
- 5 Solid-state theory

Subject index

Contents of Volume 1

Part I Theory of the electromagnetic field

Chapter 1 General theory of the electromagnetic field

§ 1	Problems of theoretical physics	1
2	The determination of the vector field from its integral characteristics	3
3	Charges and particles	9
4	The field of charges at rest	11
5	The equation of continuity	16
6	The electromagnetic field of charges moving with a constant velocity	18
7	The electromagnetic field of moving charges. The general case	23
8	Maxwell—Lorentz system of equations	28
9	The displacement current	30
10	The electromagnetic field potentials	34
11	Gauge invariance of the potentials	37
12	Energy conservation law of the electromagnetic field	40
13	Momentum conservation law of the electromagnetic field	44

Chapter 2 The electrostatic field

14	The electrostatic field	49
15	The electrostatic field of a system of point charges	52
16	Quadrupole moment	57
17	Work and energy in an external electrostatic field	62
18	The interaction energy of a system of charges and the electrostatic field energy	65

Chapter 3 The quasistationary magnetic field

§19 The field of a system of charges undergoing a slow quasistationary motion	69
20 The field of a point charge undergoing a slow uniform motion	76
21 The field of a system of charges undergoing quasistationary motion at a large distance from the system	79
22 The magnetic moment	82

Chapter 4 The electromagnetic field of arbitrarily moving charges

23 The electromagnetic field of a system of arbitrarily moving charges	85
24 General solution of D'Alembert's equation in the form of retarded potentials	94
25 The field of a point charge moving arbitrarily	102

Chapter 5 Radiation theory

26 The potentials of the electromagnetic field at a large distance from the emitter in the dipole approximation	106
27 The electromagnetic field of dipole radiation at a large distance from the emitter	112
28 Dipole radiation of simple systems	116
29 Radiation reaction	121
30 Line width of emitted radiation	125
31 Quadrupole and magnetic dipole radiation	129
32 General case of electromagnetic radiation. The spectral decomposition of fields. The radiation zone and induction zone. Effect of the proper retardation	134

Chapter 6 Electromagnetic field in a vacuum and electromagnetic wave scattering

33 The propagation of electromagnetic waves at a large distance from the emitter	142
34 Plane wave polarization	149
35 Interference and the formation of wave packets	152
36 Scattering of the electromagnetic waves by a free charge and by a bound electron	157
37 Absorption of radiation	162
38 Canonical form of the field equations	164

Chapter 7 The motion of particles in electromagnetic fields

§ 39 The motion of charged particles in constant electric and magnetic fields	174
40 The motion of charged particles in slowly varying magnetic fields	182
41 The Lagrangian and Hamiltonian for a particle moving in an electromagnetic field	187
42 The motion of a system of two charged particles and the radiation from them	189
43 The scattering of particles and associated bremsstrahlung	196

Part II Theory of relativity*Chapter 1 General principles of the theory of relativity*

§ 1 The creation and significance of the theory of relativity	215
2 Galilean transformations	216
3 Attempts to determine an absolute velocity	219
4 Postulates of the Einstein theory of relativity	222
5 The Lorentz transformation	224
6 Consequences of the Lorentz transformation. Space and time intervals	228
7 Einstein's law of addition of velocities and angular transformations	234
8 Simultaneity, short-range action and action at a distance	237
9 Absolute values in the theory of relativity. Intervals and proper time	238
10 The invariance of physical laws under Lorentz transformations. Four-dimensional formulation of the theory of relativity	242
11 Four-dimensional vectors and tensors. Four-dimensional velocity and acceleration	248

Chapter 2 Relativistic mechanics

12 The dynamical equations of a material point	256
13 Momentum, energy and mass in relativistic mechanics	260
14 Lagrange's equations; the Lagrangian and Hamiltonian	267

§ 15	The mechanics of a system of particles in the theory of relativity	268
16	The energy-momentum conservation law in nuclear physics	274
17	The theory of collisions between relativistic particles. Compton effect	286
 <i>Chapter 3 Relativistic electrodynamics</i>		
18	Charge conservation, the four-dimensional current and the equation of continuity	292
19	The relativistically invariant formulation of the equations of the electromagnetic field potentials	294
20	The field of a moving charge	296
21	The electromagnetic field tensor and Maxwell's equations	304
22	Some applications: Doppler effect, Mössbauer effect, observation of rapidly moving bodies, transformation of angles, intensities and cross sections	307
23	The Lorentz force; the Lagrangian and the Hamiltonian for a particle moving in an electromagnetic field	325
24	The motion of particles in constant electric and magnetic fields	331
25	A system of weakly interacting charged particles	340
26	The radiation emitted by a moving charge	350

Subject index		387

PART I

THEORY OF THE
ELECTROMAGNETIC FIELD

General Theory of the Electromagnetic Field

§1. Problems of theoretical physics

Physics is first of all an experimental science. However, in the work of Newton and other founders of contemporary physics, mathematical methods were successfully applied to obtain the quantitative formulation of physical laws, at first mainly in mechanics.

In the last century the application of mathematical methods to physics was so extensive that there arose the particular branch of physics known as theoretical physics. Problems facing theoretical physics are of two kinds:

1. The expression of physical laws in the form of quantitative relations, and the establishment of underlying correlations among experimental facts.
2. The application of mathematical methods of investigation to find new physical laws and the prediction of new, as yet not experimentally observed connections between physical phenomena.

Thus, theoretical physics is, in its methods, a mathematical science, and, in its content, a physical science.

From the above it is clear that it is in theoretical physics that general theoretical views concerning the essence of various physical processes are embodied and made complete.

It is best to illustrate this by a simple example. Investigators who established experimentally the planetary atomic model and the presence of dis-

crete allowed energy values in atoms and similar facts, gave a paramount contribution to theoretical physics. However, theoretical physics could not confine itself to the qualitative model representations of the atomic structure. From this it follows that theoretical physics seeks to formulate the most general quantitative physical laws expressing the essence of as wide a range of phenomena as possible. Mechanical laws (Newtonian laws), the laws of the electromagnetic field (Maxwell-Lorentz equations), and the laws of quantum mechanics etc. serve as examples.

Logical reasoning cannot be the basis of general physical laws. Only experimental facts can be this. Hence the most general quantitative relations of theoretical physics are not 'derived', but represent a generalized formulation of observed physical regularities. On the other hand, as we shall see in concrete examples, in a number of cases the quantitative expression of physical laws appeared as a result of scientific prediction.

Having at its disposal a quantitative formulation of general physical laws, theoretical physics can undertake the second part of its program — the establishment of new laws and relations by means of mathematical methods. In this way theoretical physics has achieved such great successes that in comparison with them even such examples of scientific prediction as Leverrier's discovery of the planet Neptune in the nineteenth century appear to be of minor importance.

As examples one can point to the discovery of displacement current by Maxwell and the consequent establishment of the electromagnetic nature of light; the foundation of the theory of relativity by Einstein and, in particular, establishment of the mass-energy relation; the prediction by quantum mechanics (founded by de Broglie, Schrödinger and Heisenberg) of the existence of the wave properties of microparticles — electrons, protons, etc.; the prediction by Dirac's theory of the existence and properties of the positron and other antiparticles, and so forth. The role of theoretical physics in the recent development of nuclear physics and in the application of atomic energy is well-known.

It is necessary to stress that the methods of calculation of theoretical physics are of a special character. Theoretical physics is not a branch of mathematics. In theoretical physics one does not try to find the exact physical laws defining the behaviour of even relatively simple systems. An exact calculation of all possible effects and interrelations would make even the most simple problems insoluble. The necessity of taking into account essential relations and disregarding unessential ones is borne in mind in every stage of investigation in theoretical physics. The relations and equations of theoretical physics are so complicated that one must practically always proceed by

approximate calculations. In order to find out which approximations are possible and advisable and which ones are unjustifiable and physically senseless, one must often proceed from available experimental data. At the same time, formulae and relations which in principle cannot be checked experimentally are not considered at all in theoretical physics. All efforts of theoretical as well as experimental physics are directed to explaining objectively existing relations, i.e. the physical laws of nature.

A physical theory explaining known facts but unable to predict new ones is always considered unsatisfactory. On the other hand, the highest appraisal of the validity of a physical theory is the experimental confirmation of the facts predicted by it. In its turn, the elucidation of new phenomena observed experimentally serves as a stimulus for further development of theoretical physics. Thus, experimental and theoretical physics make a single and inseparable whole.

§ 2. The determination of the vector field from its integral characteristics

We shall see in what follows that the state of an electromagnetic field is specified by its vector characteristics — i.e. the strengths of the electric and magnetic fields. For this reason, in putting forward the general theory and in solving definite problems in the theory of the electromagnetic field, extensive use is made of a specific mathematical apparatus, the so-called vector analysis.

A description of the electromagnetic field which is not based on vector analysis is possible in principle, but would require very cumbersome calculations and complicated transformations. Hence the subsequent exposition is carried out solely on the basis of vector analysis. Although we assume that the reader is familiar with its fundamentals, Appendix I gives a brief derivation of all the formulae and transformations which are to be encountered.

We shall analyse here an important problem of the mathematical theory of the arbitrary vector field. The importance of this problem in the theory of the electromagnetic field lies in the fact that the general scheme of calculation of the field theory is constructed according to the calculation of the arbitrary vector field presented below.

Let there be a vector field $\mathbf{a}(\mathbf{r})$ over all space. Some assumptions, which will be mentioned below, will be made about the behaviour of the vector $\mathbf{a}(\mathbf{r})$ at infinitely distant points of space.

Assume that at every point of space the integral characteristics of the field, the vector flux $\oint \mathbf{a} \cdot d\mathbf{S}$ and the vector circulation $\oint \mathbf{a} \cdot d\mathbf{l}$, are given. We shall see in what follows that for electromagnetic fields it is just these character-

istics which contain the quantities which can be directly measured experimentally. We shall show that, if these field characteristics are given, then the vector field $\mathbf{a}(\mathbf{r})$ can itself be found. If $\oint \mathbf{a} \cdot d\mathbf{S} = \int f(\mathbf{r}) dV$, where $f(\mathbf{r})$ is a known function of coordinates, then on the basis of the Gauss-Ostrogradsky theorem

$$\oint \mathbf{a} \cdot d\mathbf{S} = \int \nabla \cdot \mathbf{a} dV = \int f(\mathbf{r}) dV, \quad (2.1)$$

and in view of the arbitrary character of the integration range over a volume V , we have

$$\nabla \cdot \mathbf{a} = f(\mathbf{r}). \quad (2.2)$$

Thus, the definition of the vector flux through a closed surface at every point of space is equivalent to the definition of the divergence of the vector.

Further, on the basis of Stokes' theorem,

$$\oint \mathbf{a} \cdot d\mathbf{l} = \oint (\nabla \times \mathbf{a}) \cdot d\mathbf{S} = \int \boldsymbol{\omega}(\mathbf{r}) \cdot d\mathbf{S}, \quad (2.3)$$

where $\boldsymbol{\omega}(\mathbf{r})$ is a known vector function of coordinates. Hence

$$\nabla \times \mathbf{a} = \boldsymbol{\omega}(\mathbf{r}). \quad (2.4)$$

The definition of the vector circulation is equivalent to the definition of its curl.

We shall show how the vector field $\mathbf{a}(\mathbf{r})$ can be found if the divergence and curl of the vector \mathbf{a} are known over all space.

We resolve the field \mathbf{a} into two fields: $\mathbf{a} = \mathbf{a}_1 + \mathbf{a}_2$, so that the following relations hold:

$$\nabla \cdot \mathbf{a}_1 = f(\mathbf{r}), \quad (2.5)$$

$$\nabla \times \mathbf{a}_1 = 0, \quad (2.5')$$

$$\nabla \cdot \mathbf{a}_2 = 0, \quad (2.6)$$

$$\nabla \times \mathbf{a}_2 = \boldsymbol{\omega}(\mathbf{r}). \quad (2.6')$$

The vector field \mathbf{a}_1 is vortex-free; its lines begin and end in the sources and sinks whose intensity is given by the function $f(\mathbf{r})$. The vector field \mathbf{a}_2 has no sources and no sinks, and is a solenoidal field.

Let us begin with the consideration of the field \mathbf{a}_1 . Since the field \mathbf{a}_1 is

vortex-free, the vector \mathbf{a}_1 can be written in the form of the gradient of a certain auxiliary scalar function

$$\mathbf{a}_1 = \nabla \varphi(\mathbf{r}), \quad (2.7)$$

where $\varphi(\mathbf{r})$ is a function called the scalar potential. Substituting eq. (2.7) into (2.5), we find $\nabla \cdot \nabla \varphi = f(\mathbf{r})$, or

$$\nabla^2 \varphi = f(\mathbf{r}), \quad (2.8)$$

where

$$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$$

is the Laplacian.

Eq. (2.8) represents a second order partial differential equation, called Poisson's equation. We shall obtain its general solution in § 24. Here we shall give only the final result and convince ourselves of the fact that this solution satisfies eq. (2.8). It turns out that the solution of Poisson's equation has the form

$$\begin{aligned} \varphi(\mathbf{r}) &= -\frac{1}{4\pi} \int \frac{f(\mathbf{r}_0) dV_0}{|\mathbf{r} - \mathbf{r}_0|} = \\ &= -\frac{1}{4\pi} \int \frac{f(x_0, y_0, z_0) dx_0 dy_0 dz_0}{\sqrt{(x - x_0)^2 + (y - y_0)^2 + (z - z_0)^2}}, \end{aligned} \quad (2.9)$$

where x, y, z are the coordinates of the point of observation, i.e. of that point at which the value of the function φ is sought, while x_0, y_0, z_0 are the variables of integration. The quantity

$$|\mathbf{r} - \mathbf{r}_0| = \sqrt{(x - x_0)^2 + (y - y_0)^2 + (z - z_0)^2}$$

represents the distance from the point \mathbf{r}_0 to the point of observation \mathbf{r} . Substituting (2.9) into (2.8) one can easily verify that the expression given indeed satisfies the initial equation:

$$\begin{aligned}
\nabla^2 \varphi &= - \nabla^2 \frac{1}{4\pi} \int \frac{f(x_0, y_0, z_0) dx_0 dy_0 dz_0}{|\mathbf{r} - \mathbf{r}_0|} = \\
&= - \frac{1}{4\pi} \int f(x_0, y_0, z_0) dV_0 \nabla^2 \frac{1}{|\mathbf{r} - \mathbf{r}_0|} = \\
&= \int f(x_0, y_0, z_0) \delta(x - x_0) \delta(y - y_0) \delta(z - z_0) dx_0 dy_0 dz_0 = \\
&= f(x, y, z).
\end{aligned}$$

Here we have made use of the properties of the δ -function and the function $1/|\mathbf{r} - \mathbf{r}_0|$ (see Appendix III). The operator ∇^2 denotes differentiation with respect to the coordinates \mathbf{r} and can be brought under the integration sign with respect to the coordinates \mathbf{r}_0 .

If the integration is carried out over all space, it is necessary for the existence and convergence of the integral (2.9) that the integrand $f(\mathbf{r}_0)$ should satisfy the obvious requirement

$$|f(\mathbf{r}_0) \cdot r_0^{2+\lambda}| < A \quad \text{as} \quad r_0 \rightarrow \infty, \quad (2.10)$$

where A is a finite quantity and $\lambda > 0$. In other words, the function $f(\mathbf{r}_0)$ must decrease more rapidly than the function $1/r_0^2$ as $r_0 \rightarrow \infty$. When this condition is fulfilled the integral (2.9) converges, and the function $\varphi(r)$ decreases as its argument increases indefinitely according to the law

$$|\varphi(r)| < 1/r. \quad (2.11)$$

Assuming the condition (2.10) to be fulfilled, we can state that (2.9) represents the solution of eq. (2.8).

Knowing the function $\varphi(\mathbf{r})$ and making use of the definition (2.7), we find

$$\mathbf{a}_1(\mathbf{r}) = \nabla \varphi(\mathbf{r}) = - \frac{1}{4\pi} \nabla \int \frac{f(\mathbf{r}_0) dV_0}{|\mathbf{r} - \mathbf{r}_0|}. \quad (2.12)$$

We now pass on to the determination of the vector $\mathbf{a}_2(\mathbf{r})$. The vector \mathbf{a}_2 is of a solenoidal character and, consequently, can be written in the form of the curl of a certain auxiliary vector $\mathbf{A}(\mathbf{r})$:

$$\mathbf{a}_2 = \nabla \times \mathbf{A}(\mathbf{r}) \quad (2.13)$$

The vector function $\mathbf{A}(\mathbf{r})$ is called the vector potential. From the definition (2.13) it is clear that eq. (2.6) is satisfied automatically:

$$\nabla \cdot \nabla \times \mathbf{A}(\mathbf{r}) = 0.$$

To determine the vector potential \mathbf{A} completely it is necessary in addition to give the value of its divergence $\nabla \cdot \mathbf{A}$, which for the present remains arbitrary. We assume

$$\nabla \cdot \mathbf{A} = 0. \quad (2.14)$$

Somewhat later we shall verify the fact that the above assumption does not restrict the general character of our reasoning. Substituting (2.13) into (2.6'), we have

$$\nabla \times [\nabla \times \mathbf{A}(\mathbf{r})] = \nabla [\nabla \cdot \mathbf{A}(\mathbf{r})] - \nabla^2 \mathbf{A}(\mathbf{r}) = \boldsymbol{\omega}(\mathbf{r}).$$

Taking into account (2.14), we find

$$\nabla^2 \mathbf{A}(\mathbf{r}) = -\boldsymbol{\omega}(\mathbf{r}) \quad (2.15)$$

or, in the scalar form,

$$\nabla^2 A_x = -\omega_x(\mathbf{r}), \quad \nabla^2 A_y = -\omega_y(\mathbf{r}), \quad \nabla^2 A_z = -\omega_z(\mathbf{r}).$$

The components of the vector potential satisfy the same equations as the scalar potential φ . Their solutions read:

$$A_x = \frac{1}{4\pi} \int \frac{\omega_x(\mathbf{r}_0)}{|\mathbf{r} - \mathbf{r}_0|} dV_0, \quad (2.16)$$

$$A_y = \frac{1}{4\pi} \int \frac{\omega_y(\mathbf{r}_0)}{|\mathbf{r} - \mathbf{r}_0|} dV_0, \quad (2.16')$$

$$A_z = \frac{1}{4\pi} \int \frac{\omega_z(\mathbf{r}_0)}{|\mathbf{r} - \mathbf{r}_0|} dV_0 \quad (2.16'')$$

If the functions ω_x , ω_y and ω_z satisfy the same conditions at infinity as those which must be satisfied by the function $f(\mathbf{r}_0)$ in (2.9), then the integrals in the expressions (2.16)–(2.16'') converge. In this case formulae (2.16)–

(2.16'') determine the vector potential \mathbf{A} . Knowing the vector potential \mathbf{A} , one can find the vector \mathbf{a}_2 by a simple differentiation:

$$\mathbf{a}_2(\mathbf{r}) = \nabla \times \left[\frac{1}{4\pi} \int \frac{\boldsymbol{\omega}(\mathbf{r}_0)}{|\mathbf{r} - \mathbf{r}_0|} dV_0 \right]. \quad (2.17)$$

By differentiation one can also show that the vector potential obtained satisfies the condition (2.14).

Thus, the vector field $\mathbf{a}(\mathbf{r})$ is completely determined if the values of its divergence, $f(\mathbf{r}_0)$ and curl, $\boldsymbol{\omega}(\mathbf{r}_0)$ in all space are given:

$$\begin{aligned} \mathbf{a}(\mathbf{r}) &= \mathbf{a}_1 + \mathbf{a}_2 = \nabla \varphi + \nabla \times \mathbf{A} = \\ &= -\frac{1}{4\pi} \nabla \left[\int \frac{f(\mathbf{r}_0)}{|\mathbf{r} - \mathbf{r}_0|} dV_0 \right] + \frac{1}{4\pi} \nabla \times \left[\int \frac{\boldsymbol{\omega}(\mathbf{r}_0)}{|\mathbf{r} - \mathbf{r}_0|} dV_0 \right]. \end{aligned} \quad (2.18)$$

Since the divergence and curl of the vector \mathbf{a} are uniquely related to the flux and circulation of this vector, it can also be stated that the vector field $\mathbf{a}(\mathbf{r})$ is completely determined by the flux and circulation of this vector.

We shall now dwell on the important problem of the possibility of choosing $\nabla \cdot \mathbf{A}$ in the form of (2.14). The vector potential \mathbf{A} is not given uniquely by the definition (2.13). One can add to it the gradient of an arbitrary function ψ , i.e. it can be assumed that

$$\mathbf{A}' = \mathbf{A} + \nabla \psi. \quad (2.19)$$

We have, obviously,

$$\nabla \times \mathbf{A}' = \nabla \times \mathbf{A}.$$

Thus, the addition of the gradient of an arbitrary function ψ to \mathbf{A} leads to the previous value of the vector \mathbf{a} .

Let, contrary to the condition (2.14), $\nabla \cdot \mathbf{A} \neq 0$. Then it is always possible to transform to a new vector potential \mathbf{A}' according to formula (2.19). For it we have

$$\nabla \cdot \mathbf{A}' = \nabla \cdot \mathbf{A} + \nabla \cdot \nabla \psi = \nabla \cdot \mathbf{A} + \nabla^2 \psi.$$

It is always possible, without restricting the general character of the reasoning, to choose the arbitrary function ψ in such a way that for any $\nabla \cdot \mathbf{A} \neq 0$ the equality

$$\nabla^2 \psi = -\nabla \cdot \mathbf{A}$$

will hold. This means that it can always be assumed that

$$\nabla \cdot \mathbf{A}' = 0$$

and, consequently, that condition (2.14) is of a general character.

Finally, it is easy to show that the expression obtained for \mathbf{a} is the only solution of eqs. (2.2)–(2.4) *.

The expression which we have found for the vector field \mathbf{a} , depending on the values of its divergence, $f(\mathbf{r})$, and curl, $\omega(\mathbf{r})$, is not connected with any assumptions about the physical meaning and character of the quantities under consideration. At the same time, it represents the prototype of those calculations which one usually has to make in the theory of the electromagnetic field in order to find the electric and magnetic fields.

§3. Charges and particles

According to contemporary ideas, there are in nature elementary particles and systems which have a complex structure made up of elementary particles, e.g. atoms and molecules. Elementary particles and systems consisting of a relatively small number of elementary particles — individual atoms and molecules — are called microparticles and microsystems.

At present a large number of elementary particles, exceeding 20, is known. The interrelations between elementary particles are very far from the simple scheme which was adopted in physics a relatively short time ago, when only two elementary particles, the proton and the electron, were known.

We shall acquaint ourselves with the basic properties of microparticles and microsystems in what follows, and mainly in Part V of the book. The most profound problems concerning the structure and properties of elementary particles are not as yet elucidated in contemporary physics, and a number of established principles are so complex that we cannot present them within the framework of this book.

* See, for example, N. E. Kochin, *Vektornoe ischislenie i nachala tenzornovo ischisleniya* (Vector calculus and the principles of tensor calculus) (Izdatelstvo AN SSSR, 1965) p. 213; H. Lass, *Vector and tensor analysis* (McGraw-Hill, New York, 1950) p. 119.

In Part I of the book some properties of microparticles and microsystems will be considered in the approximation of classical physics. What this consists of and the limits of its applicability will be seen from what follows.

The most important characteristic of all microparticles is the law of interaction between them. Microparticles can interact when they are at a distance from each other. At present it is known that there are several different kinds of interaction between microparticles: the electromagnetic, gravitational and nuclear interactions. Each kind of interaction is associated with a definite characteristic of the particle. In Part I of this book we shall be interested solely in the electromagnetic interaction. This is understood to be a well defined interaction force between certain particles, the character of which will be considered below. The electromagnetic interaction does not depend on the masses of the particles, which determine their gravitational interaction. It turns out that in the simplest case of identical particles at rest with respect to each other the force of interaction is determined only by the distance between them and the unique characteristic of the particles called their charge.

The law of interaction between particles at rest with respect to each other is expressed by the well-known formula

$$\mathbf{F} = \frac{e_1 e_2}{r^3} \mathbf{r},$$

where \mathbf{F} is the force, \mathbf{r} is the distance between the particles, and the e_i are their charges. This is the so-called Coulomb law.

The charge of a particle of given type is one of its fundamental characteristics. The force of interaction between particles of a given type — electrons, protons and so on — is always a force of repulsion between them. The interaction between particles of different types can have the character of repulsion as well as attraction. The convention is adopted that electrons are negatively charged, and that protons are positively charged. The sign of the charge of other charged elementary particles — muons, pions, kaons and hyperons — is determined with respect to electrons and protons in the following way: particles having a charge of the same sign repel each other, whereas oppositely charged particles attract each other.

Neutrons, neutrinos and neutral π -mesons may serve as examples of neutral particles. No charge differing from zero can be ascribed to any neutral particle.

A striking feature of the charge is the fact that it has one and the same absolute value for all elementary particles. In the CGSE system, which we shall use in what follows, the elementary charge is equal to

$$|e| = 4.77 \times 10^{-10} \text{ g}^{1/2} \text{ cm}^{3/2} \text{ sec}^{-1}.$$

Another property of the charge, expressing its fundamental importance as a characteristic of particles, is that it is conserved. In all processes occurring in nature the algebraic sum of charges does not change (the charge conservation law). The charge conservation law is one of the most important laws of nature.

Most bodies in terrestrial conditions are made of atoms and molecules — quasi-neutral systems for which the positive charge of the nucleus is equal to the negative charge of the electron shell. When an atom is ionized, i.e. when it becomes charged, it loses one or more electrons. Because of the charge conservation law, on ionization there arises a positive ion with a charge $N|e|$ and N electrons each with a charge $-|e|$, where N is an integer. When an extra electron is added to an atom, the latter may be transformed into a negative ion with the charge $-|e|$. Thus the charge of any system is an integer multiple of the elementary charge e .

In the microscopic classical field theory we shall study the behaviour of systems consisting of a relatively small number of particles, for example, individual electrons or protons, ions and so on. We shall assume individual elementary particles to have no extension and to move according to the laws of classical mechanics. We shall not be interested in the internal structure of elementary particles. As will be clear from what follows, such an idealization appears to be too crude in a number of cases. The laws of classical physics have a restricted applicability to microsystems, and sometimes are not applicable to them at all. In particular, they are unsuitable for the consideration of phenomena taking place in a very small region of space near the charge. Hence in a number of cases, which will be considered later, our simplifying assumptions will lead to difficulties and contradictions.

In quantum mechanics (Part V) the concepts of the laws determining the motion and properties of microscopic particles will essentially be developed and improved.

Since for the present we shall be interested only in the properties of particles associated with their electromagnetic interaction, we shall simply speak about the interaction of charges.

§ 4. The field of charges at rest

Let there be fixed charges e_i at certain points of space \mathbf{r}_i . In the region of space near this set of charges we put a charge ϵ so small that the change in the

properties of the system caused by ϵ can be disregarded. We shall call such a charge the test charge. Observing the test charge, we shall find out that at each point of space \mathbf{r} it is acted upon by a force \mathbf{F} proportional to the value of the charge ϵ , i.e.

$$\mathbf{F} = \epsilon \mathbf{E}(\mathbf{r}). \quad (4.1)$$

Strictly speaking, a force \mathbf{F} acts on the test charge located at any distance from the fixed charges. However, since the value of the force decreases (see below) rapidly with increasing distance, the action of the force \mathbf{F} is manifested practically only in the vicinity of the charges. That region of space in which a force \mathbf{F} acts on the test charge will be called by us the region of the electric field of charges at rest or the electrostatic field. Sufficiently distant regions of space in which the force \mathbf{F} becomes negligibly small will be assumed, approximately, to be infinitely distant, and it will be considered that there is no field in them.

Since the test charge does not affect the properties of the field of the system of charges, a vector \mathbf{E} characterizes the properties of this field. We shall henceforth call \mathbf{E} the electric field strength or, briefly, the electric field.

Investigating the force \mathbf{F} acting on the test charge one can determine the value of the vector \mathbf{E} at every point of the field and thus establish the properties of the electric field of the fixed charges. It turns out that it is possible to find certain general properties of the fields of fixed charges which do not depend on the exact nature of the disposition or the values of the charges.

Experiment shows that the electric field of a system of charges at rest possesses additive properties: the strength of the total electric field produced by several charges is equal to the vector sum of the fields \mathbf{E}_i produced by each charge, i.e.

$$\mathbf{E} = \sum \mathbf{E}_i. \quad (4.2)$$

This most important property of electric fields is usually called the property of superposition.

Investigating the motion of the test charge one can find the vector lines of the electrostatic field \mathbf{E} .

Knowing the distribution of the field \mathbf{E} in space, one can determine the distribution and interaction of the charges producing it. The introduction of a field as a mathematical method may seem a natural convenient way of describing an interaction. We shall see below that in fact this is not so and that the field is as real as the particles. One can ascribe to the field the same

characteristics as to particles — energy, momentum, mass and so on. Moreover, we shall show that spatially separated particles cannot act directly on each other (the so-called long-range action). The particle changes the state of field in the immediate vicinity of itself. This change in the state of field, a perturbation, is propagated from point to point and reaches the other particle. Such is the concept of the field action, or the theory of short-range action. The theory of short-range action will be considered in more detail in §24 of Part I and §8 of Part II.

It turns out that the work performed by the electrostatic field on the test charge as the latter is displaced from a point \mathbf{r}_1 to a point \mathbf{r}_2 does not depend on the path over which this displacement takes place. This means that the work of displacement of the charge over a closed path is equal to zero, i.e.

$$W = e \oint \mathbf{E} \cdot d\mathbf{l} = 0.$$

Thus, for the lines of the electrostatic field the equality

$$\oint \mathbf{E} \cdot d\mathbf{l} = 0 \quad (4.3)$$

always holds in integration over an arbitrary closed contour.

In connection with what was said earlier we pass over from the equality (4.3) to the differential characteristic of the field. For this we make use of Stokes' theorem, which gives

$$\oint \mathbf{E} \cdot d\mathbf{l} = \int (\nabla \times \mathbf{E}) \cdot d\mathbf{S} = 0. \quad (4.4)$$

Since the surface of integration in (4.4) is arbitrary, it follows from (4.4) that

$$\nabla \times \mathbf{E} = 0. \quad (4.5)$$

This formula shows that the electrostatic field is vortex-free. In it there are no closed field lines. Consequently, there must exist sources and sinks in which the lines of the field begin and end.

Experiment shows that in the electrostatic field the sources and sinks of the field lines are electric charges. It is assumed that the lines of the field originate on positive charges and end on negative ones. Since charges are the sources and sinks, the flux of the vector \mathbf{E} across any closed surface surrounding each charge is different from zero. If a certain amount of charge $\sum e_i$, where the summation denotes algebraic summation over all the charges, lies within a surface of integration S , then the flux of the vector \mathbf{E} must be pro-

portional to this sum, i.e.

$$\oint \mathbf{E} \cdot d\mathbf{S} = \text{const} \sum e_i. \quad (4.6)$$

This statement is called Gauss' theorem.

We stress that within the framework of our approximation the charges have a point character, and the value of the charge of any system is a multiple of the elementary charge.

To simplify the mathematical operations we take an important step and to pass over from the discrete, discontinuous distribution of charges to the continuous one.

Let there be in a certain small volume δV a sufficiently large number of charges. Since the charges are located at small distances from each other it is convenient for the mathematical description of them to replace the true distribution of the discrete point charges by a fictitious continuous distribution. Namely, replacing the volume δV by an infinitely small volume dV and assuming that an infinitely small charge de is confined in the infinitely small volume, one can write that

$$de = \rho dV,$$

where $\rho = de/dV$ is the charge density, i.e. the ratio of the charge to the volume it occupies at the given point of space. For charges at rest, ρ is a continuous function of the position $\rho(\mathbf{r})$.

It should be emphasized that the transition to the continuous distribution is of a purely mathematical character. It should not be confused with an analogous operation with which we shall become acquainted in Part IV where the electromagnetic processes in matter will be studied.

The connection between the mathematical description of the discrete distribution of point charges and the continuous function $\rho(\mathbf{r})$ can be established by means of the δ -function (see Appendix III). Namely, since the total charge in an arbitrary volume can be expressed in the form

$$e = \int \rho(\mathbf{r}) dV = \sum e_i,$$

where the summation is carried out over all the charges which are in the volume V , we can write

$$\rho(\mathbf{r}) = \sum_i e_i \delta(\mathbf{r} - \mathbf{r}_i),$$

where \mathbf{r}_i is the radius vector of the i th charge. Indeed, substituting this value $\rho(\mathbf{r})$, we have

$$\int \rho(\mathbf{r}) dV = \sum_i e_i \int \delta(\mathbf{r} - \mathbf{r}_i) dV = \sum_i e_i.$$

In particular, the charge density corresponding to one charge located at the point \mathbf{r}_0 can be written in the form

$$\rho(\mathbf{r}) = e \delta(\mathbf{r} - \mathbf{r}_0).$$

The importance of the introduction of the continuous charge density lies in the fact that by its introduction the field itself as well as the charge distribution are described by continuous functions of position.

Making use of the definition of charge density, we can write Gauss' theorem in the form

$$\oint \mathbf{E} \cdot d\mathbf{S} = \text{const} \int \rho dV, \quad (4.7)$$

where the integral on the right is taken over the volume confined by the surface S . According to the Gauss-Ostrogradsky theorem,

$$\oint \mathbf{E} \cdot d\mathbf{S} = \int \nabla \cdot \mathbf{E} dV. \quad (4.8)$$

Hence from formulae (4.7) and (4.8) we obtain

$$\nabla \cdot \mathbf{E} = \text{const} \rho. \quad (4.9)$$

Formula (4.9) determines the field divergence at every point of space. The value of the factor of proportionality in formula (4.9) can be determined only from experimental data (for example, from the Coulomb law).

In the CGSE system, which we shall use, this constant is equal to 4π , so that

$$\nabla \cdot \mathbf{E} = 4\pi\rho. \quad (4.10)$$

For reasons which will be explained below, we shall call eqs. (4.5) and (4.10) Maxwell's equations for the electrostatic field or, briefly, the equations of electrostatics.

Since the electrostatic field is vortex-free, in correspondence with the gen-

eral methods of describing the vector field one can introduce a scalar φ called the electrostatic potential and determined by the relation

$$\mathbf{E} = -\nabla\varphi. \quad (4.11)$$

The minus sign means that the vector \mathbf{E} is oriented in the direction of the most rapid decrease of the potential φ . The choice of such a direction is arbitrary.

The quantity

$$\int_1^2 \mathbf{E} \cdot d\mathbf{l} = - \int_1^2 \nabla\varphi \cdot d\mathbf{l} = \varphi_1 - \varphi_2, \quad (4.12)$$

called the electromotive force or, briefly, e.m.f., will occur often in what follows. (It should be noted that the electromotive force is not a force either in its nature or its dimensionality. The term e.m.f. has the vindication of historical tradition.) In the electrostatic field the electromotive force is equal to the difference between the electrostatic potentials at corresponding points.

Substituting the definition (4.11) into the equations of the electrostatic field (4.5) and (4.10), we see that (4.5) is satisfied identically, while (4.10) gives

$$\nabla \cdot \nabla\varphi = -4\pi\rho,$$

or, using formula (I. 49),

$$\nabla^2\varphi = -4\pi\rho. \quad (4.13)$$

This equation, called Poisson's equation, will be discussed in §14.

§5. The equation of continuity

Later on we shall have to pass over to the consideration of the more complicated case of the fields of moving charges. The motion of electric charges in space leads to the charge transport called electric current or, briefly, current. We characterize electric current by the current density vector $\mathbf{j}(\mathbf{r}, t)$, defined by the equality

$$\mathbf{j} = \sum e_i \mathbf{v}_i,$$

where e_i is the value of the charge, and \mathbf{v}_i is the velocity vector of the i th charge. The summation is carried out over all charges present at time t in a unit volume surrounding the point \mathbf{r} .

In the case of a continuous charge distribution the current density can be written in the form

$$\mathbf{j} = \rho \mathbf{v}. \quad (5.1)$$

The current density vector obviously represents the value of the charge perpendicular to the velocity per second crossing an imaginary unit area at the point \mathbf{r} at time t .

The values of the functions ρ and \mathbf{v} , i.e. charge density and the velocity of displacement of charge cannot be arbitrary but must satisfy the requirements of the charge conservation law.

Consider a closed surface, inside which there is a certain charge $e = \int \rho \, dV$, and find the derivative

$$-\frac{\partial}{\partial t} \int \rho \, dV.$$

Here the integration is carried out over the volume V enclosed within the surface S . The value of the derivative (taken with the minus sign) represents the decrease per unit time of the charge inside the surface S . Since electric charges do not vanish, and do not arise spontaneously, the rate of decrease of the charge in the volume V is equal to the flow of charge per second, out of the surface S enclosing this volume. Consequently, the equality

$$-\frac{\partial}{\partial t} \int \rho \, dV = \oint \rho \mathbf{v} \cdot d\mathbf{S} \quad (5.2)$$

holds. Passing over, in the last integral, to integration over the volume, we obtain

$$-\frac{\partial}{\partial t} \int \rho \, dV = \int \nabla \cdot (\rho \mathbf{v}) \, dV$$

On changing the order of the independent operations of integration and differentiation with respect to volume and time respectively, we have

$$-\int \frac{\partial \rho}{\partial t} \, dV = \int \nabla \cdot (\rho \mathbf{v}) \, dV$$

Because the integration volume is arbitrary, this equality gives

$$\left. \begin{aligned} \frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) &= 0, \\ \frac{\partial \rho}{\partial t} + \nabla \cdot \mathbf{j} &= 0. \end{aligned} \right\} \quad (5.3)$$

or

Formula (5.3), representing the mathematical expression of the charge conservation law, is called the equation of continuity.

For steady state processes, when the charge density distribution is not changing in time, the equation of continuity reads

$$\left. \begin{aligned} \nabla \cdot (\rho \mathbf{v}) &= 0, \\ \nabla \cdot \mathbf{j} &= 0. \end{aligned} \right\} \quad (5.4)$$

or

Equations (5.4) show that, for steady state processes, the current density vector is of solenoidal character. The trajectories of moving charges are closed, and the lines representing the vector \mathbf{j} form closed, non-intersecting, current tubes*.

Hence we shall make use of the notion of the total current I through a surface S . By definition

$$I = \int \mathbf{j} \cdot d\mathbf{S} = \int j_n dS,$$

where the integration is carried out with respect to the surface S . The current I gives the value of the total charge passing per second through the surface S .

§6. The electromagnetic field of charges moving with a constant velocity

We now go on to the study of the field of moving charges. We shall call this field the electromagnetic field. The properties of the electromagnetic field are essentially more complex than those of the electrostatic field. The establishment of the basic rules determining the behaviour of electromagnetic fields was in part the result of an experimental investigation of electromag-

* In the particular case of a system of spreading charges, current tubes are not closed, but go off at one end to infinity.

netic phenomena (Oersted, Ampère, Ohm and Faraday) and in part the result of a theoretical prediction (Maxwell) which was only later on confirmed experimentally (Hertz).

The exposition of the history of the development of electromagnetism is outside the scope of this book. However, it should be stressed that, since the atomic character of charge was discovered only in experiments at the end of the 19th and the beginning of the 20th century, all previous experiments and their theoretical interpretation referred to phenomena in material media. We shall present the results of these experiments in the language of microscopic physics which deals with charges moving in vacuum. In other words, without dwelling on the set-up of the experiments themselves, we shall present their results in a general form, in which the effect of the medium and actual conditions of the performance of the experiments are excluded.

The basic laws of the electromagnetic field, which will be set out below, at present rest not only on numerous and various experimental data but constitute the basis of contemporary electrical and radio technology.

We shall consider first of all the motion with a constant velocity of a set of charges along a tube or a line L (fig. I.1). In other words, we assume that an electric current, whose density \mathbf{j} does not depend on time, flows along the

Fig. I.1

line. In practice an electric current can be realized most simply in metal conductors. However, since in this chapter we shall not deal with the motion of charges in material media, the current line will be understood to be not a metal conductor but a certain imaginary surface — a tube enclosing a set of curves — the trajectories of charged particles moving in vacuum.

We put a test charge in the vicinity of the path of the constant current. We are not interested in the effect of the charges moving along the path on the test charge e when at rest. If the test charge moves with respect to the current line with velocity v , new facts are observed. It turns out that a moving test charge allows one to detect a field which is inseparably associated with moving charges in the path of the current and whose character differs from that of the electrostatic field. This field is called the magnetic field. This term is connected with the fact that a similar field is produced by permanent magnets.

The magnetic field, like the electrostatic field, has a vector character. It is characterized by a certain vector \mathbf{H} , called the magnetic field strength or, briefly, the magnetic field.

Experiment shows that the test charge is acted upon by a force

$$\mathbf{F}_m = \frac{e}{c} \mathbf{v} \times \mathbf{H}. \quad (6.1)$$

This force is called the Lorentz force *.

As is seen from formula (6.1), the Lorentz force is perpendicular to the test charge velocity v and to the vector \mathbf{H} , and forms with them a right-hand screwed system.

The numerical factor of proportionality is determined experimentally, if it is required that the vector \mathbf{H} should have the same dimensions as the vector \mathbf{E} . In the CGSE system the numerical factor c is equal to $3 \times 10^{10} \text{ cm sec}^{-1}$, and is a universal constant numerically the same value as the velocity of light in vacuum.

As for any vector field, we introduce the basic characteristic of the magnetic field, the integral $\oint \mathbf{H} \cdot d\mathbf{l}$, called the magnetomotive force **.

A study of the magnetic fields of direct currents has shown that the value of the magnetomotive force is equal to

* We shall often call the Lorentz force the total force acting on a charged particle in an electric and magnetic field, equal to the sum of the forces caused by both fields.

** By analogy with the electromotive force in electrostatics. It should be stressed that the magnetomotive force, like the electromotive one, is a scalar and is called a force only by tradition.

$$\oint \mathbf{H} \cdot d\mathbf{l} = \frac{4\pi I}{c}, \quad (6.2)$$

where $I = \int \mathbf{j} \cdot d\mathbf{S}_0$ represents the total current per second passing through the cross section S_0 of the contour (tube) of the current.

Formula (6.2) shows that the magnetomotive force differs from zero only over a path which encloses the tube of current. In the simplest case of a rectilinear current (or a rectilinear segment of current), the vector lines of the magnetic field form a system of concentric circles about the current line (fig. 1.2). The value of the magnetomotive force is proportional to the total current I in the line. Formula (6.2) expresses the law of Oersted, who established in the years 1820–1826 the connection between the electric current and magnetic phenomena.

Fig. 1.2

As in electrostatics, experiment leads to an integral relation between the characteristics of the charge (the current I) and the field \mathbf{H} . In order to obtain a differential relation characterizing the field, we replace the integration surface S_0 in the expression for the total current by an arbitrary surface S drawn through the path of the current (fig. 1.1). The current density \mathbf{j} differs from zero only when the integration is carried out with respect to the cross section S_0 of the tube of current. Outside this cross section the current density is equal to zero, so that it can be written that

$$I = \int \mathbf{j} \cdot d\mathbf{S}_0 = \int \mathbf{j} \cdot d\mathbf{S}.$$

We then have

$$\oint \mathbf{H} \cdot d\mathbf{l} = \frac{4\pi}{c} \int \mathbf{j} \cdot d\mathbf{S}.$$

Making use of Stokes' theorem, we find

$$\int (\nabla \times \mathbf{H}) \cdot d\mathbf{S} = \frac{4\pi}{c} \int \mathbf{j} \cdot d\mathbf{S},$$

whence, in view of the arbitrariness of the surface S , it follows that

$$\nabla \times \mathbf{H} = \frac{4\pi}{c} \mathbf{j}. \quad (6.3)$$

We see that the magnetic field has vortex character. Eq. (6.3) determines the curl of the magnetic field at every point of space as a function of the value of the current density \mathbf{j} at every point of space.

Eq. (6.3) agrees with the stationary equation of continuity (5.4) and, hence, is self-consistent. Indeed, calculating the divergence of the two sides of (6.3) we arrive at the equality

$$\nabla \cdot (\nabla \times \mathbf{H}) = \frac{4\pi}{c} \nabla \cdot \mathbf{j} = 0. \quad (6.4)$$

Formula (6.3) shows that the motion of electric charges is inseparably associated with a magnetic field or, less rigorously, the motion of charges gives rise to a magnetic field.

In order to determine a magnetic field uniquely it is necessary to know the second differential relation $-\nabla \cdot \mathbf{H}$. To find it we shall consider the flux of the vector \mathbf{H} through an arbitrary closed surface $\oint \mathbf{H} \cdot d\mathbf{S}$. The experimental study of the distribution of the magnetic fields of direct currents shows that the magnetic fields are always of a purely solenoidal character, and

$$\oint \mathbf{H} \cdot d\mathbf{S} = 0. \quad (6.5)$$

Consequently,

$$\oint \mathbf{H} \cdot d\mathbf{S} = \int \nabla \cdot \mathbf{H} dV = 0$$

or, because of the arbitrariness of the volume of integration,

$$\nabla \cdot \mathbf{H} = 0. \quad (6.6)$$

Thus, the magnetic field has neither sources nor sinks. The lines of the magnetic field are always closed or go off to infinity *.

Eqs. (6.3) and (6.6) determine completely the magnetic field of direct currents. The magnetic field of direct currents possesses additive properties, as does the electrostatic field. This follows, in particular, from the linear character of the field eqs. (6.3) and (6.6). The magnetic and electrostatic fields are independent of each other. An electrostatic field (for a given distribution of moving charges) has no effect on the magnetic field of the charges.

In conclusion we note one more very important feature of the magnetic field \mathbf{H} . In contrast to the electrostatic field \mathbf{E} , which is characterized by a polar vector, the vector of the strength of the magnetic field \mathbf{H} is an axial vector or a pseudo-vector. This is seen from the formula for the Lorentz force (6.1). Indeed, from the definition of the field strength by formula (6.1) it is seen that the behaviour of the vector \mathbf{H} in the reflection $\mathbf{r} \rightarrow (-\mathbf{r})$ through the origin is determined by the behaviour of the polar vectors \mathbf{F} and \mathbf{v} and the properties of their vector product. In substituting $\mathbf{r} \rightarrow (-\mathbf{r})$ the directions of the vectors \mathbf{F} and \mathbf{v} become reversed, and the sign of the vector product is changed. Consequently, in substituting $\mathbf{r} \rightarrow (-\mathbf{r})$ the vector \mathbf{H} must remain unchanged. It is just this property that is an indication of an axial vector.

§ 7. The electromagnetic field of moving charges. The general case

In considering the non-steady state motion of charges or, what is the same, the non-steady currents in certain contours, further results are obtained.

It should be stressed, first of all, that eq. (6.3) cannot remain valid for non-steady currents. As we have just seen, eq. (6.3) leads to the charge conservation law in the form of (5.4). However, for non-steady state processes the law is expressed by formula (5.3). Thus, for these processes the relation (6.3) contradicts the charge conservation law.

The most important fact which in essence distinguishes non-stationary magnetic and electric fields from stationary ones is the existence of an interrelation between them.

Faraday observed that a change of a magnetic field in time entails the appearance of an electric field (the phenomenon of electromagnetic induc-

* Strictly speaking, for complex configurations of currents there may also exist lines of field which are not closed but fill a surface densely. See: I. E. Tamm, *Osnovy teorii elektrichestva (Introduction to the theory of electricity)* (Gostekhizdat, 1954) p. 53.

tion). Maxwell predicted theoretically that a change of an electric field in time leads to the appearance of a magnetic field. This theoretical prediction subsequently found confirmation in Hertz' experiments.

Faraday's experiments established that a change in time of the flux of a magnetic field vector through an arbitrary surface S is accompanied by the appearance of an electromotive force in the contour enclosing this surface, i.e.

$$\oint \mathbf{E} \cdot d\mathbf{l} = - \frac{1}{c} \frac{\partial}{\partial t} \int \mathbf{H} \cdot d\mathbf{S}. \quad (7.1)$$

The factor of proportionality c turned out to be numerically equal to $3 \times 10^{10} \text{ cm sec}^{-1}$, i.e. to the velocity of light in vacuum. Fig. 3 shows schematically the relation between the change in the magnetic field $\partial \mathbf{H} / \partial t$ and the electromotive force. If the lines of the field vector $\partial \mathbf{H} / \partial t$ are represented by straight lines going from the left to the right, then the lines of the electric field are represented by concentric circles embracing the corresponding straight lines. The directions of the vectors of the electric field \mathbf{E} and $\partial \mathbf{H} / \partial t$ are shown in fig. 1.3 by arrows.

Fig. 1.3

Fig. 1.4

Formula (7.1) represents the generalized Faraday law of induction (1831). The generalization consists in the following. The experimental data of Faraday referred to a circuit of a metal wire. The appearance of an induced electric field in a conductor corresponds to the appearance of a current in the circuit. It was this current that was measured directly. In formula (7.1) the integration is carried out over a completely arbitrary contour independent of the presence of conductors. This means that the primary factor is the appearance of the field in the contour. The electric current is some secondary phenomenon associated with the material nature of the contour — the presence of a conductivity in it. The generalized Faraday law of induction in the

form (7.1) establishes the interrelation between the magnetic and electric field. The sign in formula (7.1) corresponds to the well-known Lenz rule.

Maxwell put forward the hypothesis, subsequently confirmed experimentally, that in addition to the law (7.1) there is an analogous relation between the change of an electric field in time and the magnetic field.

Namely, when the flux of an electric field through a surface S changes in time,

$$\frac{\partial}{\partial t} \int \mathbf{E} \cdot d\mathbf{S},$$

there arises in the contour embracing the surface S a magnetomotive force equal to

$$\oint \mathbf{H} \cdot d\mathbf{l} = \frac{1}{c} \frac{\partial}{\partial t} \int \mathbf{E} \cdot d\mathbf{S}, \quad (7.2)$$

where the coefficient c has the same value as in formula (7.1). Fig. 1.4 illustrates the relation between the change of the electric field, characterized by the vector $\partial \mathbf{E} / \partial t$, and the lines of the magnetic field. If the vector $\partial \mathbf{E} / \partial t$ at every point of the field is represented by a family of straight lines, then the lines of the magnetic field are represented by concentric circles about these straight lines.

We shall postpone till §9 the discussion of the considerations which lead to the establishment of the relation between the change of the electric field and the magnetic field circulation. As to the connection of the law (7.2) with experimental data, it turns out that the existence of electromagnetic waves is associated with (7.2). If the line L , along which the magnetic field circulation is calculated, links the contour defining the electric current, then the total magnetomotive force is expressed by the formula (see (6.2) and (7.2))

$$\oint \mathbf{H} \cdot d\mathbf{l} = \frac{4\pi}{c} \int \mathbf{j} \cdot d\mathbf{S} + \frac{1}{c} \frac{\partial}{\partial t} \int \mathbf{E} \cdot d\mathbf{S}. \quad (7.3)$$

From formulae (7.1) and (7.3), containing the integral characteristics of the fields \mathbf{E} and \mathbf{H} , one can pass over to differential characteristics. By means of Stokes' theorem formula (7.1) can be rewritten in the form

$$\int (\nabla \times \mathbf{E}) \cdot d\mathbf{S} = -\frac{1}{c} \frac{\partial}{\partial t} \int \mathbf{H} \cdot d\mathbf{S} = -\frac{1}{c} \int \frac{\partial \mathbf{H}}{\partial t} \cdot d\mathbf{S}. \quad (7.4)$$

We have changed the order of carrying out the independent operations of differentiation with respect to time and integration with respect to a surface fixed in space (see, however, Part IV, §23).

In view of the arbitrariness of the integration surface in formula (7.4), there follows from the equality of the integrals the equality of the integrands:

$$\nabla \times \mathbf{E} = -\frac{1}{c} \frac{\partial \mathbf{H}}{\partial t}. \quad (7.5)$$

We see that a time varying electric field is, in general, rotational, in contrast to the electrostatic field. The value of the curl of the vector \mathbf{E} at a given point is determined by the rate of change in time of the magnetic field at the same point.

Transforming the integral relation (7.3) in a completely analogous way, we have

$$\nabla \times \mathbf{H} = \frac{4\pi}{c} \mathbf{j} + \frac{1}{c} \frac{\partial \mathbf{E}}{\partial t} \quad (7.6)$$

This relation shows that the curl of the magnetic field at every point of space is determined by the current density of the charges \mathbf{j} and the change of the electric field in time.

The symmetry of the equations for the curls of the electric and magnetic fields (7.5) and (7.6) is striking. A change in the magnetic field is accompanied by the appearance of a rotational electric field. Conversely, a change in the electric field is associated with the appearance of a rotational magnetic field. However, besides the similarity between these equations there is also an extremely important difference between them. First, eqs. (7.5) and (7.6) differ from each other by the sign before the time derivatives. Second, in general the curl of the magnetic field depends not only on the rate of change of the electric field but also on the current density \mathbf{j} . However, there are no 'magnetic charges' which can move in space and produce a 'current of magnetic charges'.

Eqs. (7.3) and (7.5) determine the curls of the electric and magnetic fields. For a single-valued determination of the fields there must also be given the divergences of the electric and magnetic fields.

In order to determine these we shall find the divergences of both sides of eqs. (7.5) and (7.6). We start from the latter equation. We have

$$\nabla \cdot (\nabla \times \mathbf{H}) = 0 = \frac{4\pi}{c} \nabla \cdot \mathbf{j} + \frac{1}{c} \nabla \cdot \frac{\partial \mathbf{E}}{\partial t} = \frac{4\pi}{c} \nabla \cdot \mathbf{j} + \frac{1}{c} \left(\frac{\partial}{\partial t} \nabla \cdot \mathbf{E} \right).$$

By means of the charge conservation law (5.3) the above equation can easily be transformed into

$$\frac{\partial}{\partial t} (\nabla \cdot \mathbf{E} - 4\pi\rho) = 0,$$

whence

$$\nabla \cdot \mathbf{E} = 4\pi\rho + f(\mathbf{r}),$$

where the function $f(\mathbf{r})$ is any function depending only on coordinates but not on time.

Let us assume that at an arbitrary initial instant of time, the charges were at rest. Then at the initial instant the electrostatic field equation (4.10) must have been satisfied, and the function $f(\mathbf{r})$ was equal to zero. Since $f(\mathbf{r})$ does not depend on time, this means that $f(\mathbf{r})$ is always equal to zero. The electric field divergence for stationary as well as non-stationary fields is determined by the formula

$$\nabla \cdot \mathbf{E} = 4\pi\rho. \quad (7.7)$$

Similarly, taking the divergence of (7.5), we find

$$\nabla \cdot (\nabla \times \mathbf{E}) = 0 = \nabla \cdot \left[\frac{1}{c} \frac{\partial \mathbf{H}}{\partial t} \right]$$

or

$$\nabla \cdot \mathbf{H} = f_1(\mathbf{r}).$$

Assuming again that at the initial moment the magnetic field had a stationary character, and repeating the reasoning just presented, we arrive at the conclusion

$$\nabla \cdot \mathbf{H} = 0 \quad (7.8)$$

The magnetic field for stationary as well as non-stationary fields has a purely rotational (solenoidal) character. Neither in stationary nor in variable fields are there magnetic charges on which the lines of the magnetic field begin and end.

§8. Maxwell-Lorentz system of equations

The system of eqs. (7.5)–(7.8) which we have obtained for the electromagnetic field in a vacuum is called Maxwell's equations. They were established by Maxwell in 1873 for the more general case of electromagnetic fields in material media, and by Lorentz in 1895 for a system of charges moving in vacuum.

Let us write once again Maxwell's equations, grouping them into two pairs:

	Differential form	Integral form	
Pair I	$\begin{cases} \nabla \times \mathbf{E} = -\frac{1}{c} \frac{\partial \mathbf{H}}{\partial t}, \\ \nabla \cdot \mathbf{H} = 0, \end{cases}$	$\begin{cases} \oint \mathbf{E} \cdot d\mathbf{l} = -\frac{1}{c} \frac{\partial}{\partial t} \int \mathbf{H} \cdot d\mathbf{S}; \\ \oint \mathbf{H} \cdot d\mathbf{S} = 0 \end{cases}$	(8.1) (8.2)

Pair II	$\begin{cases} \nabla \times \mathbf{H} = \frac{1}{c} \frac{\partial \mathbf{E}}{\partial t} + \frac{4\pi \mathbf{j}}{c}, \\ \nabla \cdot \mathbf{E} = 4\pi \rho \end{cases}$	$\begin{cases} \oint \mathbf{H} \cdot d\mathbf{l} = \frac{4\pi}{c} I + \frac{1}{c} \frac{\partial}{\partial t} \int \mathbf{E} \cdot d\mathbf{S}; \\ \oint \mathbf{E} \cdot d\mathbf{S} = 4\pi e. \end{cases}$	(8.3) (8.4)
---------	---	--	----------------

Assuming that the distributions of the currents and charges are known, one can find by means of Maxwell's equations the six unknown components of the field vectors \mathbf{E} and \mathbf{H} . As we have seen in the preceding paragraph, the equations for the divergence of \mathbf{E} and \mathbf{H} follow from those for the curl and the initial conditions. Hence in the Maxwell system of eight scalar differential equations there are only six independent equations.

Eq. (8.1), representing a generalization of the Faraday induction law, establishes that a magnetic field changing with time gives rise to a rotational electric field. Eq. (8.2) shows that the magnetic field has a solenoidal character and that the lines of the magnetic field are either closed or go off to infinity.

From eq. (8.3) it follows that a rotational magnetic field is produced when charges are moving and when the electric field changes with time. By analogy with the electric current, the quantity $(1/4\pi)(\partial \mathbf{E}/\partial t)$ in the first term on the right is called the *displacement current*, while the sum of the two terms is called the *total current*. It can then be said that the rotational magnetic field is produced by the total current into which the two terms enter equivalently. Finally, eq. (8.4) shows that the sources of the electric field are electric charges. For given density distribution of charges and currents Maxwell's

equations determine completely the electric field $\mathbf{E}(\mathbf{r}, t)$ and the magnetic field $\mathbf{H}(\mathbf{r}, t)$.

Maxwell's equations represent a system of linear partial differential equations. By virtue of the linearity of the equations, the principle of superposition of electromagnetic fields holds. If \mathbf{E}_i and \mathbf{H}_i are solutions of the Maxwell equations, then $\mathbf{E} = \sum \mathbf{E}_i$ and $\mathbf{H} = \sum \mathbf{H}_i$ are also solutions of these equations.

The integration of partial differential equations becomes definite only in the case where a set of boundary and initial conditions is given. We shall discuss boundary and initial conditions later, in § 24.

Up to now we have said nothing about the distribution of the charges and their motion in space. However, the distribution of the charges and their velocities cannot be given quite arbitrarily. The charge density and the current density (the velocities of the charges) are interrelated by the charge conservation law:

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \mathbf{j} = 0. \quad (8.5)$$

Charges moving in an electromagnetic field are acted upon by the Lorentz force. The equations of motion of a charge can be written in the form

$$\frac{d\mathbf{p}}{dt} = e \left(\mathbf{E} + \frac{1}{c} \mathbf{v} \times \mathbf{H} \right), \quad (8.6)$$

where \mathbf{p} is the momentum of the particle.

The field which must be substituted into (8.6) represents the total field including that produced by the charge itself as well as the external field produced by other charges. The former must also have an effect on the motion of the particle. However, in most cases one can assume the self field to be weak and not take it into account (see § 29). In this approximation the vectors \mathbf{E} and \mathbf{H} in (8.6) stand for the external field acting on the particle. The law of motion (8.6) can also be written for continuously distributed charges, if \mathbf{p}_0 is understood to be the momentum of the particles in unit volume and if the force density (i.e. the force per unit volume) is substituted for the Lorentz force. Then

$$\frac{d}{dt} \int \mathbf{p}_0 dV = \int \rho \left(\mathbf{E} + \frac{1}{c} \mathbf{v} \times \mathbf{H} \right) dV, \quad (8.7)$$

or

$$\frac{d}{dt} \mathbf{p}_0 = \rho \left(\mathbf{E} + \frac{1}{c} \mathbf{v} \times \mathbf{H} \right). \quad (8.8)$$

We have already mentioned that field equations were initially formulated by Maxwell for electromagnetic processes in matter. Lorentz established their applicability to a system consisting of a field and charges, and supplemented them by the equation of motion of the charges.

Hence the eqs. (8.1)–(8.8) are often called the Maxwell-Lorentz equations. The Maxwell-Lorentz equations contain the complete description of the behaviour of a system consisting of fields and charges. If the values of the functions ρ and \mathbf{v} and the initial values of the fields \mathbf{E} and \mathbf{H} are given, then the integration of these equations allows one to find the electric and magnetic field distribution in space at any subsequent instant of time. Thus, in electrodynamics, as in mechanics, if the state of a system at the initial moment and the law of change of state are given one can determine uniquely the state at a subsequent moment.

It should be noted that, within the framework of this chapter, the Lorentz force acting on a moving charge should be assumed as an empirical formula. In Chapter II it will be shown that the expression for the Lorentz force follows, as a consequence, from more general laws of physics.

The range of applicability of the Maxwell-Lorentz equations is extremely large. They determine the character of electromagnetic processes on the cosmic scale, constitute the basis of contemporary electrical and radio technology, and allow one to investigate electromagnetic phenomena taking place with individual charges. But, nevertheless, as we shall see in what follows, the Maxwell-Lorentz equations and the classical field theory based on them are not an expression of the universal laws of nature, and have a restricted region of applicability.

A number of electromagnetic processes and, above all, intra-atomic ones, lie beyond the limits of applicability of the Maxwell-Lorentz equations. The problem of establishment of these limits will be discussed more than once later on.

§9. The displacement current

In contrast with the electric current \mathbf{j} , which has a very simple and obvious meaning, the displacement current $(1/4\pi)(\partial\mathbf{E}/\partial t)$ is not associated with the motion of any charges.

The displacement current was introduced by Maxwell who interpreted it in terms of ether theory, which was generally accepted at the time but which has now been abandoned as erroneous.

It is readily understood why, in the middle of the 19th century, one could not have had recourse to experimental data in order to obtain formula (7.6). The velocities of motion of electric charges are, as a rule, very large. Hence the current ρv is always large in comparison with the displacement current $(1/4\pi)(\partial E/\partial t)$, provided the electric field is not changing very rapidly in time. Estimates show that the two terms of the total current may be of the same order of magnitude for periodic variation of the vector E with a frequency of the order of $10^6 - 10^7 \text{ sec}^{-1}$ or higher.

This is a range of radio frequencies which was unknown in physics in the middle of the 19th century. It was only in 1888 that Hertz was the first to establish experimentally the existence of electromagnetic waves, and hence prove the reality of the displacement current.

The fact that the current j cannot always be responsible for the appearance of a magnetic field is very clearly illustrated by the following reasoning. Let an electric charge e be moving in space. We seek to determine the strength of the magnetic field produced by this charge along a certain contour L (fig. 1.5). According to Stokes' theorem,

$$\oint \mathbf{H} \cdot d\mathbf{l} = \int (\nabla \times \mathbf{H}) \cdot d\mathbf{S} = \frac{4\pi}{c} \int \mathbf{j} \cdot d\mathbf{S},$$

where the integration surface is any surface enclosed by the contour L .

Let us consider at a certain instant two surfaces S_1 and S_2 enclosed by the contour L . It is clear that from the standpoint of the electric current passing through them they are not equivalent. No current passes through the surface S_1 at the given instant because the charge e has not yet reached it. On the

Fig. 1.5

contrary, the surface S_2 is crossed by the charge and the current through it differs from zero. Thus, we arrive at the obvious contradiction:

$$\int_{S_1} (\nabla \times \mathbf{H}) \cdot d\mathbf{S}_1 = 0 \quad \text{and} \quad \int_{S_2} (\nabla \times \mathbf{H}) \cdot d\mathbf{S}_2 \neq 0,$$

although according to Stokes' theorem these integrals must be equal to each other. In reality the moving charge produces at the surface S_1 a certain electric field changing in time. A calculation which will be performed in §20 shows that the derivative of this electric field with respect to time, integrated with respect to the surface S_1 , gives exactly the same value for $\oint \mathbf{H} \cdot d\mathbf{l}$ in the contour L as the integral $4\pi \int \mathbf{j} \cdot d\mathbf{S}$ with respect to the surface S_2 . Thus, it is necessary to assume equivalence (in the sense of producing circulation of the magnetic field in a certain contour) of the charge current and the change in the electric field for any moving charge.

The introduction of displacement current can be made on the basis of the following formal reasoning: it is necessary to find a generalization of the law (6.3) such that it does not contradict the charge conservation law (5.3) for a non-stationary change of the field.

Writing (6.3) in the form

$$\nabla \times \mathbf{H} = \frac{4\pi}{c} (\mathbf{j} + \mathbf{C}), \quad (9.1)$$

where \mathbf{C} is an unknown vector, and taking the divergence of both sides of (9.1), we find

$$\nabla \cdot (\nabla \times \mathbf{H}) = 0 = \frac{4\pi}{c} (\nabla \cdot \mathbf{j} + \nabla \cdot \mathbf{C}),$$

or

$$\nabla \cdot (\mathbf{j} + \mathbf{C}) = 0. \quad (9.2)$$

The unknown vector \mathbf{C} supplements the current density \mathbf{j} in such a way that the quantity $(\mathbf{j} + \mathbf{C})$ possesses the properties of a solenoidal vector having closed current lines.

The divergence of the vector \mathbf{C} can be found from eqs. (9.2), (5.3) and (4.10). We have

$$\nabla \cdot \mathbf{C} = -\nabla \cdot \mathbf{j} = \frac{\partial \rho}{\partial t} = \frac{1}{4\pi} \frac{\partial}{\partial t} \nabla \cdot \mathbf{E} = \frac{1}{4\pi} \nabla \cdot \frac{\partial \mathbf{E}}{\partial t},$$

whence it follows that the vector \mathbf{C} is equal to

$$\mathbf{C} = \frac{1}{4\pi} \frac{\partial \mathbf{E}}{\partial t} + \mathbf{b}(\mathbf{r}, t),$$

where $\mathbf{b}(\mathbf{r}, t)$ is any vector satisfying the condition

$$\nabla \cdot \mathbf{b}(\mathbf{r}, t) = 0.$$

There are no grounds to assume beforehand that the vector \mathbf{b} is equal to zero.

The brilliant idea of Maxwell consisted in his assumption that a profound symmetry and interrelation exist between the electric and magnetic fields. We emphasized this symmetry in considering the properties of Maxwell's equations. To obtain symmetry between the fields it is necessary to assume $\mathbf{b} \equiv 0$. Then

$$\nabla \times \mathbf{H} = \frac{4\pi}{c} \mathbf{j} + \frac{1}{c} \frac{\partial \mathbf{E}}{\partial t} \quad (9.3)$$

and, in particular, in the space region in which there are no moving charges $\mathbf{j} = 0$ and the equation for $\nabla \times \mathbf{H}$ is of the form

$$\nabla \times \mathbf{H} = \frac{1}{c} \frac{\partial \mathbf{E}}{\partial t}$$

The curl of the vector \mathbf{H} is determined by the rate of change of the vector \mathbf{E} , whereas, according to Faraday's law of induction (7.5), the curl of the vector \mathbf{E} is determined by the rate of change of the vector \mathbf{H} . Only in those regions of space where the current density differs from zero is the symmetry between electric and magnetic field violated. Since there are no real magnetic charges and since the magnetic field is always of purely solenoidal character, then in the equation for the electromagnetic induction (7.5) there is no term analogous to the $(4\pi/c)\mathbf{j}$ of eq. (9.3). On the contrary, if the vector \mathbf{b} were different from zero, no symmetry would exist between the electric and magnetic fields.

In conclusion we emphasize that since the displacement current in vacuum $(1/4\pi)(\partial \mathbf{E}/\partial t)$ is not connected with displacement or change of state of any particles, it cannot be compared with any mechanical model allowing one to picture this physical quantity in a simple way. For the sake of clarity, particles at rest or in motion — e.g. small spheres or pellets — were associated

with the ideas of "charge density" or "current density". The field vectors \mathbf{E} and \mathbf{H} were represented by lines of force or field lines, which were previously pictured in the form of tensions in an elastic medium — the electromagnetic ether. Such mechanical models were undoubtedly useful, because they helped one to understand clearly the meaning of the corresponding quantities. Displacement current in a vacuum is the first quantity we encounter which cannot be described by means of a mechanical analogue. In what follows we shall have to deal with a very large number of important physical notions and quantities having no mechanical analogues. Like the displacement current in vacuum, they cannot be represented by any obvious model.

§ 10. The electromagnetic field potentials

In § 2 we have seen that it is convenient to introduce auxiliary quantities defined by relations (2.7) and (2.13), in order to find the stationary vector field from the values of divergence and curl given in each point of space. It turns out that one can proceed in exactly the same way in the more general case of a non-stationary system of vector fields — electric and magnetic.

The magnetic field vector is always solenoidal and its divergence is equal to zero. Hence, as in § 2, we assume that

$$\mathbf{H} = \nabla \times \mathbf{A}, \quad (10.1)$$

where the auxiliary vector \mathbf{A} is called the vector potential. The vector potential $\mathbf{A}(\mathbf{r}, t)$ is a function of space and time. The eq. (8.2) is automatically satisfied, since for any $\mathbf{A}(\mathbf{r}, t)$

$$\nabla \cdot (\nabla \times \mathbf{A}) = 0$$

Substitution of the relation (10.1) into (8.1) gives

$$\nabla \times \mathbf{E} = -\frac{1}{c} \nabla \times \frac{\partial \mathbf{A}}{\partial t}$$

or

$$\nabla \times \left(\mathbf{E} + \frac{1}{c} \frac{\partial \mathbf{A}}{\partial t} \right) = 0.$$

The last equation shows that the vector

$$\mathbf{E} + \frac{1}{c} \frac{\partial \mathbf{A}}{\partial t}$$

is a potential vector, i.e. it can be written in the form

$$\mathbf{E} + \frac{1}{c} \frac{\partial \mathbf{A}}{\partial t} = -\nabla \varphi,$$

where φ is a function of coordinates and time which we shall call the scalar potential.

In contrast with the electrostatic case, the electric field vector, having a vortex nature, cannot be written in the form of the gradient of a potential. It is expressed through the totality of scalar and vector potentials by the formula

$$\mathbf{E} = -\nabla \varphi - \frac{1}{c} \frac{\partial \mathbf{A}}{\partial t}, \quad (10.2)$$

where the second term, connecting the electric field with magnetic quantities, expresses the law of electromagnetic induction.

For the determination of \mathbf{A} and φ we have in addition eqs. (8.3) and (8.4). The former equation gives

$$\nabla \times (\nabla \times \mathbf{A}) = -\frac{1}{c^2} \frac{\partial^2 \mathbf{A}}{\partial t^2} - \frac{1}{c} \nabla \frac{\partial \varphi}{\partial t} + \frac{4\pi}{c} \mathbf{j},$$

or, according to formula (I. 50),

$$\nabla (\nabla \cdot \mathbf{A}) - \nabla^2 \mathbf{A} = -\frac{1}{c^2} \frac{\partial^2 \mathbf{A}}{\partial t^2} - \frac{1}{c} \nabla \frac{\partial \varphi}{\partial t} + \frac{4\pi}{c} \mathbf{j}.$$

We rewrite the last equation in the form

$$\nabla^2 \mathbf{A} - \frac{1}{c^2} \frac{\partial^2 \mathbf{A}}{\partial t^2} = -\frac{4\pi}{c} \mathbf{j} + \nabla \left(\nabla \cdot \mathbf{A} + \frac{1}{c} \frac{\partial \varphi}{\partial t} \right). \quad (10.3)$$

Eq. (8.4) gives in turn

$$\nabla^2 \varphi = -4\pi\rho - \frac{1}{c} \frac{\partial}{\partial t} \nabla \cdot \mathbf{A}. \quad (10.4)$$

The potentials \mathbf{A} and φ are auxiliary quantities, introduced in order to simplify the field equations. We shall impose upon them those conditions which will allow us to make eqs. (10.3) and (10.4) independent without changing relations (10.1) and (10.2). Relation (10.1) determines the curl of the vector potential \mathbf{A} . However, the vector potential \mathbf{A} is in itself still undetermined, since its divergence is not given. If the divergence of \mathbf{A} is given by the relation

$$\nabla \cdot \mathbf{A} + \frac{1}{c} \frac{\partial \varphi}{\partial t} = 0, \quad (10.5)$$

called the Lorentz relation, then (10.3) will turn into

$$\nabla^2 \mathbf{A} - \frac{1}{c^2} \frac{\partial^2 \mathbf{A}}{\partial t^2} = -\frac{4\pi}{c} \mathbf{j}. \quad (10.6)$$

Eq. (10.4) will assume the completely analogous form

$$\nabla^2 \varphi - \frac{1}{c^2} \frac{\partial^2 \varphi}{\partial t^2} = -4\pi \rho. \quad (10.7)$$

The equations obtained for the electromagnetic potentials are equivalent to Maxwell's equations. If the distributions of the charge $\rho(\mathbf{r}, t)$ and the currents $\mathbf{j}(\mathbf{r}, t)$ (satisfying the continuity equation) are given, then integration of eqs. (10.6) and (10.7) allows us to find the vector potential and scalar potential. The field vectors will be found by differentiating according to formulae (10.1) and (10.2).

An equation of the type

$$\nabla^2 \varphi - \frac{1}{c^2} \frac{\partial^2 \varphi}{\partial t^2} = \psi(\mathbf{r}, t),$$

where $\psi(\mathbf{r}, t)$ is a function of coordinates and time, is called D'Alembert's equation. It is often written by means of the so-called D'Alembert differential operator (D'Alembertian):

$$\square = \nabla^2 - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} - \frac{1}{c^2} \frac{\partial^2}{\partial t^2}$$

in the more compact form:

$$\square\varphi = \psi(\mathbf{r}, t) .$$

In the particular case of the homogeneous equation for which $\psi(\mathbf{r}, t) = 0$, the so-called wave equation,

$$\nabla^2\varphi - \frac{1}{c^2} \frac{\partial^2\varphi}{\partial t^2} = 0 ,$$

is obtained from D'Alembert's equation. In another particular case, that of time-independent functions $\varphi(\mathbf{r})$ and $\psi(\mathbf{r})$, D'Alembert's equation reduces to Poisson's equation which is already known (see (2.8)) from electrostatics:

$$\nabla^2\varphi = \psi(\mathbf{r}) .$$

From the mathematical standpoint the second-order equations — Poisson's equation, the wave equation and D'Alembert's equation — are simpler than Maxwell's first-order equations in partial derivatives. As we shall see in what follows, the general solution of D'Alembert's equation and the wave equation can be obtained in integral form, as for Poisson's equation (see (2.9)). It is for this reason that, in investigating the properties of electromagnetic fields, as well as in solving a number of concrete problems, the use of potentials is very convenient and the potential method represents the basic mathematical apparatus of the field theory.

§ 11. Gauge invariance of the potentials

We have already emphasized that the potentials \mathbf{A} and φ represent auxiliary quantities having no direct physical meaning. The field strengths \mathbf{E} and \mathbf{H} , which have a definite value at every point of the field and at any instant, have a real meaning. They can be measured by means of the forces acting on a test charge moving in the field.

The values of \mathbf{A} and φ cannot be measured and, therefore, the potentials by themselves should not be involved in the final expressions of the field theory. Indeed, determination of the potentials \mathbf{A} and φ from formulae (10.1) and (10.2) is not unique and allows a certain arbitrariness.

We now have to discuss the question of the degree of arbitrariness in the determination of the potentials in the general case. From the definition of the vector potential (10.1) it follows that if we perform the transformation

$$\mathbf{A} \rightarrow \mathbf{A}' + \nabla \psi(\mathbf{r}, t), \quad (11.1)$$

where $\psi(\mathbf{r}, t)$ is an arbitrary function of coordinates and time, then we arrive at the same value of the field strength \mathbf{H} :

$$\mathbf{H} = \nabla \times \mathbf{A} = \nabla \times (\mathbf{A}' + \nabla \psi(\mathbf{r}, t)) = \nabla \times \mathbf{A}' + \nabla \times \nabla \psi = \nabla \times \mathbf{A}'.$$

Now consider the determination of the scalar potential φ given by formula (10.2). The transformation (11.1) leads to the value

$$\mathbf{E} = -\nabla \varphi - \frac{1}{c} \frac{\partial \mathbf{A}'}{\partial t} - \frac{1}{c} \nabla \frac{\partial \psi}{\partial t} = -\nabla \left(\varphi + \frac{1}{c} \frac{\partial \psi}{\partial t} \right) - \frac{1}{c} \frac{\partial \mathbf{A}'}{\partial t}.$$

Substituting

$$\varphi \rightarrow \varphi' - \frac{1}{c} \frac{\partial \psi}{\partial t}, \quad (11.2)$$

we arrive at the previous expression for the electric field strength.

Thus, the vector potential is determined to within a vector representing the gradient of an arbitrary function of coordinates and time $\psi(\mathbf{r}, t)$, while the scalar potential is determined to within the derivative of the same function with respect to time. In particular, in the case of a time-independent electric field, one can add an arbitrary constant to the potential φ and arrive at the same value of the field strength $\mathbf{E} = -\nabla(\varphi + \text{const}) = -\nabla \varphi$.

In general it can be said that two fields described by the system of potentials \mathbf{A}' and φ' and \mathbf{A} and φ respectively, are physically identical if \mathbf{A} and \mathbf{A}' , φ and φ' can be connected with each other by the relations (11.1) and (11.2). The same fact can be expressed by the words: electromagnetic field equations are invariant under the transformations (11.1) and (11.2).

Different ways of choosing the potentials \mathbf{A} and φ , leaving the field strengths \mathbf{E} and \mathbf{H} unchanged, are called different gauges of the potentials. The invariance of the fields \mathbf{E} and \mathbf{H} and all other relations of the field theory with respect to different gauges are called gauge invariance. The property of gauge invariance permits one, by allowing a certain degree of arbitrariness in choosing electromagnetic potentials, to select them in such a way that the relations of the field theory may take the simplest form.

Lorentz's condition, introduced in the previous paragraph, serves as an example of such a selection.

We can now show that Lorentz's condition corresponds to a definite gauge

of potentials (Lorentz gauge). Let the Lorentz condition not be fulfilled for certain A_0 and φ_0 , so that

$$\nabla \cdot A_0 + \frac{1}{c} \frac{\partial \varphi_0}{\partial t} = \chi(\mathbf{r}, t) \neq 0.$$

We perform the gauge transformation (11.1) and (11.2):

$$A_0 \rightarrow A + \nabla \psi,$$

$$\varphi_0 \rightarrow \varphi - \frac{1}{c} \frac{\partial \psi}{\partial t}.$$

Then we have

$$\nabla \cdot A + \frac{1}{c} \frac{\partial \varphi}{\partial t} = \chi(\mathbf{r}, t) - \nabla^2 \psi + \frac{1}{c^2} \frac{\partial^2 \psi}{\partial t^2}. \quad (11.3)$$

If it is required that the function ψ should satisfy D'Alembert's equation

$$\nabla^2 \psi - \frac{1}{c^2} \frac{\partial^2 \psi}{\partial t^2} = \chi(\mathbf{r}, t), \quad (11.4)$$

then the Lorentz condition will be fulfilled for the transformed potentials A and φ . We have already mentioned that D'Alembert's equation always has a solution. Hence, for a given value of χ it is always possible to select a function ψ satisfying (11.4).

It should be stressed that the arbitrary function $\psi(\mathbf{r}, t)$ is not determined completely by eq. (11.4). One can add to it a function $\psi_0(\mathbf{r}, t)$ representing the solution of the homogeneous equation

$$\nabla^2 \psi_0 - \frac{1}{c^2} \frac{\partial^2 \psi_0}{\partial t^2} = 0.$$

Performing the transformations

$$A \rightarrow A' + \nabla \psi_0,$$

$$\varphi \rightarrow \varphi' - \frac{1}{c} \frac{\partial \psi_0}{\partial t},$$

we arrive again at the same values of field strengths \mathbf{E} and \mathbf{H} :

$$\mathbf{H} = \nabla \times \mathbf{A}',$$

$$\mathbf{E} = -\frac{1}{c} \frac{\partial \mathbf{A}'}{\partial t} - \nabla \varphi',$$

and the potentials \mathbf{A}' and φ' satisfy the Lorentz condition:

$$\nabla \cdot \mathbf{A}' + \frac{1}{c} \frac{\partial \varphi'}{\partial t} = 0.$$

Therefore, remaining within the framework of the Lorentz gauge, one can choose the function ψ in such a way that an additional condition, imposed upon one of the four values φ, A_x, A_y, A_z , can be fulfilled.

In addition to the Lorentz gauge use is sometimes made (particularly in quantum field theory) of another gauge, the so-called Coulomb gauge, for which

$$\nabla \cdot \mathbf{A} = 0.$$

In this gauge the equations for potentials (eqs. (10.3) and (10.4)) assume the form

$$\nabla^2 \mathbf{A} - \frac{1}{c^2} \frac{\partial^2 \mathbf{A}}{\partial t^2} - \frac{1}{c} \nabla \frac{\partial \varphi}{\partial t} = -\frac{4\pi}{c} \mathbf{j},$$

$$\nabla^2 \varphi = -4\pi\rho,$$

and the scalar potential φ is determined by the distribution of charges as if they were at rest. It goes without saying that the field strengths \mathbf{E} and \mathbf{H} found from the solutions of the equations for the potentials with the Coulomb gauge and with the Lorentz gauge are the same. In this book we shall, as a rule, make use of the Lorentz gauge.

§ 12. Energy conservation law of the electromagnetic field

The first important general consequence following from Maxwell's equations is the existence of the electromagnetic field energy. In order to find this

energy we shall consider a closed system consisting of a field and particles. Let us find the work W done by the field forces on the particles in a volume V . By considering the rate at which this is done, assuming the charges to be continuously distributed in space, and making use of (8.8), we can write that

$$\begin{aligned}
 \frac{dW}{dt} &= \int \mathbf{F} \cdot \mathbf{v} dV = \int \rho \left(\mathbf{E} + \frac{1}{c} \mathbf{v} \times \mathbf{H} \right) \cdot \mathbf{v} dV = \\
 &= \int \rho \mathbf{E} \cdot \mathbf{v} dV + \frac{1}{c} \int \rho (\mathbf{v} \times \mathbf{H}) \cdot \mathbf{v} dV = \\
 &= \int \mathbf{j} \cdot \mathbf{E} dV + \frac{1}{c} \int \rho (\mathbf{v} \times \mathbf{v}) \cdot \mathbf{H} dV = \int \mathbf{j} \cdot \mathbf{E} dV.
 \end{aligned} \tag{12.1}$$

The work of the magnetic field force is equal to zero, since this force is perpendicular to the velocity of the particle.

We transform the relation (12.1), making use of one of Maxwell's equations. Expressing the current density in terms of the field vectors by means of (8.3), we have

$$\frac{dW}{dt} = \int \mathbf{j} \cdot \mathbf{E} dV = \frac{c}{4\pi} \int \mathbf{E} \cdot (\nabla \times \mathbf{H}) dV - \frac{1}{4\pi} \int \mathbf{E} \cdot \frac{\partial \mathbf{E}}{\partial t} dV. \tag{12.2}$$

As we have stressed more than once, there must exist a symmetry between the electric and magnetic fields. However, eq. (12.2) is asymmetric. We can make it have the symmetric form by adding to its right side the expression

$$- \frac{c}{4\pi} \int \mathbf{H} \cdot \left(\nabla \times \mathbf{E} + \frac{1}{c} \frac{\partial \mathbf{H}}{\partial t} \right) dV,$$

which, from the Maxwell eq. (8.1), is equal to zero. This gives

$$\begin{aligned}
 \frac{dW}{dt} &= \int \mathbf{j} \cdot \mathbf{E} dV = \\
 &= \frac{c}{4\pi} \int [\mathbf{E} \cdot (\nabla \times \mathbf{H}) - \mathbf{H} \cdot (\nabla \times \mathbf{E})] dV - \int \frac{\partial}{\partial t} \left(\frac{E^2 + H^2}{8\pi} \right) dV
 \end{aligned} \tag{12.3}$$

The first integral in the right-hand side of eq. (12.3) can be transformed into a surface integral. Namely, according to formula (I. 44) we have

$$-\mathbf{E} \cdot (\nabla \times \mathbf{H}) - \mathbf{H} \cdot (\nabla \times \mathbf{E}) = \nabla \cdot (\mathbf{E} \times \mathbf{H}).$$

Hence

$$\begin{aligned} \int [\mathbf{E} \cdot (\nabla \times \mathbf{H}) - \mathbf{H} \cdot (\nabla \times \mathbf{E})] dV &= - \int \nabla \cdot (\mathbf{E} \times \mathbf{H}) dV = \\ &= - \oint (\mathbf{E} \times \mathbf{H}) \cdot d\mathbf{S}, \end{aligned}$$

and instead of (12.3) one can write

$$\frac{dW}{dt} = \int \mathbf{j} \cdot \mathbf{E} dV = - \frac{c}{4\pi} \oint (\mathbf{E} \times \mathbf{H}) \cdot d\mathbf{S} - \frac{\partial}{\partial t} \int \frac{E^2 + H^2}{8\pi} dV. \quad (12.4)$$

Consider the case when the integration volume V increases indefinitely until it covers all space. If the field vectors \mathbf{E} and \mathbf{H} tend to zero more rapidly than $1/r$ as $r \rightarrow \infty$, then the surface integral reduces to zero. Indeed, the integrand decreases more rapidly than $1/r^2$, while the magnitude of the surface increases as r^2 . Then (12.4) reduces to the equality

$$\frac{dW}{dt} = - \frac{d}{dt} \int u_0 dV, \quad (12.5)$$

where

$$u_0 = \frac{E^2 + H^2}{8\pi}. \quad (12.6)$$

Since the left-hand side of (12.5) represents the work done per second, the right-hand side represents the decrease in field energy per unit time.

In a closed system consisting of a field and particles the work done by the electromagnetic field on the particles is equal to the decrease in the energy of the field itself. In this case one has to ascribe to the electromagnetic field an energy whose density u_0 is expressed by formula (12.6). The expression

$$u = \int \frac{E^2 + H^2}{8\pi} dV$$

cannot be reduced to quantities which are determined only by the relative position and motion of charges. Hence it cannot be assumed to be the potential energy of the system of interacting particles. In particular the field energy density differs from zero in a region of space which is free of particles.

The possession of an energy by the electromagnetic field obviously shows that the field can in no way be considered as a mathematical fiction, a convenient method of calculating the interaction between charged particles. On the contrary, the field is as real as the particles. We shall convince ourselves more than once of the reality of the electromagnetic field on the basis of other facts also. However, within the framework of classical electrodynamics the interrelation between the field and the charges remains unexplained. Only quantum electrodynamics, which will be expounded briefly in Part V of this book, allows one to comprehend more profoundly the essence of the interrelation between the field and particles.

Let us now consider a region of the field which has a finite volume V and a limited surface S . Then eq. (12.4), expressing the energy conservation law, shows that the decrease in the field energy per unit time

$$\frac{\partial}{\partial t} \int \frac{E^2 + H^2}{8\pi} dV$$

in a certain volume V is equal to the work done by the field forces dW/dt per unit time on the charges contained in the same volume, together with the flux

$$\frac{c}{4\pi} \oint (\mathbf{E} \times \mathbf{H}) \cdot d\mathbf{S},$$

flowing through the closed surface S surrounding the volume V . It is obvious that this flux must be interpreted as an energy flux flowing out of the volume V . The energy flux is the electromagnetic field energy flux, since it also differs from zero when no particles pass through the surface carrying away energy. The electromagnetic field energy flux is characterized by a vector σ , called the Poynting vector, which is equal to

$$\sigma = \frac{c}{4\pi} \mathbf{E} \times \mathbf{H}. \quad (12.7)$$

The Poynting vector σ represents the field energy flux flowing through 1 cm^2 in the direction perpendicular to the field vectors \mathbf{E} and \mathbf{H} , and forms with them a right-handed screw system of coordinates.

Later we shall present a number of examples of the calculation of the Poynting vector. Here we shall confine ourselves only to the following remark. The vector σ is determined formally only with an accuracy to within

the curl of a certain vector \mathbf{a} . Assuming $\boldsymbol{\sigma}' = \boldsymbol{\sigma} + \nabla \times \mathbf{a}$, we have

$$\oint \boldsymbol{\sigma}' \cdot d\mathbf{S} = \oint \boldsymbol{\sigma} \cdot d\mathbf{S} + \oint (\nabla \times \mathbf{a}) \cdot d\mathbf{S} = \oint \boldsymbol{\sigma} \cdot d\mathbf{S},$$

since the integral of $\nabla \times \mathbf{a}$ over a closed surface is always equal to zero.

In reality, however, as will be shown in Part II, $\boldsymbol{\sigma}$ should be interpreted as the density of the field energy flux, assuming $\nabla \times \mathbf{a} = 0$. Sometimes as an example of the inadequacy of such an interpretation of $\boldsymbol{\sigma}$ the case of crossed static electric and magnetic fields is quoted. Formally, in this case $\boldsymbol{\sigma} \neq 0$, although there is no energy flux. However, it is forgotten that the vector $\boldsymbol{\sigma}$ must enter into the energy conservation law expressed by formula (12.4). The latter loses any sense in static fields, if it is assumed that $\boldsymbol{\sigma} \neq 0$.

In deriving formula (12.5) we have assumed that the integral $\oint \boldsymbol{\sigma} \cdot d\mathbf{S}$ reduces to zero in integrating over a closed surface of infinitely large radius. We shall see that in the problems of radiation theory fields are encountered which decrease with increasing distance according to the law $|\mathbf{E}| \sim |\mathbf{H}| \sim 1/r$ as $r \rightarrow \infty$. In this case the integral $\oint \boldsymbol{\sigma} \cdot d\mathbf{S}$, taken over an infinitely distant surface, will have a finite value. Physically this means that the system losing a part of its energy emits radiation.

Writing the energy conservation law in the differential form

$$\frac{\partial}{\partial t} \frac{E^2 + H^2}{8\pi} = -\mathbf{j} \cdot \mathbf{E} - \nabla \cdot \boldsymbol{\sigma}, \quad (12.8)$$

we draw attention to its analogy with the continuity eq. (8.5), expressing the charge conservation law. The left-hand side of formula (12.8) represents the change in the field energy of unit volume (change of a conserved quantity), while on the right-hand side there stands the work produced on the charges contained in this volume, as well as the divergence of the flux of the conserved quantity (the energy density).

§13. Momentum conservation law of the electromagnetic field

The electromagnetic field possesses momentum density as well as energy density.

We shall consider the change in the momentum of the particles confined in a volume V . The calculations are carried out in the same way as in deriving the energy conservation law.

From eq. (8.8) we have

$$\begin{aligned}
\frac{d\mathbf{P}_{\text{part}}}{dt} &= \frac{d}{dt} \int \mathbf{p}_0 dV = \int \rho \left(\mathbf{E} + \frac{1}{c} \mathbf{v} \times \mathbf{H} \right) dV = \\
&= \int \rho \mathbf{E} dV + \int \frac{1}{c} \mathbf{j} \times \mathbf{H} dV,
\end{aligned} \tag{13.1}$$

where \mathbf{P}_{part} is the total momentum of the particles. Expressing ρ and \mathbf{j} in terms of the field strengths according to (8.4) and (8.3), we find

$$\begin{aligned}
\frac{d}{dt} \mathbf{P}_{\text{part}} &= \frac{1}{4\pi} \int \mathbf{E} (\nabla \cdot \mathbf{E}) dV - \frac{1}{4\pi c} \int \frac{\partial \mathbf{E}}{\partial t} \times \mathbf{H} dV \\
&\quad + \frac{1}{4\pi} \int (\nabla \times \mathbf{H}) \times \mathbf{H} dV.
\end{aligned} \tag{13.2}$$

We symmetrize the above equation by adding to its right-hand side the expression

$$\frac{1}{4\pi} \left(\nabla \times \mathbf{E} + \frac{1}{c} \frac{\partial \mathbf{H}}{\partial t} \right) \times \mathbf{E} + \frac{1}{4\pi} \mathbf{H} (\nabla \cdot \mathbf{H}), \tag{13.3}$$

which is equal to zero. Then we have

$$\begin{aligned}
\frac{d}{dt} \mathbf{P}_{\text{part}} &= - \frac{1}{4\pi c} \frac{\partial}{\partial t} \int \mathbf{E} \times \mathbf{H} dV \\
&\quad + \frac{1}{4\pi} \int \{ \mathbf{E} (\nabla \cdot \mathbf{E}) + \mathbf{H} (\nabla \cdot \mathbf{H}) - \mathbf{E} \times (\nabla \times \mathbf{E}) - \mathbf{H} \times (\nabla \times \mathbf{H}) \} dV.
\end{aligned} \tag{13.4}$$

The second integral can be transformed into a surface integral. This transformation will be carried out below. It is clear that a surface integral containing field vectors to the second power will tend to zero as the surface increases indefinitely, provided the field vectors decrease more rapidly than the function $1/r$. Then, passing over to an infinitely large volume and discarding the second integral in (13.4), we arrive at the expression

$$\mathbf{P}_{\text{part}} + \frac{1}{4\pi c} \int \mathbf{E} \times \mathbf{H} dV = \text{const}. \tag{13.5}$$

Formula (13.5) shows that the total momentum of a closed system con-

sisting of a field and particles is conserved. The quantity

$$\mathbf{g} = \frac{1}{4\pi c} \mathbf{E} \times \mathbf{H} \quad (13.6)$$

represents the momentum density (the momentum per unit volume) of the electromagnetic field. For the interaction between a field and particles there holds, in addition to the total energy conservation law, the total momentum conservation law. The transfer of a momentum to the particles is accompanied by a decrease in the momentum of the field. A momentum loss of the particles (for example, in the emission of radiation) leads to an increase in the momentum of the field.

Now we shall show that the second integral in the form of (13.4) can be reduced to a surface integral. Since the integral

$$\int \{ \mathbf{E}(\nabla \cdot \mathbf{E}) + \mathbf{H}(\nabla \cdot \mathbf{H}) - \mathbf{E} \times (\nabla \times \mathbf{E}) - \mathbf{H} \times (\nabla \times \mathbf{H}) \} dV$$

is symmetric with respect to the vectors \mathbf{E} and \mathbf{H} , we shall consider only the integral

$$I = \int \{ \mathbf{E}(\nabla \cdot \mathbf{E}) - \mathbf{E} \times (\nabla \times \mathbf{E}) \} dV. \quad (13.7)$$

Making use of the vector identities (I. 53) and (I. 48) we can write

$$\int (\mathbf{E} \cdot \nabla) \mathbf{E} dV = \oint (\mathbf{E} \cdot \mathbf{n}) \mathbf{E} dS - \int \mathbf{E}(\nabla \cdot \mathbf{E}) dV, \quad (13.8)$$

$$\int (\mathbf{E} \cdot \nabla) \mathbf{E} \cdot dV = \int \nabla \cdot \frac{1}{2} E^2 dV - \int \mathbf{E} \times (\nabla \times \mathbf{E}) dV. \quad (13.9)$$

Subtracting (13.9) from (13.8) we find

$$\int \{ \mathbf{E}(\nabla \cdot \mathbf{E}) - \mathbf{E} \times (\nabla \times \mathbf{E}) \} dV = - \int \nabla \cdot \frac{1}{2} E^2 dV + \oint (\mathbf{E} \cdot \mathbf{n}) \mathbf{E} dS.$$

Taking into account (I.23), we obtain

$$I = \oint \{ (\mathbf{E} \cdot \mathbf{n}) \mathbf{E} - \mathbf{n} \cdot \frac{1}{2} E^2 \} dS.$$

An analogous expression can be written for the magnetic part of the integral which interests us. Thus, finally,

$$\int \{ \mathbf{E}(\nabla \cdot \mathbf{E}) - \mathbf{E} \times (\nabla \times \mathbf{E}) + \mathbf{H}(\nabla \cdot \mathbf{H}) - \mathbf{H} \times (\nabla \times \mathbf{H}) \} dV = \\ = \oint \{ \mathbf{E} \cdot \mathbf{n} \} \mathbf{E} - \mathbf{n} \frac{1}{2} E^2 + \{ \mathbf{H} \cdot \mathbf{n} \} \mathbf{H} - \mathbf{n} \frac{1}{2} H^2 \} dS. \quad (13.10)$$

Letting the radius of the integration surface go to infinity and assuming that the fields \mathbf{E} and \mathbf{H} decrease at infinity more rapidly than $1/r$, we arrive at the statement expressed earlier that the whole surface integral is equal to zero.

We shall not dwell on the consideration of a more complex case when the integration in (13.4) is carried out over a finite volume *.

We shall only state the result of such a case: the change in the total momentum of a field in a certain volume, $\int \mathbf{g} dV$, is equal to a change in the momentum of the particles confined in the volume and to the momentum flux through the surface bounding the volume.

The theoretical prediction of the existence of field momentum was first confirmed experimentally by P. N. Lebedev in 1901 in the form of the pressure of light. The electromagnetic field momentum is small under ordinary conditions and often lies below the limit of experimental errors. However, in the realm of atomic phenomena the electromagnetic field momentum becomes comparable with the momentum of particles and plays a paramount role in all processes of interaction between radiation and matter. Besides, in the realm of atomic phenomena, the radiation pressure plays a most essential role in processes taking place inside stars and star atmospheres and in other astrophysical phenomena.

It is interesting to note that between the momentum density vector \mathbf{g} and the Poynting vector there is the relation

$$\mathbf{g} = \frac{1}{c^2} \boldsymbol{\sigma}. \quad (13.11)$$

In the chapter devoted to the theory of relativity we shall see that there is a very general relation between the energy and momentum, from which the formula (13.9) is obtained as a consequence.

* See R. Becker, *Electromagnetic fields and interactions* (Blackie, London, 1964); I. E. Tamm, *Osnovy teorii elektrichestva (Introduction to the theory of electricity)* (Gostekhizdat, 1954) p. 506; and in particular, Y. I. Frenkel, *Elektrodinamika (Electrodynamics)* (GTTI, 1934) p. 235, where a more complete interpretation of the expression (13.6) is given.

In addition to the vector of the field momentum density \mathbf{g} one can consider the angular momentum density

$$\mathbf{k}_0 = \mathbf{r} \times \mathbf{g} = \frac{1}{4\pi c} \mathbf{r} \times (\mathbf{E} \times \mathbf{H}).$$

The field angular momentum in a volume V is equal to

$$\mathbf{k} = \frac{1}{4\pi c} \int \mathbf{r} \times (\mathbf{E} \times \mathbf{H}) dV.$$

It can be shown that a conservation law holds for the angular momentum, as well as for the energy and linear momentum. The angular momentum of the electromagnetic field plays an important role in atomic processes. In phenomena on the macroscopic scale the angular momentum has been measured relatively recently *.

The Electrostatic Field

§ 14. The electrostatic field

Having formulated the general equations of the electromagnetic field and discussed the basic consequences following from them, we can proceed to the discussion of particular cases of electromagnetic fields. We shall progress successively from the most simple to more complex cases.

The simplest example of the electromagnetic field is the field of charges at rest.

We write Maxwell's equations for this case

Differential form

$$\nabla \cdot \mathbf{E} = 4\pi\rho, \quad (14.1)$$

$$\nabla \times \mathbf{E} = 0, \quad (14.2)$$

$$\nabla \cdot \mathbf{H} = 0, \quad (14.3)$$

$$\nabla \times \mathbf{H} = 0, \quad (14.4)$$

Integral form

$$\oint \mathbf{E} \cdot d\mathbf{S} = 4\pi \sum e_i, \quad (14.1')$$

$$\oint \mathbf{E} \cdot d\mathbf{l} = 0, \quad (14.2')$$

$$\oint \mathbf{H} \cdot d\mathbf{S} = 0, \quad (14.3')$$

$$\oint \mathbf{H} \cdot d\mathbf{l} = 0. \quad (14.4')$$

The system of equations of the electromagnetic field reduces here to systems of independent equations for the electric and magnetic fields. The solution of the equations for the magnetic field, which does not depend on

time, has the trivial form

$$\mathbf{H} = 0.$$

This means that charges at rest are not surrounded by a magnetic field. The electric field associated with charges at rest is, as we have already mentioned, irrotational. Its sources and sinks are the charges.

In practice one most often needs to find the electric field distribution when the distribution of the charge density in space, $\rho(\mathbf{r})$, is known. For this it is necessary to integrate the system of differential eqs. (14.1) and (14.2) for a given function $\rho(\mathbf{r})$. This is the so-called direct problem of electrostatics.

An incomparably simpler, but more seldom encountered problem of electrostatics is the inverse one — finding the charge density $\rho(\mathbf{r})$ from a given field distribution $\mathbf{E}(\mathbf{r})$. In order to solve the inverse problem of electrostatics, it is sufficient, according to (14.1), to find the divergence of the given field.

As we have already mentioned in §4, to find the general solution of the equations of the electrostatic field it is convenient to make use of the method of electrostatic potential. According to (4.11) or (10.2), it can be assumed that

$$\mathbf{E} = - \nabla \varphi. \quad (14.5)$$

From (14.1) we obtain Poisson's equation:

$$\nabla^2 \varphi = - 4\pi \rho. \quad (14.6)$$

Eq. (14.2) will be satisfied automatically by introducing the potential according to formula (14.5), since for an arbitrary form of the function $\varphi(\mathbf{r})$ there holds the equality

$$\nabla \times \nabla \varphi = 0.$$

Consequently, Maxwell's equations for the electrostatic field (14.1) and (14.2) are completely equivalent to Poisson's equation. Knowing its solution — the scalar potential $\varphi(\mathbf{r})$ — one can determine the strength of the field \mathbf{E} by differentiation.

It should be stressed that only the field strength \mathbf{E} has a physical meaning. The scalar potential is only an auxiliary, though very convenient, quantity. The value of the potential is determined in electrostatics to within an arbitrary constant: adding any constant a to the potential φ , we arrive at a potential

$\varphi' = \varphi + a$, which corresponds to a field $\mathbf{E} = -\nabla \varphi' = -\nabla \varphi$. This transformation is a particular case of the gauge transformation considered in § 11. Because of the incomplete determination of the potential it is senseless to speak about the numerical value of the potential φ at a given point of the field.

Henceforth, in considering solutions of Poisson's equation, and in discussing other properties of the potential, we shall assume a definite behaviour of the potential φ at infinity. If it is assumed that all the charges are distributed in a finite region of space surrounding the point chosen as the origin, then as $r \rightarrow \infty$ the field strength will not decrease more slowly than $1/r^2$. In accordance with this, the solutions of the Poisson equation must satisfy the requirement

$$\varphi \rightarrow 0 \quad \text{as} \quad r \rightarrow \infty. \quad (14.7)$$

From the mathematical standpoint Poisson's equation, a second order partial differential equation, is in some respects more convenient and simpler for the calculation than the field eqs. (14.1) and (14.2), which are first order partial differential equations. If the potential φ at infinity satisfies the condition (14.7), then the solution of Poisson's equation can be written in a general form.

In § 2 the general solution of the eq. (14.6),

$$\begin{aligned} \varphi(\mathbf{r}) &= \int \frac{\rho(\mathbf{r}') dV'}{R} = \int \frac{\rho(\mathbf{r}') dV'}{|\mathbf{r} - \mathbf{r}'|} = \\ &= \int \frac{\rho(x', y', z') dx' dy' dz'}{\sqrt{(x - x')^2 + (y - y')^2 + (z - z')^2}}, \end{aligned} \quad (14.8)$$

was given without proof (the latter will be given in § 24). Knowing the distribution of the charge density in space $\rho(x', y', z')$ and integrating over all space, one can find the value of φ at any point (x, y, z) .

The actual calculation of the field according to formula (14.8), requiring the calculation of a triple integral, often turns out to be impracticable. Later, in Part IV, we shall discuss briefly the basic methods of solving the problems of electrostatics taking into account the specific properties of physical bodies — dielectrics and metals. Here we shall confine ourselves only to the simplest system — a system of point charges.

§15. The electrostatic field of a system of point charges

The contrivance of considering the charges as spread out in space and the description of the properties of a system of charges by means of the continuous function $\rho(\mathbf{r}')$ allowed us to pass over from the integral relation (14.1') to the differential equation (14.1). The importance of this transition is clear from the fact that it made it possible to formulate differential field equations. Nevertheless, in some cases it is inadmissible to disregard the point structure of the charges forming real systems. Moreover, in a number of cases it turns out that it is more convenient to carry out the calculations for point systems than for distributed systems.

We write the charge density, characterizing a system of point charges, in the form

$$\rho = \sum e_i \delta(\mathbf{r}' - \mathbf{r}'_i),$$

where \mathbf{r}'_i is the radius-vector of the charge e_i . Substituting this expression into (14.8), we find the field potential of a system of point charges,

$$\varphi = \int \frac{\rho dV'}{|\mathbf{r} - \mathbf{r}'|} = \sum e_i \int \frac{\delta(\mathbf{r}' - \mathbf{r}'_i)}{|\mathbf{r} - \mathbf{r}'|} dV' = \sum \frac{e_i}{R_i}, \quad (15.1)$$

where $R_i = |\mathbf{r} - \mathbf{r}'_i|$, and \mathbf{r} is the radius-vector of the observation point. Here we have made use of the basic property of the delta-function (see III.3). Thus, the solution of the equation

$$\nabla^2 \varphi = -4\pi e \delta(\mathbf{r} - \mathbf{r}_0) \quad (15.2)$$

is the function

$$\varphi = \frac{e}{|\mathbf{r} - \mathbf{r}_0|}. \quad (15.3)$$

Formula (15.3) represents a useful relation which we shall use in what follows.

The field of a system of point charges is given by the formula

$$\mathbf{E} = -\nabla \varphi = \sum \frac{e_i}{R_i^3} \mathbf{R}_i. \quad (15.4)$$

In the case of a single charge, formula (15.4) gives

$$\mathbf{E} = \frac{e}{R^3} \mathbf{R}. \quad (15.5)$$

For the force acting on a test charge ϵ placed in the field of a single charge one obtains the Coulomb law

$$\mathbf{F} = \frac{\epsilon e}{R^3} \mathbf{R}. \quad (15.6)$$

If the number of charges in the system is large, the sums in formula (15.1) and (15.4) contain a large number of terms, and these formulae become of little use for practical calculations. However, formula (15.1) allows a substantial simplification at distances from the system which substantially exceed its spatial extension. Distances which are large in comparison with the dimensions of the system will be called, for brevity, large distances. If the observation point N is located at a large distance from the system, then there holds the inequality (fig. 1.6)

$$|\mathbf{r}| \gg |\mathbf{r}'_i|.$$

Let us consider one of the terms in formula (15.1). In order not to encumber subsequent formulae by indices, we shall not write the sign of the sum, and the distance from the i th charge to the observation point will be written

Fig. 1.6

in the form

$$\begin{aligned} \frac{1}{R_i} &= \frac{1}{|\mathbf{r} - \mathbf{r}'_i|} = \frac{1}{\sqrt{(x - x'_i)^2 + (y - y'_i)^2 + (z - z'_i)^2}} = \\ &= \frac{1}{\sqrt{\sum_{\alpha=1}^3 (x_{\alpha} - x'_{i\alpha})^2}}, \end{aligned} \quad (15.7)$$

where the index α signifies the three components of the corresponding vectors. Since $|x'_{i\alpha}| \ll |x_{\alpha}|$, expanding (15.7) in the Taylor series we have

$$\begin{aligned} \frac{1}{R_i} &= \frac{1}{|\mathbf{r} - \mathbf{r}'_i|} = \frac{1}{r} - \sum_{\alpha} x'_{i\alpha} \left\{ \frac{\partial}{\partial x_{\alpha}} \left(\frac{1}{r} \right) \right\}_0 + \\ &+ \frac{1}{2} \sum_{\alpha, \beta} x'_{i\alpha} x'_{i\beta} \left\{ \frac{\partial^2}{\partial x_{\alpha} \partial x_{\beta}} \left(\frac{1}{r} \right) \right\}_0 + \dots \end{aligned} \quad (15.8)$$

Substituting the expansion (15.8) into formula (15.1), we find

$$\begin{aligned} \varphi &= \frac{\sum e_i}{r} - \sum_{\alpha} \left(\sum_i e_i x'_{i\alpha} \right) \frac{\partial}{\partial x_{\alpha}} \left(\frac{1}{r} \right) + \\ &+ \frac{1}{2} \sum_{\alpha, \beta} \sum_i (e_i x'_{i\alpha} x'_{i\beta}) \frac{\partial^2}{\partial x_{\alpha} \partial x_{\beta}} \left(\frac{1}{r} \right) + \dots = \\ &= \varphi_0 + \varphi_1 + \varphi_2 + \dots, \end{aligned} \quad (15.9)$$

where

$$\varphi_0 = \frac{\sum e_i}{r} = \frac{e}{r}, \quad (15.10)$$

$$\varphi_1 = - \sum_{\alpha} \left(\sum_i e_i x'_{i\alpha} \right) \frac{\partial}{\partial x_{\alpha}} \left(\frac{1}{r} \right), \quad (15.11)$$

$$\varphi_2 = \frac{1}{2} \sum_{\alpha, \beta} \left(\sum_i e_i x'_{i\alpha} x'_{i\beta} \right) \frac{\partial^2}{\partial x_{\alpha} \partial x_{\beta}} \left(\frac{1}{r} \right). \quad (15.12)$$

The summation with respect to i is carried out over all charges of the system. Hence $\sum_i e_i = e$ represents the total charge of the system.

We see that at large distances the ratio between two successive terms of the expansion of the potential is of the order of magnitude of the ratio $\frac{\text{size of the system}}{\text{distance to the observation point}}$. The first term of the expansion φ_0 is the same as the potential of the field produced at the given point N by a charge e equal to the total charge of the system. Every subsequent term of the expansion contains the above mentioned ratio, of size of the system ($\sim |\mathbf{x}'|$) to the distance to the observation point $|\mathbf{r}|$, to a higher power.

In the case of an electrically neutral system the total charge $e = \sum_i e_i = 0$, and the first term of the series (15.9) vanishes. We shall deal with such systems very often. It is sufficient to point out, for example, that all atoms and molecules are electrically neutral systems. The potential of the field produced by an electrically neutral system of charges is given by the expansion (15.9) beginning with the second term φ_1 . Let us consider it in more detail. We write φ_1 in the vector form

$$\begin{aligned}\varphi_1 &= -\sum_{\alpha} \left(\sum_i e_i x'_{i\alpha} \right) \frac{\partial}{\partial x_{\alpha}} \left(\frac{1}{r} \right) = -\sum_i e_i \left(\nabla \frac{1}{r} \right) \cdot \mathbf{r}'_i = \\ &= -\left(\nabla \frac{1}{r} \right) \cdot \sum_i e_i \mathbf{r}'_i,\end{aligned}\quad (15.13)$$

where the gradient is taken with respect to the coordinates of the observation point. The quantity

$$\mathbf{d} = \sum e_i \mathbf{r}'_i = \int \rho \mathbf{r}' dV' \quad (15.14)$$

is called the dipole moment of the system. In the particular case of a system consisting of two charges of the same magnitude but opposite sign, which is called a dipole, the dipole moment is equal to

$$\mathbf{d} = e_1 \mathbf{r}'_1 + e_2 \mathbf{r}'_2 = |e| (\mathbf{r}'_1 - \mathbf{r}'_2),$$

i.e. to the product of the value of the charge and the vector $\mathbf{l} = (\mathbf{r}'_1 - \mathbf{r}'_2)$.

The field of an electrically neutral system in the first approximation (called the dipole approximation) is written in the form

$$\varphi \approx \varphi_1 = -\mathbf{d} \cdot \left(\nabla \frac{1}{r} \right) = \frac{\mathbf{d} \cdot \mathbf{r}}{r^3} = \frac{d \cos \theta}{r^2}, \quad (15.15)$$

where θ is the angle between the dipole moment and the radius-vector drawn to the observation point. Thus, the potential of the field of an electrically neutral system decreases (at large distances from the system) according to the law $\varphi \sim 1/r^2$.

Just as we have passed over from point charges to a charge distributed continuously in space with density ρ , one can introduce the notion of the dipole moment density \mathbf{p} distributed continuously in space. By definition, \mathbf{p} is the dipole moment per unit volume. The potential of the field produced by the overall system can, obviously, be written in the form

$$\varphi = -\int \mathbf{p} \cdot \left(\nabla \frac{1}{r} \right) dV',$$

where $\mathbf{p} \cdot (\nabla(1/r))dV'$ is the potential produced at the point N by the dipole moment contained in a volume dV' , and the integration is carried out over the entire volume of the system. It should be noted that instead of the differentiation with respect to the coordinates of the observation point one often makes use of the differentiation with respect to the coordinates of the source. Then according to (1.17) we have $\nabla(1/r) = -\nabla'(1/r)$ and instead of (15.15) we can write

$$\varphi = \mathbf{d} \cdot \left(\nabla' \frac{1}{r} \right), \quad (15.16)$$

or

$$\varphi = \int \mathbf{p} \cdot \left(\nabla' \frac{1}{r} \right) dV. \quad (15.17)$$

We shall need formula (15.17) later (see Part IV).

Consider the problem of the dependence of the dipole moment on the choice of the origin. Assume that we locate a new origin at an arbitrary constant vector \mathbf{a} with respect to the old origin, i.e. we perform the transformation

$$\mathbf{r}'_i = \mathbf{r}''_i + \mathbf{a}.$$

Then the dipole moment will be equal to

$$\mathbf{d} = \sum e_i \mathbf{r}'_i = \sum e_i \mathbf{r}''_i + \sum e_i \mathbf{a} = \mathbf{d}' + \mathbf{a} \sum e_i,$$

where $\mathbf{d}' = \sum e_i \mathbf{r}''_i$. If the system as a whole is electrically neutral, then $\sum e_i = 0$ and $\mathbf{d}' = \mathbf{d}$. In this case the value of the dipole moment does not change when the origin is displaced. If, on the contrary, the system possesses a total charge, then $\mathbf{d}' \neq \mathbf{d}$ and, consequently, the dipole moment of the system depends on the choice of the origin. It is then always possible to find a value of \mathbf{a} such that the dipole moment reduces to zero. Thus, the dipole moment of any system possessing a total charge may be considered as equal to zero.

We now determine the field of an electrically neutral system in the dipole approximation.

We have

$$\begin{aligned} \mathbf{E} &= -\nabla\varphi \approx -\nabla\varphi_1 = -\nabla\left(\frac{\mathbf{d} \cdot \mathbf{r}}{r^3}\right) = \\ &= -\frac{1}{r^3} \nabla(\mathbf{d} \cdot \mathbf{r}) - (\mathbf{d} \cdot \mathbf{r}) \left(\nabla \frac{1}{r^3}\right). \end{aligned}$$

Calculation by means of formulae (1.47) gives

$$\mathbf{E} = \frac{3\mathbf{r}(\mathbf{r} \cdot \mathbf{d}) - r^2 \mathbf{d}}{r^5}. \quad (15.18)$$

At large distances the field of an electrically neutral system decreases according to the law $\mathbf{E} \sim 1/r^3$ and has a strongly pronounced asymmetry. In polar coordinates (r, θ) its components (according to 1.71) have the form

$$\begin{aligned} E_r &= -\frac{\partial\varphi}{\partial r} = \frac{2d \cos \theta}{r^3} = \text{radial component}, \\ E_\theta &= -\frac{1}{r} \frac{\partial\varphi}{\partial \theta} = \frac{d \sin \theta}{r^3} = \text{meridional component}. \end{aligned}$$

§ 16. Quadrupole moment

If the dipole moment of an electrically neutral system of charges is equal

to zero, then in the expansion of the potential (15.9) one has to take into account the expansion term φ_2 .

An example of an electrically neutral system with dipole moment zero is the system of two dipoles of the same magnitude with opposite directions of the dipole moments placed an infinitely small distance apart. Such a system is called a quadrupole.

The potential of the field produced by a quadrupole has the form

$$\varphi \approx \varphi_2 = \frac{1}{2} \sum_{\alpha, \beta} \sum_i e_i x'_{i\alpha} x'_{i\beta} \frac{\partial^2}{\partial x_\alpha \partial x_\beta} \left(\frac{1}{r} \right). \quad (16.1)$$

In order to obtain φ one has to calculate the expression

$$\begin{aligned} \frac{\partial^2}{\partial x_\alpha \partial x_\beta} \left(\frac{1}{r} \right) &= \frac{\partial}{\partial x_\alpha} \left(\frac{\partial}{\partial x_\beta} \frac{1}{r} \right) = - \frac{\partial}{\partial x_\alpha} \frac{x_\beta}{r^3} = \\ &= -x_\beta \frac{\partial}{\partial x_\alpha} \left(\frac{1}{r^3} \right) - \frac{1}{r^3} \frac{\partial x_\beta}{\partial x_\alpha} = -\frac{1}{r^3} \delta_{\alpha\beta} + \frac{3x_\alpha x_\beta}{r^5}, \end{aligned}$$

where $\delta_{\alpha\beta}$ is the Kronecker symbol, α, β assume the values 1, 2, 3, and x_α, x_β represent an abbreviated notation of the coordinates $x_1 = x, x_2 = y, x_3 = z$. We then have

$$\varphi_2 = \frac{1}{2} \sum_{\alpha, \beta} \sum_i e_i x'_{i\alpha} x'_{i\beta} \left(\frac{3x_\alpha x_\beta}{r^5} - \frac{\delta_{\alpha\beta}}{r^3} \right).$$

The whole set of the quantities $\sum_i e_i x'_{i\alpha} x'_{i\beta}$ is a second-rank tensor. This tensor is called the quadrupole moment of the system and is denoted by $D_{\alpha\beta}$. Then

$$\varphi_2 = \frac{1}{2} \sum_{\alpha, \beta} D_{\alpha\beta} \left(\frac{3x_\alpha x_\beta}{r^5} - \frac{\delta_{\alpha\beta}}{r^3} \right), \quad (16.2)$$

$$D_{\alpha\beta} = \sum_i e_i x'_{i\alpha} x'_{i\beta}. \quad (16.3)$$

If one passes over to a continuous distribution of charge, the quadrupole moment can be written in the form

$$D_{\alpha\beta} = \int \rho x'_\alpha x'_\beta dV'. \quad (16.3')$$

Omitting for brevity the index of summation over all the particles, we can write the expression for φ_2 in the coordinate representation:

$$\varphi_2 = \frac{1}{2} \sum e \left\{ x'^2 \left(\frac{3x^2}{r^5} - \frac{1}{r^3} \right) + y'^2 \left(\frac{3y^2}{r^5} - \frac{1}{r^3} \right) + z'^2 \left(\frac{3z^2}{r^5} - \frac{1}{r^3} \right) + \right. \\ \left. + 2x'y' \frac{3xy}{r^5} + 2x'z' \frac{3xz}{r^5} + 2y'z' \frac{3yz}{r^5} \right\}.$$

This expression is usually rearranged by adding to it the quantity

$$\frac{1}{3} r'^2 \frac{3}{r^3} \left(\frac{x^2 + y^2 + z^2}{r^2} - 1 \right),$$

which is equal to zero, and by re-grouping the terms in the form

$$\begin{aligned} \varphi_2 &= \frac{1}{2} \sum e \left\{ \left(x'^2 - \frac{1}{3} r'^2 \right) \left(\frac{3x^2}{r^5} - \frac{1}{r^3} \right) + \right. \\ &\quad + \left(y'^2 - \frac{1}{3} r'^2 \right) \left(\frac{3y^2}{r^5} - \frac{1}{r^3} \right) + \left(z'^2 - \frac{1}{3} r'^2 \right) \left(\frac{3z^2}{r^5} - \frac{1}{r^3} \right) + \\ &\quad + 2x'y' \frac{3xy}{r^5} + 2x'z' \frac{3xz}{r^5} + 2y'z' \frac{3yz}{r^5} \Big\} = \\ &= \frac{1}{2} \sum_{\alpha, \beta} D_{\alpha\beta} \left(\frac{3x_{\alpha}x_{\beta}}{r^5} - \frac{\delta_{\alpha\beta}}{r^3} \right). \end{aligned} \quad (16.4)$$

In this case the quadrupole moment $D_{\alpha\beta}$ is defined as

$$D_{\alpha\beta} = \sum_i e_i \left(x'_{i\alpha} x'_{i\beta} - \frac{1}{3} r'^2 \delta_{\alpha\beta} \right). \quad (16.5)$$

The set of the quantities $D_{\alpha\beta}$ is easily written in the explicit form:

$$\begin{aligned} D_{xx} &= \sum e_i [(x'_i)^2 - \frac{1}{3} r'^2_i], & D_{xy} &= D_{yx} = \sum e_i x'_i y'_i, \\ D_{yy} &= \sum e_i [(y'_i)^2 - \frac{1}{3} r'^2_i], & D_{yz} &= D_{zy} = \sum e_i y'_i z'_i, \\ D_{zz} &= \sum e_i [(z'_i)^2 - \frac{1}{3} r'^2_i], & D_{zx} &= D_{xz} = \sum e_i z'_i x'_i. \end{aligned}$$

All of the nine quantities $D_{\alpha\beta}$ forming the quadrupole moment depend, obviously, only on the positions and values of the charges of the system.

From the definition (16.5) it is clear that the quadrupole moment tensor is symmetric, so that

$$D_{\alpha\beta} = D_{\beta\alpha}.$$

The symmetric second-rank tensor has six independent components.

Further we note that the sum of all diagonal components of the quadrupole moment is equal to zero:

$$D_{xx} + D_{yy} + D_{zz} = 0. \quad (16.6)$$

This reduces the number of independent components of the quadrupole moment to five.

Like any symmetric tensor, $D_{\alpha\beta}$ can be reduced to principal axes. This procedure is completely analogous to the reduction of the inertia tensor to principal axes in mechanics. Namely, we perform a rotation of the coordinate frame. Then to the coordinates x'_i, y'_i, z'_i there will correspond new coordinates x_i, y_i, z_i . We choose the coefficients of the corresponding linear transformation in such a way that the components of $D_{\alpha\beta}$ with different values of the indices α and β reduce to zero. It can be shown that such a choice of the coefficients is always possible.

With the new axes we shall have:

$$D_1 = \frac{1}{3} \sum e_i (2x_{i1}^2 - x_{i2}^2 - x_{i3}^2) = D_{11},$$

$$D_2 = \frac{1}{3} \sum e_i (2x_{i2}^2 - x_{i1}^2 - x_{i3}^2) = D_{22},$$

$$D_3 = -(D_1 + D_2) = D_{33}.$$

An important case is the system of charges whose arrangement possesses axial symmetry. Let the symmetry axis be the x_3 -axis. The condition of symmetry with respect to the x_3 -axis allows one to write

$$\sum e_i x_{i1}^2 = \sum e_i x_{i2}^2,$$

so that the quadrupole moment has the components

$$D_1 = \frac{1}{3} \sum e_i (x_{i1}^2 - x_{i3}^2) = -\frac{1}{2} D,$$

$$D_2 = \frac{1}{3} \sum e_i (x_{i2}^2 - x_{i3}^2) = -\frac{1}{2} D,$$

$$D_3 = D.$$

The sign of the quantity D is called the sign of the quadrupole moment. According to (16.4), the potential of the quadrupole field is equal to

$$\varphi_2 = -\frac{3}{4} D \frac{r^2 - 3x_3^2}{r^5} = -\frac{3}{4} D \frac{1 - 3 \cos^2 \theta}{r^3},$$

where θ is the angle between the symmetry axis x_3 and the radius-vector \mathbf{r} of the observation point. The general character of the law of decrease of the quadrupole potential with increasing distance r is

$$\varphi_2 \sim 1/r^3.$$

Correspondingly, the electric field decreases according to the law

$$|\mathbf{E}| \sim 1/r^4.$$

As we have already mentioned in the preceding paragraph, if a system of charges as a whole is not electrically neutral, then the value of the dipole moment depends on the choice of the origin. The same also holds for the quadrupole moment. For the case of a system with a total charge differing from zero it is convenient to locate the origin at a point with a coordinate

$$\mathbf{r}_0 = \frac{\sum e_i \mathbf{r}_i}{\sum e_i}.$$

This point can be called the centre of charge of the system. If the origin is located at the centre of charge, then the dipole moment of the system of charges reduces automatically to zero. However, this does not hold for its quadrupole moment. Namely, if the disposition of the charges in the system is not spherically symmetric, then some or all components of the quadrupole moment differ from zero. Hence the presence of a quadrupole moment in a system of charges allows one to infer something about the symmetry of the system. Thus, for example, the presence of axial symmetry leads to the field distribution written above.

In connection with this fact the discovery of a quadrupole-moment in a number of atomic nuclei is of great significance. The presence of the quadrupole moment of nuclei showed that their form is non-spherical.

If the distribution of charges in a system possesses a very high symmetry, its quadrupole moment may turn out to be equal to zero. As an example, we cite a system of eight charges situated at the vertices of an infinitely small parallelepiped with a regular alternation of the signs of the charges. Such a system of charges, called an octupole, has neither dipole nor quadrupole moment. The potential of the octupole field is obtained by taking into account the fourth term of the expansion (15.9).

Continuing the process of expansion (15.9) one can obtain the field potential of multipoles of an arbitrary order.

§17. Work and energy in an external electrostatic field

According to the above, the work of displacement of a test charge from one point of a field to another can be expressed in terms of the change in the potential in the form

$$\begin{aligned} W &= \int_1^2 \mathbf{F} \cdot d\mathbf{l} = \epsilon \int_1^2 \mathbf{E} \cdot d\mathbf{l} = -\epsilon \int_1^2 \nabla \varphi \cdot d\mathbf{l} = \\ &= \epsilon [\varphi(\mathbf{r}_1) - \varphi(\mathbf{r}_2)] = -\epsilon \Delta \varphi. \end{aligned} \quad (17.1)$$

If a displacement of the charges of a system takes place, then the work of the displacement by vectors $d\mathbf{l}_i$ is equal to

$$dW = \sum e_i \mathbf{E} \cdot d\mathbf{l}_i.$$

Later we shall need the expression for the rate at which work is done on a system of charges. We find

$$\frac{dW}{dt} = \sum e_i \mathbf{E} \cdot \frac{d\mathbf{l}_i}{dt} = \sum e_i \mathbf{E} \cdot \mathbf{v}_i. \quad (17.2)$$

For the case of distributed charges

$$\frac{dW}{dt} = \int \rho \mathbf{v} \cdot \mathbf{E} dV = \int \mathbf{j} \cdot \mathbf{E} dV. \quad (17.3)$$

Knowing the work of displacement of a test charge, we can write its potential energy in the electrostatic field in the form

$$-\delta U(\mathbf{r}) = \delta W = -e\delta\varphi(\mathbf{r}),$$

where $U(\mathbf{r})$ is the potential energy at the point \mathbf{r} , and $\varphi(\mathbf{r})$ is the electrostatic potential at the same point. The form of the potential energy does not depend on the choice of the coordinate frame. Hence the relation

$$U = e\varphi \quad (17.4)$$

is valid not only in Cartesian coordinates but also in any generalized coordinates q_i . The generalized forces acting on the test charge can be written in the form

$$Q_i = -e \frac{\partial \varphi}{\partial q_i}. \quad (17.5)$$

Formulae (17.4) and (17.5) can be applied to the case where instead of a test charge an arbitrary system of charges is placed in an external field. In this case it is assumed that the external field \mathbf{E} is strong in comparison with the field produced by the charges of the system. It is assumed moreover that the potential of the external field varies sufficiently slowly from point to point. The potential energy of the system of charges can be written in the form

$$U = \sum e_i \varphi(\mathbf{r}'_i), \quad (17.6)$$

where $\varphi(\mathbf{r}'_i)$ is the potential of the external field at a point \mathbf{r}'_i . Choosing the origin inside the system, we can write the potential in the form

$$\varphi(\mathbf{r}'_i) = \varphi(x', y', z'),$$

where x', y', z' are the distances from the origin to the charge. We now make use of the slowness of the variation of the potential of the external field in the region of space occupied by the charges. The slowly varying function φ can be expanded in a series in the quantities x', y', z' characterizing the extension of the system, and we can confine ourselves to the first terms of the expansion. This gives

$$\begin{aligned}\varphi(\mathbf{r}') &\approx \varphi(0, 0, 0) + x' \frac{\partial \varphi}{\partial x} + y' \frac{\partial \varphi}{\partial y} + z' \frac{\partial \varphi}{\partial z} = \\ &= \varphi(0) + \mathbf{r}' \cdot \nabla \varphi = \varphi(0) - \mathbf{r}' \cdot \mathbf{E}(0).\end{aligned}$$

Here $\varphi(0)$ and $\mathbf{E}(0)$ are respectively the potential and strength of the external field at the origin. Substituting the last expression for $\varphi(\mathbf{r}')$ into (17.6), we find

$$\begin{aligned}U &= \sum e_i \varphi_i \approx \sum e_i \varphi(0) - \sum e_i \mathbf{r}'_i \cdot \mathbf{E}(0) = \\ &= \varphi(0) \sum e_i - \mathbf{E}(0) \cdot \sum e_i \mathbf{r}'_i = e \varphi(0) - \mathbf{E}(0) \cdot \mathbf{d}.\end{aligned}\quad (17.7)$$

In the first approximation the potential energy of a system of charges in an external field is equal to the energy of one charge of the value $e = \sum e_i$, located at the origin. In the case of an electrically neutral system $e = 0$ and

$$U = -\mathbf{d} \cdot \mathbf{E} = -dE \cos \theta, \quad (17.8)$$

where θ is the angle between the dipole moment of the system and the external field vector.

Let us find the generalized forces acting on a system (assuming the latter to be undeformable, so that the distribution of the charges in the system is fixed). The generalized force corresponding to coordinates x, y, z is equal to

$$\mathbf{F} = -\nabla U = \nabla(\mathbf{d} \cdot \mathbf{E}),^*$$

or, evaluating the gradient of the product by means of formula (I.47) and taking into account that \mathbf{d} is a constant vector, we obtain

$$\mathbf{F} = (\mathbf{d} \cdot \nabla) \mathbf{E} + \mathbf{d} \times (\nabla \times \mathbf{E}) = (\mathbf{d} \cdot \nabla) \mathbf{E}. \quad (17.9)$$

In a uniform field ($\mathbf{E} = \text{const}$) an electrically neutral system with a dipole moment is not acted upon by any forces tending to displace it in space. Such forces exist only in a field which is non-uniform.

The generalized force corresponding to the generalized coordinate θ , which determines the orientation of the dipole moment vector, according to a well-known proposition of classical mechanics * represents a couple:

* Landau and E. M. Lifshitz, *Mechanics* (Pergamon, Oxford, 1960).

$$M = - \frac{\partial U}{\partial \theta} = dE \sin \theta . \quad (17.10)$$

The couple tends to turn the system in such a way that its dipole moment will be orientated parallel to the field.

The formulae found above allow one to find easily the law of charge-dipole and dipole-dipole interaction. For this $E(0)$ is understood to be the field produced at the point 0 by the charge or the dipole respectively.

For the potential energy of the charge-dipole interaction we find

$$U = - \mathbf{d} \cdot \mathbf{E} = - \frac{e \mathbf{r} \cdot \mathbf{d}}{r^3}, \quad (17.11)$$

where \mathbf{r} is the vector directed from the charge to the system, the value of which is equal to the distance from the charge to the system (in this approximation we have to disregard the spatial dimensions of the system).

The dipole-dipole potential energy, according to (15.18), is

$$U = - \mathbf{d}_1 \cdot \mathbf{E}_2 = \frac{(\mathbf{d}_1 \cdot \mathbf{d}_2)r^2 - 3(\mathbf{d}_1 \cdot \mathbf{r})(\mathbf{d}_2 \cdot \mathbf{r})}{r^5}, \quad (17.12)$$

where \mathbf{r} is the vector connecting the two dipoles.

§ 18. The interaction energy of a system of charges and the electrostatic field energy

We pass on to the calculation of the energy of a system of interacting charges. This energy can be calculated most simply in the following way. Let a charge e_1 be fixed at a certain point of space. A charge e_2 , which was initially at infinity, is displaced to a point located at a distance r_{12} from the first charge. In this case the external source must do work against the forces of the field:

$$W_{12} = e_2 [\varphi_1(r_{12}) - \varphi_1(r \rightarrow \infty)] = e_2 \varphi_1(r_{12}).$$

Since the potential of the field of the first charge at infinity is equal to zero, $\varphi_1(r_{12})$ represents the potential of the field of the first charge at the point r_{12} , which is equal to

$$\varphi_1(r_{12}) = e_1/r_{12}.$$

Hence the work of displacement of the second charge is equal to

$$W_{12} = \frac{e_1 e_2}{r_{12}}.$$

If a third charge is added to a system of two charges, it is necessary to produce the work

$$W_{123} = \frac{e_1 e_3}{r_{13}} + \frac{e_2 e_3}{r_{23}}.$$

Continuing with such a procedure for a system of N charges, we find that for this one has to expend the work

$$\begin{aligned} W = \frac{1}{2} e_1 \left[\frac{e_2}{r_{12}} + \frac{e_3}{r_{13}} + \dots + \frac{e_N}{r_{1N}} \right] + \frac{1}{2} e_2 \left[\frac{e_1}{r_{21}} + \frac{e_3}{r_{23}} + \dots + \right. \\ \left. + \frac{e_N}{r_{2N}} \right] + \dots = \frac{1}{2} \sum_i \sum_k \frac{e_i e_k}{r_{ik}} \quad (i \neq k). \end{aligned} \quad (18.1)$$

The coefficient $\frac{1}{2}$ is introduced because in the double sum the same terms, corresponding to each pair of particles, for example $e_1 e_2 / r_{12}$ and $e_2 e_1 / r_{21}$ are encountered twice. In order not to introduce a complicated restriction upon the performance of the summation, in (18.1) all such terms are taken into account and the result is reduced by a factor of two.

Introducing φ_i which is the potential produced by all the charges except the i th one at the locus of the latter, we can rewrite (18.1) in the form

$$W = \frac{1}{2} \sum e_i \varphi_i.$$

The work done in forming the charge distribution is equal to the potential energy stored in the system of particles. Thus,

$$U = \frac{1}{2} \sum e_i \varphi_i = \frac{1}{2} \sum e_i e_k / r_{ik}. \quad (18.2)$$

Passing over from point charges to a continuous charge density distribution, one can write (18.2) in the form

$$U = \frac{1}{2} \int \rho \varphi dV = \frac{1}{2} \iint \frac{\rho(\mathbf{r}) \rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} dV dV'. \quad (18.3)$$

The potential energy of the interaction (18.2) is determined by the instantaneous positions of all charges in the system. Formulae (18.2) and (18.3) can be interpreted in the following way: each charge contained in the system possesses a potential energy $\frac{1}{2} e_i \varphi_i$, and the energy of the system is made up of the energies of the charges constituting it.

We now transform formula (18.3), making use of the field equations. Expressing ρ in terms of \mathbf{E} according to (14.1), we find by means of (18.3)

$$\begin{aligned} U &= \frac{1}{8\pi} \int \varphi \nabla \cdot \mathbf{E} dV = \frac{1}{8\pi} \left[\int \nabla \cdot (\varphi \mathbf{E}) dV - \int \mathbf{E} \cdot (\nabla \varphi) dV \right] = \\ &= \int \frac{E^2}{8\pi} dV + \frac{1}{8\pi} \oint \varphi \mathbf{E} \cdot d\mathbf{S}. \end{aligned}$$

The integral over an infinite surface vanishes, since as $r \rightarrow \infty$ we have

$$\varphi < 1/r, \quad E < 1/r^2, \quad S \sim r^2.$$

Hence we find finally

$$U = \int \frac{E^2}{8\pi} dV. \quad (18.4)$$

Formula (18.4) is completely equivalent to (18.3). However, it does not contain any quantities characterizing the electric charges.

It is quite clear that the expression (18.4) is a particular case of the general expression for the electromagnetic field energy, and its derivation is a particular case of the proof presented in §12. However, it is inherent within the framework of electrostatics that neither of the two alternative formulae (18.3) and (18.4) is more fundamental. Since formula (18.3) does not contain any field characteristics, then in electrostatics the field can be treated as an auxiliary, purely mathematical method of describing the interaction between particles. The state of the system and its energy in electrostatics are determined solely by the values of the charges and their relative positions.

We have already emphasized earlier that in the general case of a system of moving charges and fields varying in time the situation differs radically from that in electrostatics. The electromagnetic field cannot in general be treated

as a purely mathematical concept. It is a physical object as real as charged particles.

It is interesting to apply formula (18.4) to a single elementary charge — an electron or proton. Its energy is equal to

$$U = e\varphi(0),$$

where $\varphi(0)$ is the field potential at the point at which the charge is located. Since the field considered is the field of the charge itself, its potential $\varphi = e/r$ increases indefinitely as r tends to zero. This means that a point particle would have an infinitely large self energy.

Thus, the concept of particles as point objects having no spatial extension leads to a physically senseless result. In this connection a number of attempts have been made to construct an electrodynamic theory of elementary particles having finite dimensions (theory of the extended electron). As we shall see in Part II, this theory turned out to be incompatible with the basic propositions of the theory of relativity.

In the problem of the self energy of an elementary charge, classical electrodynamics encountered an insurmountable difficulty. It was clear that the laws of classical electrodynamics, which had been in excellent agreement with experimental facts in the field of macroscopic physics, had a limited region of applicability. In going down to very small distances they must undergo fundamental changes. We shall speak about the limits of applicability of classical electrodynamics in later paragraphs of Part I.

The Quasistationary Magnetic Field

§ 19. The field of a system of charges undergoing a slow quasistationary motion

Next in degree of complexity is the case of the field of charges performing a slow quasistationary motion.

We shall call the motion of a system of charges slow when the velocities $|v|$ are small in comparison with the value of c , the unique characteristic quantity with the dimension of velocity contained in Maxwell's equations. We shall see later that the velocity c represents the velocity of propagation in space of all electromagnetic interactions.

Thus, the assumption of a slow motion of charges means that the finite velocity of propagation of electromagnetic fields can be disregarded (see § 23). For a slow motion it can be assumed that the field at any instant of time is determined approximately by the instantaneous disposition of the charges.

We shall understand quasistationary motion to be a motion of charges in a certain limited region which the charges do not leave during the motion. In this region the charges may move periodically or non-periodically. In the latter case, however, over a very long time the particles will inevitably either pass through the same sequences of states as in a periodic motion, or, in any case, through sequences of similar states. In other words, the motion will be almost periodic. It will be shown below that under these conditions the time

derivatives of fields in Maxwell's equations are small compared with spatial derivatives. Hence the term quasistationary motion.

Since the particles cannot go out of the region, the following condition must be fulfilled at the surface S_1 bounding the region:

$$j_n = 0. \quad (19.1)$$

Here j_n is the component of the current density normal to the surface.

For a slow motion of charges the variation of the charge density in time can be considered small, i.e. it can be assumed that

$$\nabla \cdot \mathbf{j} = 0. \quad (19.2)$$

Thus, for a quasistationary motion the current density vector has a solenoid character. In other words, the quasistationary character of the motion of the charges allows one to represent their trajectories in the form of closed tubes or threads. Each of these tubes is closed on itself inside the region of motion. Such a representation is particularly obvious in the case of macroscopic direct currents flowing, for example, along closed conductors (see § 17, Part IV).

For every closed tube of current there holds the equality

$$\mathbf{j} dV = \mathbf{j} dS dl = j dS dl = dl dl, \quad (19.3)$$

Fig. 1.7

where dS is the cross section, $j dS$ is the direct current flowing through the cross section of the tube, and dl is an element of the tube length. The directions of the vectors \mathbf{j} and $d\mathbf{l}$ are obviously the same. The integral of the current density over the entire volume is

$$\int \mathbf{j} dV = \int \oint dI d\mathbf{l} = \int dI \oint d\mathbf{l} = 0, \quad (19.4)$$

since the integral along the closed tube is $\oint d\mathbf{l} = 0$. The meaning of this equality is very simple. Let us consider, for example, its x -component. The integral $\int j_x dy dz$ represents the total current through the plane (yz) crossing the current tube (fig. 1.7). In a quasistationary state of the system the total current through any cross section is equal to zero. The number of charges passing along the normal to the cross section through all current tubes in both directions must be the same, since the charges are moving in a limited region of space.

We now pass over to the formulation of Maxwell's equations for the field of a system of charges performing a slow quasistationary motion.

In order to find out which simplifications can be introduced into Maxwell's equations for such a motion, we shall estimate the order of magnitude of the terms of the equations. Such methods of estimation are widely used in theoretical physics.

We begin with the estimation of the time derivatives appearing in Maxwell's equations. Since the system considered performs a periodic or almost periodic motion, the order of magnitude of the quantities $|\partial \mathbf{E} / \partial t|$ and $|\partial \mathbf{H} / \partial t|$ can be estimated by writing

$$\left| \frac{\partial \mathbf{E}}{\partial t} \right| \sim \frac{E}{T}, \quad \left| \frac{\partial \mathbf{H}}{\partial t} \right| \sim \frac{H}{T},$$

where T is the characteristic period of motion. The quantities E and H are the characteristic mean absolute values of field strengths in the region of space occupied by the system of charges. Of course, it makes no sense to seek to define these quantities more precisely by relating them to a definite instant of time or to a definite point of space. The relations written have the meaning of rough estimates of the order of magnitude.

Further, let us find the order of magnitude of the spatial derivatives of the field in the same region of space. The fields \mathbf{E} and \mathbf{H} in real systems performing a quasistationary motion vary from point to point in general reasonably smoothly. If the mean dimensions of the system are denoted by L , then the order of magnitude of all spatial derivatives can be written in the form

$$\left| \frac{\partial \mathbf{E}}{\partial x} \right| \sim \left| \frac{\partial \mathbf{E}}{\partial y} \right| \sim \left| \frac{\partial \mathbf{E}}{\partial z} \right| \sim \frac{E}{L}.$$

In this rough estimate we disregard the field distribution in the system and the specific dependence on different coordinates.

The quasistationary condition is that the temporal variations of the fields should be sufficiently slow that in Maxwell's equations one can discard the terms containing the time derivatives which have small coefficients compared with those of the terms characterizing the spatial variation of the fields. For this the following inequalities must be fulfilled (to order of magnitude):

$$\left| \frac{\partial \mathbf{E}_i}{\partial x_k} \right| \gg \frac{1}{c} \left| \frac{\partial \mathbf{H}_i}{\partial t} \right|,$$

$$\left| \frac{\partial \mathbf{H}_i}{\partial x_k} \right| \gg \frac{1}{c} \left| \frac{\partial \mathbf{E}_i}{\partial t} \right|,$$

or

$$\frac{E}{L} \gg \frac{1}{c} \frac{H}{T}, \quad \frac{H}{L} \gg \frac{1}{c} \frac{E}{T}. \quad (19.4')$$

However, in this case the following equalities must be fulfilled:

$$\frac{\partial \mathbf{E}_i}{\partial x_k} \approx \frac{\partial \mathbf{E}_k}{\partial x_i}, \quad \frac{\partial \mathbf{H}_i}{\partial x_k} \approx \frac{\partial \mathbf{H}_k}{\partial x_i},$$

so that the differences between the spatial derivatives contained in the Maxwell equations compensate mutually for each other, and the derivatives with respect to time (with the coefficient $1/c$) turn out to be quantities of a higher degree of smallness.

Multiplying the inequalities (19.4') we arrive at the condition of quasistationarity

$$T \gg L/c. \quad (19.5)$$

The inequality (19.5) and the equivalent inequality

$$c \gg L/T \sim v, \quad (19.5')$$

where the quantity $v \sim L/T$ can be interpreted as the characteristic velocity

of the motion of charges in the system, have an obvious meaning. Later, in § 23, it will be shown that the velocity c contained in Maxwell's equations represents the velocity of propagation of the electromagnetic field in vacuum. For a quasistationary motion of charges their velocities must be small in comparison with the velocity of propagation of the field.

In this case the variation of the electromagnetic field in time is slow, so that the derivatives of the field with respect to time are of a higher degree of smallness than the spatial derivatives, and may be discarded.

Those electromagnetic fields for which the inequality (19.5) is valid and in which the displacement current can be regarded as small are called quasistationary fields.

For quasistationary fields the Maxwell equations assume the following form:

$$\nabla \times \mathbf{H} = \frac{4\pi}{c} \mathbf{j}, \quad (19.6)$$

$$\nabla \cdot \mathbf{H} = 0, \quad (19.7)$$

$$\nabla \times \mathbf{E} = 0, \quad (19.8)$$

$$\nabla \cdot \mathbf{E} = 4\pi\rho. \quad (19.9)$$

Thus, in the approximation of quasistationary fields the displacement current does not enter into the field equations. We have already seen that the absence of the displacement current corresponds to the solenoidal character of the current lines. Conversely, if current tubes are almost closed, while the motion of charges takes place in a limited volume and is almost periodic, then the displacement current must be very small in comparison with the current of the moving charges.

Maxwell's equations turn out to be resolved into equations for independent fields: the magnetic field due to currents and the electric field due to charges.

The charge density ρ in eq. (19.9) depends on time as a parameter. In the approximation of slowly moving charges the solution of the equations for the electric field leads to the following obvious result: at every instant of time the electric field is the same as the electrostatic field of the given configuration of charges.

The magnetic field of a system of charges performing a slow quasistationary motion can be found by integrating (19.6)–(19.7). We introduce the vector potential according to formula (10.1). Since the time dependence of the charge density ρ and the current \mathbf{j} can be disregarded, the strengths of the

magnetic and electric fields and, consequently, also the electromagnetic potentials do not depend on time. Hence the equations for the vector potential (10.6) and the Lorentz condition (10.5) assume the form

$$\nabla^2 \mathbf{A} = -\frac{4\pi}{c} \mathbf{j}, \quad (19.10)$$

$$\nabla \cdot \mathbf{A} = 0. \quad (19.11)$$

Eq. (19.10) represents a set of three scalar equations:

$$\nabla^2 A_i = -\frac{4\pi}{c} j_i \quad (i = x, y, z),$$

each of which is Poisson's equation.

We shall assume that all the components of the vector potential of a system of charges performing a slow quasistationary motion decrease at infinity not more slowly than $1/r$:

$$A_i \sim O(1/r) \rightarrow 0 \quad \text{as } r \rightarrow \infty. \quad (19.12)$$

Here the symbol O means that the discarded terms are of an order of magnitude less than $1/r$. The solution of eq. (19.10) satisfying the requirement (19.12) can be written according to formula (3.16) in the form

$$\mathbf{A}(\mathbf{r}) = \frac{1}{c} \int \frac{\mathbf{j}(\mathbf{r}') dV'}{R} = \frac{1}{c} \int \frac{\mathbf{j}(x', y', z') dx' dy' dz'}{\sqrt{(x-x')^2 + (y-y')^2 + (z-z')^2}}, \quad (19.13)$$

where $\mathbf{j}(\mathbf{r}')$ is the current density at a point \mathbf{r}' , and $R = |\mathbf{r} - \mathbf{r}'|$ is the distance from this point to the observation point \mathbf{r} at which the value of the vector potential is sought.

It is easy to see that the solution (19.13) of eq. (19.10) satisfies the additional condition (19.11). Indeed, we have

$$\nabla \cdot \mathbf{A} = \frac{1}{c} \nabla_{\mathbf{r}} \cdot \int \frac{\mathbf{j}(\mathbf{r}') dV'}{R} = \frac{1}{c} \int \nabla_{\mathbf{r}} \cdot \left(\frac{\mathbf{j}(\mathbf{r}')}{R} \right) dV',$$

where the divergence is taken with respect to the coordinates of the observation point. In view of the independence of the operations of differentiation with respect to the coordinates \mathbf{r} and integration with respect to the coor-

dinates \mathbf{r}' their order can be altered. The density of the current $\mathbf{j}(\mathbf{r}')$ could be brought outside the sign $\nabla_{\mathbf{r}'}$, but this serves no purpose. A substitution of the variable of differentiation according to a formula analogous to (I.17) gives

$$\nabla \cdot \mathbf{A} = -\frac{1}{c} \int \nabla_{\mathbf{r}'} \cdot \left(\frac{\mathbf{j}(\mathbf{r}')}{R} \right) dV' = -\frac{1}{c} \oint \frac{\mathbf{j} \cdot d\mathbf{S}}{R} = -\frac{1}{c} \oint \frac{j_n dS}{R} = 0,$$

by virtue of the condition (19.1).

Thus, formula (19.13) gives a solution of the problem satisfying all necessary conditions. Knowing the vector potential one can find the magnetic field

$$\mathbf{H} = \frac{1}{c} \nabla \times \int \frac{\mathbf{j} dV'}{R} = \frac{1}{c} \int \nabla_{\mathbf{r}'} \times \frac{\mathbf{j} dV'}{R}. \quad (19.14)$$

In differentiating with respect to the coordinates \mathbf{r} the density of the current $\mathbf{j}(\mathbf{r}')$ must be assumed to be constant. Then according to formula (I.43) we find

$$\nabla \times \frac{\mathbf{j}}{R} = \left(\nabla \frac{1}{R} \right) \times \mathbf{j} = \frac{\mathbf{j} \times \mathbf{R}}{R^3}.$$

Hence, finally,

$$\mathbf{H} = \frac{1}{c} \int \frac{\mathbf{j} \times \mathbf{R}}{R^3} dV'. \quad (19.15)$$

Formula (19.15) is called the Biot-Savart law. It gives, in principle, the solution of the problem posed. However, the calculation of the integral in formula (19.15) is rather complicated and can be carried through only for the simplest systems.

In the next paragraph formula (19.15) is applied to find the field of a single charge moving in vacuum. However, it is particularly important for the calculation of the fields of currents flowing in conductors. Hence further examples of calculations by means of the Biot-Savart law will be analyzed in § 17 of Part IV.

It should be stressed that all the results of this paragraph, in particular the Biot-Savart law, are of an approximate character. They are a consequence of the relations (19.5). Quasistationary fields are encountered particularly often in considering electromagnetic processes in material media. Hence we shall return to them in Part IV (§ 22), where the conditions under which a field can be assumed to be quasistationary will be discussed in more detail.

In conclusion we present a relation which we shall need later. The dimensions of that region of space in which the action of a magnetic field on a system is considered are very often sufficiently small that in the limits of this region the magnetic field can be assumed to be constant and uniform. Then the vector potential A of this constant uniform field can be written in the form

$$A = \frac{1}{2} H \times r. \quad (19.16)$$

One can verify the validity of this relation by a direct calculation according to formula (1.45).

§20. The field of a point charge undergoing a slow uniform motion

Let us consider a point charge e moving with a constant velocity v_0 (fig. 1.8). We assume the absolute value of the velocity $|v_0|$ to be small in comparison with the characteristic velocity c occurring in Maxwell's equations (see further §23).

The charge density ρ can be written in the form

$$\rho(r', t) = e\delta(r' - r_0(t)). \quad (20.1)$$

Here $r_0(t)$ is the coordinate of the charge at an instant t . Formula (20.1) means that at any given moment the charge is present at a point of space with the coordinate $r_0(t)$. Maxwell's equations for the electric field have the form

$$\nabla \times E = 0,$$

$$\nabla \cdot E = 4\pi e\delta(r - r_0(t)).$$

Fig. 1.8

Since the field is irrotational, a potential $\varphi(\mathbf{r}, t)$ can be introduced, so that

$$\mathbf{E} = - \nabla \varphi.$$

The potential satisfies the equation

$$\nabla^2 \varphi = - 4\pi e \delta(\mathbf{r} - \mathbf{r}_0(t)).$$

The solution of the equation can, according to (15.1), be written in the form

$$\begin{aligned} \varphi &= \int \frac{\rho dV'}{|\mathbf{r} - \mathbf{r}'|} = e \int \frac{\delta(\mathbf{r}' - \mathbf{r}_0(t))}{|\mathbf{r} - \mathbf{r}'|} dV' = \\ &= \frac{e}{|\mathbf{r} - \mathbf{r}_0(t)|} = \frac{e}{R(t)}. \end{aligned} \quad (20.2)$$

Here $\mathbf{R}(t)$ stands for a vector connecting the point of observation N with the instantaneous charge coordinate $\mathbf{r}_0(t)$.

From formula (20.2) it follows that the electric field of the moving charge is formally the same as that of a charge at rest, but, instead of the fixed distance from the given point of observation to the charge, the time-dependent distance $R(t)$ figures in (20.2). The field of the charge is obviously given by the formula

$$\mathbf{E} = \frac{e \mathbf{R}(t)}{R^3(t)}. \quad (20.3)$$

Since the charge is moving uniformly, its position in space can be written in the form

$$\mathbf{r}_0 = \mathbf{v}_0 t.$$

Hence the electric field strength at a point will depend on time according to the law

$$\mathbf{E}(\mathbf{r}, t) = \frac{e(\mathbf{r} - \mathbf{v}_0 t)}{|\mathbf{r} - \mathbf{v}_0 t|^3}. \quad (20.4)$$

It is obvious that at a certain point \mathbf{r} at time t the field strength will be the same as that at a point with the coordinate $\mathbf{r} + \mathbf{v}_0$ at time $t + 1$. Indeed,

$$\mathbf{E}(\mathbf{r} + \mathbf{v}_0, t + 1) = \frac{e[\mathbf{r} + \mathbf{v}_0 - \mathbf{v}_0(t + 1)]}{|\mathbf{r} + \mathbf{v}_0 - \mathbf{v}_0(t + 1)|^3} = \mathbf{E}(\mathbf{r}, t).$$

This means that the point with given value of field strength moves in space together with the charge. The field retains spherical symmetry with respect to the instantaneous position of the charge. Later we shall compare formula (20.4) with the corresponding expression for the field produced by a charge moving with a velocity $|\mathbf{v}_0| \approx c$.

Let us now pass on to the determination of the magnetic field. It can be found by means of formula (19.15), in which the current density for unit charge can be written in the form

$$\mathbf{j} = e \mathbf{v}_0 \delta(\mathbf{r} - \mathbf{r}_0).$$

Substituting the value of \mathbf{j} into (19.15), we find

$$\mathbf{H} = \frac{e}{c} \int \frac{[\mathbf{v}_0 \times (\mathbf{r} - \mathbf{r}')] \delta(\mathbf{r}' - \mathbf{r}_0)}{|\mathbf{r} - \mathbf{r}'|^3} dV' = \frac{e}{c} \frac{\mathbf{v}_0 \times \mathbf{R}}{R^3} = \frac{1}{c} \mathbf{v}_0 \times \mathbf{E}. \quad (20.5)$$

Thus, the magnetic field turns out to be perpendicular to the electric field and to the velocity of the charge. The absolute value $|\mathbf{H}| \sim (v_0/c) |\mathbf{E}|$, i.e. the absolute value of the magnetic field, is small in comparison with the electric field by the ratio v_0/c . Differentiating according to formula (1.45) one can see that the vector \mathbf{H} satisfies eq. (19.7).

In §9 we have discussed, without calculation, the problem of finding the field of a moving charge. We have shown that if the integration surface S_2 (fig. 4) passes through the point at which the moving charge is present at a given instant, the magnetic field is connected with the charge current \mathbf{j} . This picture corresponds to the calculation we have performed.

Formula (20.5) has been obtained as a result of solving eqs. (19.6) and (19.7), in which the displacement current was absent. However, it is possible to find the value of the magnetic field from the displacement current on an arbitrary surface S_1 , without making use of formula (19.15).

We write the equations for the magnetic field in the form

$$\nabla \times \mathbf{H} = \frac{1}{c} \frac{\partial \mathbf{E}}{\partial t} + \frac{4\pi}{c} e \mathbf{v}_0 \delta(\mathbf{r} - \mathbf{r}_0), \quad (20.6)$$

$$\nabla \cdot \mathbf{H} = 0. \quad (20.7)$$

The electric field \mathbf{E} of the uniformly moving charge depends on time according to formula (20.4). Differentiating \mathbf{E} with respect to time, we find

$$\frac{\partial \mathbf{E}}{\partial t} = - \left(\frac{\partial \mathbf{E}}{\partial x} v_x + \frac{\partial \mathbf{E}}{\partial y} v_y + \frac{\partial \mathbf{E}}{\partial z} v_z \right) = -(\mathbf{v}_0 \cdot \nabla) \mathbf{E}.$$

From formula (1.45) we have

$$\begin{aligned} \nabla \times (\mathbf{v}_0 \times \mathbf{E}) &= (\mathbf{E} \cdot \nabla) \mathbf{v}_0 - (\mathbf{v}_0 \cdot \nabla) \mathbf{E} + \mathbf{v}_0 (\nabla \cdot \mathbf{E}) - \mathbf{E} (\nabla \cdot \mathbf{v}_0) = \\ &= -(\mathbf{v}_0 \cdot \nabla) \mathbf{E} + \mathbf{v}_0 (\nabla \cdot \mathbf{E}), \end{aligned}$$

since \mathbf{v}_0 is a constant vector. Whence we find

$$\begin{aligned} \frac{\partial \mathbf{E}}{\partial t} &= -(\mathbf{v}_0 \cdot \nabla) \mathbf{E} = \nabla \times (\mathbf{v}_0 \times \mathbf{E}) - \mathbf{v}_0 (\nabla \cdot \mathbf{E}) = \\ &= \nabla \times (\mathbf{v}_0 \times \mathbf{E}) - 4\pi \mathbf{v}_0 e \delta(\mathbf{r} - \mathbf{r}_0), \end{aligned} \quad (20.8)$$

by virtue of (20.1).

Substituting (20.8) into (20.6), we have

$$\nabla \times \mathbf{H} = \frac{1}{c} \nabla \times (\mathbf{v}_0 \times \mathbf{E}). \quad (20.9)$$

Expression (20.5) provides the solution of (20.9) satisfying (20.7). Thus we see that the two methods of calculation lead to the same result, as was to be expected.

§ 21. The field of a system of charges undergoing quasistationary motion at a large distance from the system

Let us assume that a certain set of charges performs a slow and quasistationary motion in a limited region of space. The electromagnetic field of this system at a distance large in comparison with the dimensions of the system (dimensions of the region of motion) is often of great interest. Here, as well as in the case of electrostatics, the general formula for the vector potential (19.13) allows us to make a substantial simplification.

We make use of the expansion (15.8) writing

$$\frac{1}{R} \approx \frac{1}{r} - \left(\mathbf{r}' \cdot \nabla \frac{1}{r} \right).$$

Substituting $1/R$ into (19.13), we find

$$\mathbf{A} = \frac{1}{c} \frac{1}{r} \int \mathbf{j} dV' - \frac{1}{c} \int \mathbf{j} \left(\mathbf{r}' \cdot \nabla \frac{1}{r} \right) dV'.$$

By virtue of (19.4) for a system performing stationary motion the first integral is equal to zero. Hence

$$\mathbf{A} = -\frac{1}{c} \int \mathbf{j} \left(\mathbf{r}' \cdot \nabla \frac{1}{r} \right) dV'. \quad (21.1)$$

We transform the integrand in (21.1) by means of the identity

$$\begin{aligned} \mathbf{j} \left(\mathbf{r}' \cdot \nabla \frac{1}{r} \right) &\equiv \frac{1}{2} \left\{ \mathbf{j} \left(\mathbf{r}' \cdot \nabla \frac{1}{r} \right) - \mathbf{r}' \left(\mathbf{j} \cdot \nabla \frac{1}{r} \right) \right\} + \\ &+ \frac{1}{2} \left\{ \mathbf{j} \left(\mathbf{r}' \cdot \nabla \frac{1}{r} \right) + \mathbf{r}' \left(\mathbf{j} \cdot \nabla \frac{1}{r} \right) \right\}. \end{aligned}$$

The first bracketed pair of terms can be presented in the form of the triple vector product:

$$\left\{ \mathbf{j} \left(\mathbf{r}' \cdot \nabla \frac{1}{r} \right) - \mathbf{r}' \left(\mathbf{j} \cdot \nabla \frac{1}{r} \right) \right\} = (\mathbf{r}' \times \mathbf{j}) \times \nabla \frac{1}{r} = -\frac{(\mathbf{r}' \times \mathbf{j}) \times \mathbf{r}}{r^3}.$$

Thus the vector potential can be written in the form

$$\mathbf{A} = \frac{1}{2c} \int \frac{(\mathbf{r}' \times \mathbf{j}) \times \mathbf{r}}{r^3} dV' - \frac{1}{2c} \int \left\{ \mathbf{j} \left(\mathbf{r}' \cdot \nabla \frac{1}{r} \right) + \mathbf{r}' \left(\mathbf{j} \cdot \nabla \frac{1}{r} \right) \right\} dV'.$$

We go on to the calculation of the second integral. Introducing current tubes, according to the general theory of § 19, we can write

$$\mathbf{j} dV' = dI d\mathbf{l} = dI d\mathbf{r}'.$$

Indeed, the change of the charge position $d\mathbf{r}'$ in its motion along the current tube is identical with $d\mathbf{l}$. Hence

$$\begin{aligned}
 I &= \int \left\{ \mathbf{j} \left(\mathbf{r}' \cdot \nabla \frac{1}{r} \right) + \mathbf{r}' \left(\mathbf{j} \cdot \nabla \frac{1}{r} \right) \right\} dV' = \\
 &= \int dI \oint \left\{ d\mathbf{r}' \left(\mathbf{r}' \cdot \nabla \frac{1}{r} \right) + \mathbf{r}' \left(d\mathbf{r}' \cdot \nabla \frac{1}{r} \right) \right\} = \\
 &= \int dI \oint d \left(\mathbf{r}' \left(\mathbf{r}' \cdot \nabla \frac{1}{r} \right) \right) = 0,
 \end{aligned}$$

since the integral over a closed contour of the total differential is always equal to zero.

Thus, finally,

$$\mathbf{A} = \frac{1}{2cr^3} \int (\mathbf{r}' \times \mathbf{j}) \times \mathbf{r} dV' = \frac{1}{2cr^3} \int (\mathbf{r}' \times \mathbf{j}) dV' \times \mathbf{r}. \quad (21.2)$$

We introduce the notation

$$\mathbf{M} = \frac{1}{2c} \int \mathbf{r}' \times \mathbf{j} dV'. \quad (21.3)$$

The quantity \mathbf{M} is called the magnetic moment of the system of charges. It depends solely on the properties of the charge system — the current density distribution and the geometry of the system. We shall see further that \mathbf{M} is indeed, to a certain degree, an analogue of the dipole moment of a system of charges at rest.

The vector potential at a large distance from the system assumes the form

$$\mathbf{A} = \frac{\mathbf{M} \times \mathbf{r}}{r^3}. \quad (21.4)$$

The magnetic field is expressed, according to (1.45), by the formula

$$\mathbf{H} = \nabla \times \mathbf{A} = \nabla \times \frac{\mathbf{M} \times \mathbf{r}}{r^3} = \mathbf{M} \left(\nabla \cdot \frac{\mathbf{r}}{r^3} \right) - (\mathbf{M} \cdot \nabla) \frac{\mathbf{r}}{r^3}.$$

Since the differentiation is carried out with respect to the coordinates of the observation point, the magnetic moment of the system is constant in the differentiation.

According to (1.42) we find

$$\nabla \cdot \frac{\mathbf{r}}{r^3} = \mathbf{r} \cdot \nabla \frac{1}{r^3} + \frac{1}{r^3} \nabla \cdot \mathbf{r} = -\frac{3}{r^3} + \frac{3}{r^3} = 0.$$

Further,

$$(\mathbf{M} \cdot \nabla) \frac{\mathbf{r}}{r^3} = \frac{1}{r^3} (\mathbf{M} \cdot \nabla) \mathbf{r} + \mathbf{r} \left(\mathbf{M} \cdot \nabla \frac{1}{r^3} \right) = \frac{\mathbf{M}}{r^3} - \frac{3\mathbf{r}(\mathbf{M} \cdot \mathbf{r})}{r^5}.$$

Hence

$$\mathbf{H} = \frac{3\mathbf{r}(\mathbf{M} \cdot \mathbf{r}) - r^2 \mathbf{M}}{r^3}. \quad (21.5)$$

We see that the magnetic field at a large distance from a system of charges in slow and quasistationary motion, is expressed by the same formula as the electrostatic field of a system of charges at rest. The difference consists of the fact that, instead of the dipole moment \mathbf{d} in (15.18), the magnetic moment \mathbf{M} of the system occurs in formula (21.5).

§22. The magnetic moment

We shall consider in somewhat more detail the properties of the magnetic moment of a system. First of all it is easy to verify the fact that the value of the magnetic moment does not depend on the choice of the origin. Shifting the origin by a constant vector \mathbf{a} , i.e. assuming $\mathbf{r}' = \mathbf{r}'' + \mathbf{a}$, we find

$$\mathbf{M} = \frac{1}{2c} \int \mathbf{r}' \times \mathbf{j} dV' = \frac{1}{2c} \int \mathbf{r}'' \times \mathbf{j} dV' + \frac{1}{2c} \int \mathbf{a} \times \mathbf{j} dV'.$$

Rewriting the additional term in the form

$$\int \mathbf{a} \times \mathbf{j} dV' = \mathbf{a} \times \int \mathbf{j} dV',$$

we see by virtue of (19.4) that it is equal to zero.

Thus, the magnetic moment, like the dipole moment of a neutral system of charges, represents a quantity which depends only on the physical properties of the system but not on the choice of the origin.

Consider the expression of the magnetic moment in the case when charges

Fig. I.9

are moving along a thread or a tube (fig. I.9). Making use of (19.3), we find

$$\mathbf{M} = \frac{1}{2c} \int dI \mathbf{r}' \times d\mathbf{l} = \frac{I}{c} \frac{1}{2} \int \mathbf{r}' \times d\mathbf{l}. \quad (22.1)$$

It is easy to see that the quantity $\frac{1}{2} \mathbf{r}' \times d\mathbf{l}$ represents an area vector. The integral $\mathbf{S} = \int \frac{1}{2} \mathbf{r}' \times d\mathbf{l}$ represents the area of the lateral surface of a cone resting on the path of the current. In the particular case of a flat closed path, one can choose as \mathbf{S} the vector of the normal to the plane of the path multiplied by the area of the plane. Then

$$\mathbf{M} = \frac{IS}{c}. \quad (22.2)$$

Formula (22.2) yields to an obvious interpretation: every closed current (for example, one or several charged particles moving along closed trajectories) possesses a magnetic moment proportional to the value of the current. In this connection we note that every atom with electrons rotating in an orbit is an elementary magnet (see Part IV). We now rewrite the expression for the magnetic moment by specifying the current density in terms of the velocity of motion of the charges:

$$\mathbf{M} = \frac{1}{2c} \int \mathbf{r}' \times \rho \mathbf{v} dV' = \frac{1}{2c} \sum \mathbf{r}'_i \times e \mathbf{v}_i, \quad (22.3)$$

where the summation is carried out over all the charges in the system.

Consider the important case of a system consisting of identical or different particles having the same value of the ratio of the charge e to the mass m . Introducing this relation into (22.3), we find

$$\mathbf{M} = \frac{1}{2c} \sum \frac{e_i}{m_i} \mathbf{r}'_i \times m_i \mathbf{v}_i = \frac{e}{2mc} \sum \mathbf{r}'_i \times \mathbf{p}_i = \frac{e}{2mc} \mathbf{L}, \quad (22.4)$$

where \mathbf{L} is the angular momentum of the system.

Formula (22.4) shows that for a system of particles with a fixed value of e/m there exists a direct proportionality between the magnetic moment and the angular momentum of the system.

The proportionality between \mathbf{M} and \mathbf{L} holds also for a system consisting of two particles with an arbitrary ratio e/m . Indeed, in such a system

$$\mathbf{M} = \frac{1}{2c} [e_1 \mathbf{r}'_1 \times \mathbf{v}_1 + e_2 \mathbf{r}'_2 \times \mathbf{v}_2].$$

Locating the origin at the centre of mass, i.e. assuming

$$m_1 \mathbf{r}'_1 + m_2 \mathbf{r}'_2 = 0,$$

and introducing the relative velocity

$$\mathbf{v}_{\text{rel}} = \dot{\mathbf{r}}'_2 - \dot{\mathbf{r}}'_1 = \dot{\mathbf{r}}'_{\text{rel}},$$

we find

$$\mathbf{v}_2 = \mathbf{v}_{\text{rel}} \frac{m_1}{m_1 + m_2}, \quad \mathbf{v}_1 = -\mathbf{v}_{\text{rel}} \frac{m_2}{m_1 + m_2},$$

$$\mathbf{M} = \frac{\mu^2}{2c} \left[\frac{e_1}{m_1^2} \mathbf{r}'_{\text{rel}} \times \mathbf{v}_{\text{rel}} + \frac{e_2}{m_2^2} \mathbf{r}'_{\text{rel}} \times \mathbf{v}_{\text{rel}} \right] = \frac{1}{2c} \left(\frac{e_1}{m_1^2} + \frac{e_2}{m_2^2} \right) \mu \mathbf{L},$$

where

$$\mathbf{L} = \mathbf{r}'_{\text{rel}} \times \mathbf{p}_{\text{rel}} = \mathbf{r}'_{\text{rel}} \times \mu \mathbf{v}_{\text{rel}}$$

is the angular momentum of the relative motion, and $\mu = m_1 m_2 / (m_1 + m_2)$ is the reduced mass.

The Electromagnetic Field of Arbitrarily Moving Charges

§ 23. The electromagnetic field of a system of arbitrarily moving charges

Let us consider a system of charges performing an arbitrary motion in a certain volume V' . The distribution and motion of charges in this volume will be characterized by the charge density $\rho(\mathbf{r}, t)$ and the current density $\mathbf{j}(\mathbf{r}, t)$, varying in space and time. We shall assume that the functions $\rho(\mathbf{r}, t)$ and $\mathbf{j}(\mathbf{r}, t)$ are known for all times (i.e. for $-\infty < t < \infty$).

Equations for the space-dependent and time-dependent electromagnetic potentials are of the form

$$\nabla^2 \varphi(\mathbf{r}, t) - \frac{1}{c^2} \frac{\partial^2 \varphi(\mathbf{r}, t)}{\partial t^2} = -4\pi\rho(\mathbf{r}, t), \quad (23.1)$$

$$\nabla^2 \mathbf{A}(\mathbf{r}, t) - \frac{1}{c^2} \frac{\partial^2 \mathbf{A}(\mathbf{r}, t)}{\partial t^2} = -\frac{4\pi}{c} \mathbf{j}(\mathbf{r}, t), \quad (23.2)$$

$$\nabla \cdot \mathbf{A}(\mathbf{r}, t) + \frac{1}{c} \frac{\partial \varphi(\mathbf{r}, t)}{\partial t} = 0. \quad (23.3)$$

The system of eqs. (23.1)–(23.3) represents a system of linear partial differential equations. As is known from the theory of partial differential equations

a single-value solution of the problem — in this case finding the particular distribution of the electromagnetic field in space and time as a function of the values of the known functions $\rho(\mathbf{r}, t)$ and $\mathbf{j}(\mathbf{r}, t)$ — requires that some further conditions, called boundary and initial conditions, should be given.

As a rule, the problem of finding the electromagnetic field is defined as follows: before a certain time $t = 0$ (i.e. for all $t < 0$) the charges of the system were at rest; at time $t = 0$ the charges are set in an arbitrary motion. A change or perturbation then arises in the electromagnetic field. We shall assume that eqs. (23.1)–(23.3) involve the vector and scalar potentials of just this perturbed field. The functions $\rho(\mathbf{r}, t)$ and $\mathbf{j}(\mathbf{r}, t)$, responsible for the perturbation of the field for $t > 0$, are considered as known. For $t \leq 0$ one sets

$$\rho(\mathbf{r}, 0) = 0, \quad \mathbf{j}(\mathbf{r}, 0) = 0.$$

Correspondingly, at the initial time $t = 0$ the vectors of the electric and magnetic field are equal to zero: $\mathbf{E}(\mathbf{r}, 0) = \mathbf{H}(\mathbf{r}, 0) = 0$. Then the initial conditions for the potentials read

$$\begin{aligned} A(\mathbf{r}, t) \Big|_{t=0} &= 0, \\ \frac{\partial A(\mathbf{r}, t)}{\partial t} \Big|_{t=0} &= 0, \\ \varphi(\mathbf{r}, t) \Big|_{t=0} &= 0. \end{aligned} \tag{23.4}$$

Indeed, if the conditions (23.4) are satisfied, then from the definition of the field vectors it is seen directly that the field vectors are zero. Thus, the initial condition (23.4) is completely equivalent to the requirement that the densities of the charge and current should be equal to zero for $t = 0$ and, in general, different from zero for $t > 0$.

The requirements that at a large distance from the volume V' the field potentials should decrease not more slowly than the law

$$\begin{aligned} \varphi &\sim O(1/r) \quad \text{as } r \rightarrow \infty, \quad 0 \leq t < \infty, \\ |A| &\sim O(1/r) \quad \text{as } r \rightarrow \infty, \quad 0 \leq t < \infty, \end{aligned} \tag{23.5}$$

i.e. not more slowly than the function $1/r$, will serve as the boundary conditions.

In solving the system of field equations we shall, in this paragraph, make use of a simple but not exact method, based on the use of the principle of superposition. In the next paragraph we shall present a method which is more consistent from the mathematical standpoint and which leads to the same results.

We divide the whole system into a set of arbitrarily small charges $\delta e_i = \rho(\mathbf{r}, t) \delta V_i$, where δV_i is an arbitrarily small volume within the region V' . We seek the potential of the field produced by the charge δe_i at a certain point of observation N , assuming that there are no other charges in the space. The total field, on the basis of the principle of superposition, represents the sum of fields produced by all the charges δe_i constituting the system.

It should be emphasized that the charge conservation law does not allow the existence of a time-dependent and solitary charge δe_i . In reality a change (for example, an increase) of the charge δe_i in time assumes a simultaneous decrease of a charge δe_k in another element of the volume, so that the total charge of the system is conserved. However, in finding the potentials of the field produced by the charge δe_i we shall not formally take into account the existence of other charges. This apparent violation of the charge conservation law will not affect the final solution, in which the summation over all charges of the system will be performed.

Let us first of all find the solution of the system of equations for the potentials of the field produced in the entire space outside the small volume δV_i by the charge δe_i .

At all points of this space outside the volume δV_i the charge density, according to our assumption, is equal to zero. Hence outside the volume δV_i the equations for the electromagnetic field potentials assume the form

$$\begin{aligned}\nabla^2 \varphi - \frac{1}{c^2} \frac{\partial^2 \varphi}{\partial t^2} &= 0, \\ \nabla^2 \mathbf{A} - \frac{1}{c^2} \frac{\partial^2 \mathbf{A}}{\partial t^2} &= 0, \\ \nabla \cdot \mathbf{A} + \frac{1}{c} \frac{\partial \varphi}{\partial t} &= 0.\end{aligned}\tag{23.6}$$

We introduce spherical coordinates with the origin located in the volume δV_i . The field outside the volume δV_i possesses spherical symmetry, so that the field potentials can depend only on the distance from the volume δV_i — the radius vector \mathbf{r} — and time. From the expression for the Laplacian in

spherical coordinates, we have

$$\frac{1}{r} \frac{\partial^2}{\partial r^2} (r\varphi) - \frac{1}{c^2} \frac{\partial^2 \varphi}{\partial t^2} = 0, \quad (23.7)$$

$$\frac{1}{r} \frac{\partial^2}{\partial r^2} (rA) - \frac{1}{c^2} \frac{\partial^2 A}{\partial t^2} = 0. \quad (23.8)$$

We see that the scalar potential and all the components of the vector potential are determined by an equation of one type:

$$\frac{1}{r} \frac{\partial^2}{\partial r^2} (rf) - \frac{1}{c^2} \frac{\partial^2 f}{\partial t^2} = 0. \quad (23.9)$$

For reasons which will be clear from what follows, an equation of the type (23.9) is called a wave equation. The integration of the wave equation can be carried out most simply by D'Alembert's method. D'Alembert's method consists, roughly speaking, of the reduction of a partial differential equation of the type (23.9) to an equation with a mixed second derivative (for a more strict presentation of D'Alembert's method we refer the reader to mathematical texts *).

We rewrite eq. (23.9) in the form

$$\frac{\partial^2}{\partial r^2} (rf) - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} (rf) = 0, \quad (23.10)$$

and introduce a new unknown function

$$\psi = rf. \quad (23.11)$$

This is always possible since $r \neq 0$ outside the volume δV_i . We then have

$$\frac{\partial^2 \psi}{\partial r^2} - \frac{1}{c^2} \frac{\partial^2 \psi}{\partial t^2} = 0. \quad (23.12)$$

* See, for example, A. N. Tikhonov and A. A. Samarskii, *Partial differential equations of mathematical physics* (Holden Day, San Francisco, 1964) Ch. II.

Now we change over to new variables in eq. (23.12):

$$\xi = t - \frac{r}{c}, \quad (23.13)$$

$$\eta = t + \frac{r}{c}. \quad (23.14)$$

Whence

$$t = \frac{1}{2}(\xi + \eta), \quad r = \frac{1}{2}(\eta - \xi)c,$$

so that

$$\frac{\partial}{\partial \xi} = \frac{\partial}{\partial r} \frac{\partial r}{\partial \xi} + \frac{\partial}{\partial t} \frac{\partial t}{\partial \xi} = \frac{1}{2}c \left(-\frac{\partial}{\partial r} + \frac{1}{c} \frac{\partial}{\partial t} \right),$$

$$\frac{\partial}{\partial \eta} = \frac{\partial}{\partial r} \frac{\partial r}{\partial \eta} + \frac{\partial}{\partial t} \frac{\partial t}{\partial \eta} = \frac{1}{2}c \left(\frac{\partial}{\partial r} + \frac{1}{c} \frac{\partial}{\partial t} \right).$$

Further

$$\frac{\partial^2}{\partial r^2} - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} = \left(\frac{\partial}{\partial r} + \frac{1}{c} \frac{\partial}{\partial t} \right) \left(\frac{\partial}{\partial r} - \frac{1}{c} \frac{\partial}{\partial t} \right) = -\frac{4}{c^2} \frac{\partial}{\partial \xi} \frac{\partial}{\partial \eta} = -\frac{4}{c^2} \frac{\partial^2}{\partial \xi \partial \eta}.$$

Eq. (23.12) in new variables has the form

$$\frac{\partial^2 \psi}{\partial \xi \partial \eta} = 0. \quad (23.15)$$

This equation, containing only the mixed derivative, is integrated directly. It is obvious that the equation is satisfied by any functions $\psi_1(\eta)$ and $\psi_2(\xi)$ of one variable, ξ or η . Hence the general solution of eq. (23.15) can be written in the form

$$\psi(\xi, \eta) = \psi_1(\xi) + \psi_2(\eta), \quad (23.16)$$

where ψ_1 and ψ_2 are arbitrary functions of one variable ξ and η respectively. Returning to the previous variables r and t , we obtain

$$\psi(r, t) = \psi_1 \left(t - \frac{r}{c} \right) + \psi_2 \left(t + \frac{r}{c} \right). \quad (23.17)$$

This solution has a simple meaning. The value of the function ψ_1 at the point $(r+c)$ at time $(t+1)$ is the same as at the point r at time t . This means that $\psi_1(t-(r/c))$ describes a process which is periodic in space and time, i.e. a wave process. The wave propagates in the direction of increasing values of the distance r from the origin with a velocity equal to c . Similarly $\psi_2(t+(r/c))$ describes a wave propagating from large r 's to smaller ones in the direction toward the origin. For the function f we have

$$f = \frac{\psi_1\left(t - \frac{r}{c}\right)}{r} + \frac{\psi_2\left(t + \frac{r}{c}\right)}{r} \quad (23.18)$$

Formula (23.18), giving the general solution of eq. (23.9), represents the superposition of two waves, the one diverging from the origin (the first term) and the other converging to the origin (the second term). The surfaces of the spheres $r = \text{const}$ are the surfaces of constant value of the function f or equal-phase surfaces. Since equal-phase surfaces are spherical surfaces, it is said that the wave process described by the function f is the combination of a diverging and a converging spherical wave. The scalar potential φ and all components of the vector potential \mathbf{A} can be presented in the form of formula (23.18).

In order to make clear the meaning of the solutions obtained, we shall consider one of the particular solutions, for instance the diverging spherical wave. For concreteness we write the expression for the scalar potential:

$$\varphi(r, t) = \frac{\varphi_1\left(t - \frac{r}{c}\right)}{r} \quad (23.19)$$

For an arbitrary form of the function φ_1 formula (23.19) gives the particular solution of eq. (23.1) in the region of space outside the volume δV_i . We now require that (23.19) should pass over continuously into the solution of eq. (23.1) near the volume δV_i , i.e. near the locus of the charge $\delta e_i(t)$. If in eq. (23.1) a formal transition is made by assuming $c \rightarrow \infty$ (the meaning of such a transition will become clear from what follows), then it will obviously turn into the equation for the electrostatic potential, the solution of which is

$$\Delta \varphi_i = \frac{\delta e_i(t)}{r} = \frac{\rho(r, t) \delta V_i}{r} \quad (23.20)$$

Writing (23.19) in the form

$$d\varphi_i(r, t) = \frac{\rho \left(t - \frac{r}{c} \right) \delta V_i}{r}, \quad (23.21)$$

we arrive at the potential of the field produced by the charge δe_i , which satisfies eq. (23.7) outside the volume δV_i and turns into (23.20) near the origin.

Formula (23.21) shows that the field potential at the observation point a distance r from the origin at time t is determined by the value of the charge at the preceding instant $\tau = t - (r/c)$. The potential (23.21) is therefore called retarded potential, while the quantity r/c is called the delay time. The delay time represents the time interval during which the electromagnetic field, propagating with the velocity c , traverses the path r .

Introducing the origin at point O, located in the volume V' , and integrating the expression (23.21) over all charges of the system, we arrive at the following expression for the potential of the field produced at the point of observation N:

$$\begin{aligned} \varphi(r, t) &= \int \frac{\rho \left(\mathbf{r}', t - \frac{|\mathbf{r} - \mathbf{r}'|}{c} \right) dV'}{|\mathbf{r} - \mathbf{r}'|} = \\ &= \int \frac{\rho \left(\mathbf{r}', t - \frac{R}{c} \right) dV'}{R} = \int \frac{\rho(\mathbf{r}', \tau) dV'}{R}, \end{aligned} \quad (23.22)$$

where $\tau = t - (R/c)$, $\mathbf{R} = \mathbf{r} - \mathbf{r}'$.

According to (23.22), to obtain the potential at the point of observation N, it is necessary as in electrostatics, to evaluate the integral of the quantity ρ/R over the whole volume of the system. In this case, however, the value of the charge density is taken at time $\tau = t - |\mathbf{r} - \mathbf{r}'|/c$, where the delay time $|\mathbf{r} - \mathbf{r}'|/c$ is determined by the distance from every point \mathbf{r}' to the observation point.

Similarly, for the vector potential the particular solution of eq. (23.2) can be written in the form

$$\begin{aligned} \mathbf{A} &= \frac{1}{c} \int \frac{\mathbf{j} \left(\mathbf{r}', t - \frac{|\mathbf{r} - \mathbf{r}'|}{c} \right) dV'}{R} = \\ &= \frac{1}{c} \int \frac{\mathbf{j} \left(\mathbf{r}', t - \frac{R}{c} \right) dV'}{R} = \frac{1}{c} \int \frac{\mathbf{j}(\mathbf{r}', \tau) dV'}{R}. \end{aligned} \quad (23.23)$$

In addition to the solutions of the equations for potentials in the form of retarded potentials, one can also write other particular solutions corresponding to the function ψ_2 in the general solution (23.18):

$$\varphi^*(\mathbf{r}, t) = \int \frac{\rho\left(\mathbf{r}', t + \frac{R}{c}\right) dV'}{R}, \quad (23.24)$$

$$\mathbf{A}^*(\mathbf{r}, t) = \frac{1}{c} \int \frac{\mathbf{j}\left(\mathbf{r}', t + \frac{R}{c}\right) dV'}{R} \quad (23.25)$$

In formulae (23.24) and (23.25) the values of the functions ρ and \mathbf{j} , determining the potentials at the point \mathbf{r} at time t , are taken at the instant $\tau^* = t + (R/c)$. This means that the potentials at the instant t depend on that charge density which will appear in the point \mathbf{r} after the time interval R/c . The potentials (23.24) and (23.25) are called advanced potentials.

From retarded and advanced potentials one can make arbitrary linear combinations of the form $\alpha_1\varphi + \alpha_2\varphi^*$, $\beta_1\mathbf{A} + \beta_2\mathbf{A}^*$, which also satisfy the field equations. The general solution of the equations for the potentials is obtained from the particular solutions and general solutions found for eqs. (23.7) and (23.8).

The appearance of retarded and advanced potentials as equally valid solutions of the field equations is quite natural. Like the equations of mechanics, the electrodynamical equations are symmetric with respect to the future and the past. They do not change when t is substituted for $(-t)$ and, hence, must have a general solution invariant under the change of the sign of time.

The choice of coefficients in these linear combinations is determined by giving the above mentioned supplementary conditions characterizing the behaviour of potentials at infinity. In order that these conditions may be fulfilled it is necessary to reject the solution corresponding to the advanced potentials. Indeed, let us consider at the moment $t = 0$ a certain sphere of radius R_1 outside the volume V' . According to the boundary condition (23.5), the potential $\varphi(R_1, 0) \sim O(1/R_1)$. Correspondingly, the retarded potential

$$\varphi(R_1, 0) = \int \frac{\rho(\mathbf{r}', -R_1/c)}{R} dV',$$

since according to the condition the charge density is equal to zero for $t < 0$. On the contrary, the advanced potential

$$\varphi^*(R_1, 0) = \int \frac{\rho(\mathbf{r}', R_1/c)}{R} dV' \neq O(1/R_1).$$

In the last formula there corresponds to time $t = 0$, a non-zero value of the argument of the function $\rho(\mathbf{r}', \tau)$, because the charge density $\rho(\mathbf{r}', R_1/c)$ is not equal to zero.

It should be noted that the properties of the charge density $\rho(\mathbf{r}', 0) = 0$, $\rho(\mathbf{r}', t - (R/c)) \neq 0$, used here, correspond to the choice of initial conditions in the form of (23.4). We see that, for such properties of the density ρ , the advanced potential does not satisfy the condition (23.5) determining its behaviour at infinity. Namely, the advanced potential decreases more slowly than the function $1/r$. In order to obtain a solution of the wave equation which satisfies the system of initial and boundary conditions, one has to assume that $\alpha_2 = \beta_2 = 0$ and retain only the solution of the field equations in the form of retarded potentials. Uncomplicated, but somewhat cumbersome calculations allow one to verify the fact that the retarded potentials given by formulae (23.24) and (23.25) satisfy the Lorentz condition (23.3) for $\alpha_1 = \beta_1 = 1$.

Thus, we arrive at the very important conclusion: a system of charges, which at the moment $t = 0$ begin to perform a non-steady state motion, produce in the surrounding space an electromagnetic field whose potentials have the character of retarded potentials. The field potentials have the form of spherical waves originating from the system and propagating in vacuum with the velocity c .

We shall say that a system of non-steady state moving charges emits electromagnetic waves, and call it briefly the emitter.

The solution of the electromagnetic field equations in the form of retarded potentials is of great significance. It corresponds to a definite concept about the character of causal relationship, which differs from the concepts of classical mechanics.

As is well-known, all the propositions of classical mechanics are in accordance with the Newtonian concept of action at a distance. In classical mechanics it is assumed that the acceleration of a material point at a given instant is completely determined by the force acting on it at that instant. The force acting on a given material point depends in turn on the position of other material points, located at a finite distance from the observed point. If the position of any of the material points is changed at a certain instant t_0 , then the magnitude of the force will be changed also at the same instant. In other words, the velocity of propagation of the interaction in space is considered in classical mechanics to be infinitely large.

In the theory of the electromagnetic field the situation is radically altered. If the position of the charges located at a distance r from the point of observation is changed, then the potential at the latter point will change only after the time $\tau = r/c$. This time is needed for the perturbation of the electromagnetic field, moving from point to point with a finite velocity equal to the velocity of light c , to traverse in space the path r . The perturbation is transferred from one point of the field to the neighbouring one. The space in which the propagation of electromagnetic perturbations occurs is no more the empty "nothing" of classical mechanics, but is considered to be filled by a real electromagnetic field endowed with definite physical properties. Thus, in the theory of the electromagnetic field the infinitely large velocity of propagation of interactions and the long-range action of classical mechanics are replaced by a finite velocity of propagation of interaction and the concept of short-range action. The cause (change of the field) and the effect (motion of the test charge at the observation point) refer to one location and one instant of time. In the next part of the book the standpoint of field theory will receive further confirmation and extension.

It should be noted that, because the velocity c of propagation of the electromagnetic perturbations is very large, it can often in practice be considered as infinitely large. The concepts of classical mechanics are by this fact not simply discarded as untrue, but are retained as approximate ones, having a well defined region of application.

§ 24*. General solution of D'Alembert's equation in the form of retarded potentials

We now pass on to the exact solution of D'Alembert's equation for the potentials. We confine ourselves to finding one of the potentials, for instance the vector potential. The expression for the scalar potential can be written by analogy.

In accordance with what was said in the preceding paragraph, the equation for the potential

$$\nabla^2 \mathbf{A} - \frac{1}{c^2} \frac{\partial^2 \mathbf{A}}{\partial t^2} = - \frac{4\pi}{c} \mathbf{j} \quad (24.1)$$

must be supplemented by initial and boundary conditions.

We consider the problem in the following formulation. Before a certain time $t = 0$ (i.e. for $t < 0$) let there, for example, be a system of charges, at

rest or performing a steady state motion. Before the time $t = 0$ their configuration is given and the field has a certain distribution in space. At the moment $t = 0$ the state of the system is changed and the charges begin a non-steady state motion. We are interested in the law which gives the change of the field vectors, connected with this non-steady state motion of the charges, from the time $t = 0$ on.

Let \mathbf{E} and \mathbf{H} be field vectors associated with the motion of the charges for a time $t \geq 0$. In other words, let \mathbf{E} and \mathbf{H} be the changes in the electromagnetic field which existed at the moment $t = 0$, caused by the motion of the charges for $t \geq 0$. Then from the definition of \mathbf{E} and \mathbf{H} it follows that at the initial moment $t = 0$ they must satisfy the initial condition:

$$\mathbf{E} = \mathbf{H} = 0 \quad \text{at } t = 0 \text{ (over all space).}$$

In this case the initial condition for the vector potential has the following form:

$$\mathbf{A} = 0 \quad \text{at } t = 0, \quad \text{for arbitrary } r, \quad (24.2)$$

$$\frac{\partial \mathbf{A}}{\partial t} = 0 \quad \text{at } t = 0, \quad \text{for arbitrary } r. \quad (24.3)$$

The first of these equalities corresponds to the equality $\mathbf{H} = 0$, while the second one corresponds to the absence of the electric field, $\mathbf{E} = 0$, at the initial moment. The boundary condition at infinity has the form

$$\mathbf{A} \rightarrow O\left(\frac{1}{r}\right) \quad \text{as } r \rightarrow \infty, \quad t \geq 0. \quad (24.4)$$

In other words, we understand \mathbf{A} to be the vector potential of the field associated with the motion of charges beginning at the time $t = 0$ and taking place for $t > 0$.

To obtain the solution of this problem — i.e. finding the solution of eq. (24.1) satisfying the system of conditions (24.2)–(24.4) (called in mathematical physics the Cauchy problem) — it is most convenient to make use of the method of Fourier integrals*. We write the vector potential and current

* R. Courant and D. Hilbert, *Methods of mathematical physics* (Interscience Publishers, New York, 1953);

A. A. Vlasov, *Makroskopicheskaya elektrodinamika (Macroscopic electrodynamics)* (Gostekhizdat, Moscow, 1955) p. 166.

density in the form of the triple Fourier integrals *.

$$\mathbf{A} = \frac{1}{(2\pi)^{3/2}} \int \mathbf{a}(\mathbf{k}, t) e^{-i\mathbf{k} \cdot \mathbf{r}} d\mathbf{k}, \quad (24.5)$$

$$\mathbf{j} = \frac{1}{(2\pi)^{3/2}} \int \mathbf{p}(\mathbf{k}, t) e^{-i\mathbf{k} \cdot \mathbf{r}} d\mathbf{k}. \quad (24.6)$$

The Fourier transformations of the vector potential and current density are then given by the inversion formulae:

$$\mathbf{a}(\mathbf{k}, t) = \frac{1}{(2\pi)^{3/2}} \int \mathbf{A}(\mathbf{r}, t) e^{i\mathbf{k} \cdot \mathbf{r}} d\mathbf{r}, \quad (24.7)$$

$$\mathbf{p}(\mathbf{k}, t) = \frac{1}{(2\pi)^{3/2}} \int \mathbf{j}(\mathbf{r}, t) e^{i\mathbf{k} \cdot \mathbf{r}} d\mathbf{r}. \quad (24.8)$$

Substituting (24.5) and (24.6) into (24.1) we find

$$\frac{d^2 \mathbf{a}}{dt^2} + k^2 c^2 \mathbf{a} = 4\pi c \mathbf{p}. \quad (24.9)$$

Eq. (24.9) represents an equation in total derivatives, and its general solution can be found easily. Substitution of (24.7) into the initial conditions (24.2) and (24.3) gives:

$$\mathbf{a} = 0 \quad \text{at } t = 0, \quad (24.10)$$

$$\frac{d\mathbf{a}}{dt} = 0 \quad \text{at } t = 0. \quad (24.11)$$

The solution of eq. (24.9) with the initial conditions (24.10) and (24.11) reads **:

$$\mathbf{a} = \frac{4\pi}{k} \int_0^t \mathbf{p}(\xi) \sin [kc(t - \xi)] d\xi. \quad (24.12)$$

* In this section $d\mathbf{r}$ stands for the volume element $dx dy dz$ and $d\mathbf{k}$ for $dk_x dk_y dk_z$.

** V. I. Smirnov, *A course of higher mathematics* (Pergamon, Oxford, 1964).

To obtain the function A this value of a must be substituted into (24.5). We then have

$$A = \frac{4\pi}{(2\pi)^{3/2}} \int_0^t \int_0^\infty p(\xi) \sin \{kc(t-\xi)\} e^{-ik \cdot r} d\xi \frac{dk}{k}. \quad (24.13)$$

The current density j should be introduced instead of the Fourier transform p in (24.13). By means of (24.8) we find

$$A = \frac{4\pi}{(2\pi)^3} \int e^{-ik \cdot r} \frac{dk}{k} \int_0^t \int e^{ik \cdot r'} j(r', \xi) \sin \{kc(t-\xi)\} dr' d\xi. \quad (24.14)$$

Integration in formula (24.14) must be carried out with respect to the variables ξ and k .

We change the order of integration, writing

$$A = \frac{1}{2\pi^2} \int dr' \int_0^t j(r', \xi) d\xi \int e^{-ik \cdot (r-r')} \frac{\sin \{kc(t-\xi)\}}{k} dk. \quad (24.15)$$

We calculate the inner integral and have

$$\begin{aligned} & \int e^{-ik \cdot (r-r')} \frac{\sin \{kc(t-\xi)\}}{k} dk = \\ &= \int e^{-ik |r-r'| \cos \theta} \frac{\sin \{kc(t-\xi)\}}{k} k^2 dk \sin \theta d\theta d\varphi = \\ &= 2\pi \int_0^\infty \frac{\sin \{kc(t-\xi)\}}{k} k^2 dk \int_0^\pi e^{-ik |r-r'| \cos \theta} \sin \theta d\theta. \end{aligned}$$

But

$$\begin{aligned} \int_0^\pi e^{-ik |r-r'| \cos \theta} \sin \theta d\theta &= \int_{-1}^{+1} e^{-ik |r-r'| u} du = \\ &= 2 \frac{\sin \{k |r-r'| \}}{k |r-r'|} \end{aligned}$$

Hence

$$\begin{aligned} \int e^{-i\mathbf{k} \cdot (\mathbf{r} - \mathbf{r}')} \frac{\sin \{kc(t - \xi)\}}{k} d\mathbf{k} &= \\ &= \frac{4\pi}{|\mathbf{r} - \mathbf{r}'|} \int_0^\infty \sin \{kc(t - \xi)\} \sin \{k|\mathbf{r} - \mathbf{r}'|\} dk = \frac{4\pi}{|\mathbf{r} - \mathbf{r}'|} I, \end{aligned}$$

where I stands for the integral

$$\begin{aligned} I &= \int_0^\infty \sin \{kc(t - \xi)\} \sin \{k|\mathbf{r} - \mathbf{r}'|\} dk = \\ &= \int_0^\infty \sin \alpha k \sin \beta k dk = \frac{1}{2} \int_0^\infty \cos(\alpha - \beta) k dk - \\ &\quad - \frac{1}{2} \int_0^\infty \cos(\alpha + \beta) k dk = \frac{1}{2} \pi \delta(\alpha - \beta) - \frac{1}{2} \pi \delta(\alpha + \beta) = \\ &= \frac{1}{2} \pi \delta[c(t - \xi) - |\mathbf{r} - \mathbf{r}'|] - \frac{1}{2} \pi \delta[c(t - \xi) + |\mathbf{r} - \mathbf{r}'|]. \end{aligned}$$

In calculating I we have made use of one of the determinations of the delta function given in Appendix III.

Finally we find

$$\begin{aligned} \int e^{-i\mathbf{k} \cdot (\mathbf{r} - \mathbf{r}')} \frac{\sin \{kc(t - \xi)\}}{k} d\mathbf{k} &= \\ &= \frac{2\pi^2}{|\mathbf{r} - \mathbf{r}'|} \{ \delta[c(t - \xi) - |\mathbf{r} - \mathbf{r}'|] - \delta[c(t - \xi) + |\mathbf{r} - \mathbf{r}'|] \}. \end{aligned}$$

.Substituting this expression into (24.15), we obtain

$$\begin{aligned}
 A = & \int \frac{d\mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|} \int_0^t \mathbf{j}(\mathbf{r}', \xi) \delta[c(t - \xi) - |\mathbf{r} - \mathbf{r}'|] d\xi + \\
 & + \int \frac{d\mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|} \int_0^t \mathbf{j}(\mathbf{r}', \xi) \delta[c(t - \xi) + |\mathbf{r} - \mathbf{r}'|] d\xi.
 \end{aligned}$$

We seek to perform the integration with respect to the variable ξ , making use of the properties of the delta function.

In the first integral:

$$\begin{aligned}
 & \int_0^t \mathbf{j}(\mathbf{r}', \xi) \delta[c(t - \xi) - |\mathbf{r} - \mathbf{r}'|] d\xi = \\
 & = -\frac{1}{c} \int_{ct - |\mathbf{r} - \mathbf{r}'|}^{-|\mathbf{r} - \mathbf{r}'|} \mathbf{j}\left(\mathbf{r}', -\frac{u}{c} + t - \frac{|\mathbf{r} - \mathbf{r}'|}{c}\right) \delta(u) du = \\
 & = -\frac{1}{c} \int_{\infty}^{-\infty} \mathbf{j}\left(\mathbf{r}', -\frac{u}{c} + t - \frac{|\mathbf{r} - \mathbf{r}'|}{c}\right) \delta(u) du = \\
 & = \frac{1}{c} \mathbf{j}\left(\mathbf{r}', t - \frac{|\mathbf{r} - \mathbf{r}'|}{c}\right).
 \end{aligned}$$

We have chosen $u = c(t - \xi) - |\mathbf{r} - \mathbf{r}'|$ as a new variable.

If the inequality $t > |\mathbf{r} - \mathbf{r}'|/c$ holds, then the range of integration can be extended, as has been done here. If $t < |\mathbf{r} - \mathbf{r}'|/c$, then the integration would be carried out only with respect to negative values of the variable u (both limits would be negative). The point $u = 0$, at which $\delta(u)$ becomes infinite, would lie outside the range of integration, and by virtue of (III.3') the integral would be reduced to zero. This refers, in particular, to the time $t = 0$, which corresponds to the fulfillment of the initial condition (24.2). Similarly the second integral gives

$$\begin{aligned}
& \int_0^t \mathbf{j}(\mathbf{r}', \xi) \delta[c(t - \xi) + |\mathbf{r} - \mathbf{r}'|] d\xi = \\
& = -\frac{1}{c} \int_{ct + |\mathbf{r} - \mathbf{r}'|}^{|\mathbf{r} - \mathbf{r}'|} \mathbf{j}\left(\mathbf{r}', -\frac{u}{c} + t + \frac{|\mathbf{r} - \mathbf{r}'|}{c}\right) \delta(u) du = 0
\end{aligned}$$

where in this case the point $u = 0$ turns out to be outside the range of integration.

Thus we have obtained

$$\mathbf{A}(\mathbf{r}, t) = \frac{1}{c} \int \frac{\mathbf{j}\left(\mathbf{r}', t - \frac{|\mathbf{r} - \mathbf{r}'|}{c}\right)}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r}', \quad (24.16)$$

i.e. the expression already known for the retarded potential.

The integral with the second delta function corresponded to the advanced potential. The advanced potential gave no contribution to the vector potential only because, in obtaining the solution (24.12) of eq. (24.9), we made use of the initial conditions (24.10) and (24.11), which determined the form of $\mathbf{a}(\mathbf{k}, t)$.

If we wrote the general solution of eq. (24.9) without giving initial conditions, then the final expression for the potential would involve a linear combination of the retarded and advanced potentials, as well as the general solution of the homogeneous equation.

Later we shall need an expression for the potential in the special case when the dependence of $\mathbf{j}(\mathbf{r}, t)$ on time is expressed by a simple harmonic law:

$$\mathbf{j}(\mathbf{r}, t) = \mathbf{j}_0(\mathbf{r}) e^{i\omega t} \quad (24.17)$$

Substitution into (24.16) gives

$$\mathbf{A}(\mathbf{r}, t) = \frac{1}{c} e^{i\omega t} \int \frac{\mathbf{j}_0(\mathbf{r}') e^{-i\frac{\omega}{c} |\mathbf{r} - \mathbf{r}'|}}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r}' = \mathbf{A}_0(\mathbf{r}) e^{i\omega t}. \quad (24.18)$$

As is to be expected, the vector potential depends on time in the same way as the current. The amplitude $\mathbf{A}_0(\mathbf{r})$ is obviously equal to

$$A_0(\mathbf{r}) = \frac{1}{c} \int \frac{j_0(\mathbf{r}') e^{-i \frac{\omega}{c} |\mathbf{r} - \mathbf{r}'|}}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r}' \quad (24.19)$$

On the other hand, substituting (24.17) and (24.18) into (24.1), we have

$$\nabla^2 A_0 + \frac{\omega^2}{c^2} A_0 = -\frac{4\pi}{c} j_0. \quad (24.20)$$

Thus, formula (24.19) gives the solution of eq. (24.20) which we shall encounter later.

In conclusion it should be noted that the solution of Poisson's equation represents a particular case of the problem. Assuming in (24.20) and (24.19) that $\omega = 0$ we arrive at the relations:

$$\nabla^2 A_0 = -\frac{4\pi}{c} j_0, \quad (24.21)$$

$$A_0 = \frac{1}{c} \int \frac{j_0(\mathbf{r}') d\mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|}. \quad (24.22)$$

The expression (24.22) can also be obtained by a direct solution of (24.21) by Fourier integral expansion. Indeed, assuming that

$$A_0 = \frac{1}{(2\pi)^{3/2}} \int e^{-i\mathbf{k} \cdot \mathbf{r}} a_0(\mathbf{k}) d\mathbf{k}, \quad (24.23)$$

$$j_0 = \frac{1}{(2\pi)^{3/2}} \int e^{-i\mathbf{k} \cdot \mathbf{r}} p_0(\mathbf{k}) d\mathbf{k}, \quad (24.24)$$

and substituting (24.23) and (24.24) into (24.21), we have

$$a_0 = \frac{4\pi p_0}{ck^2}. \quad (24.25)$$

Consequently,

$$A_0 = \frac{1}{(2\pi)^{3/2}} \int e^{-i\mathbf{k} \cdot \mathbf{r}} \left(\frac{4\pi p_0}{ck^2} \right) d\mathbf{k}. \quad (24.26)$$

By means of the inversion formula we obtain from (24.24) .

$$\mathbf{p}_0 = \frac{1}{(2\pi)^{3/2}} \int e^{i\mathbf{k} \cdot \mathbf{r}} \mathbf{j}_0(\mathbf{r}) d\mathbf{r} ,$$

Substitution of this expression into (24.26) leads to the formula

$$\begin{aligned} \mathbf{A}_0 &= \frac{4\pi}{(2\pi)^3} \frac{1}{c} \int \mathbf{j}_0(\mathbf{r}') d\mathbf{r}' \int e^{-i\mathbf{k} \cdot (\mathbf{r} - \mathbf{r}')} \frac{d\mathbf{k}}{k^2} = \\ &= \frac{1}{2\pi^2} \frac{1}{c} \int \mathbf{j}_0(\mathbf{r}') d\mathbf{r}' \int_0^\infty \int_0^\pi \int_0^{2\pi} e^{-i\mathbf{k} \cdot |\mathbf{r} - \mathbf{r}'| \cos \theta} \sin \theta d\theta d\varphi dk = \\ &= \frac{2}{\pi c} \int \mathbf{j}_0(\mathbf{r}') d\mathbf{r}' \int_0^\infty \frac{\sin \{k|\mathbf{r} - \mathbf{r}'|\}}{k|\mathbf{r} - \mathbf{r}'|} dk = \frac{1}{c} \int \frac{\mathbf{j}_0(\mathbf{r}') d\mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|} , \end{aligned}$$

where we have made use of the equality

$$\int_0^\infty \frac{\sin \{k|\mathbf{r} - \mathbf{r}'|\}}{k|\mathbf{r} - \mathbf{r}'|} dk = \frac{1}{|\mathbf{r} - \mathbf{r}'|} \int_0^\infty \frac{\sin u}{u} du = \frac{\pi}{2|\mathbf{r} - \mathbf{r}'|} .$$

§ 25*. The field of a point charge moving arbitrarily

The case of a single point charge moving arbitrarily is an important example of the application of the formula for retarded potentials. If the velocity of the charge is equal to $\mathbf{v}_0(t)$, then its coordinate is $\mathbf{r}_0 = \int \mathbf{v}_0 dt$. The charge density and current density can be written in the form

$$\rho = e \delta(\mathbf{r}' - \mathbf{r}_0) ,$$

$$\mathbf{j} = \rho \mathbf{v}_0 = e \delta(\mathbf{r}' - \mathbf{r}_0) \mathbf{v}_0(t) .$$

Then the following expressions are obtained for the retarded potentials:

$$\begin{aligned}
 A(\mathbf{r}, t) &= \frac{e}{c} \int \frac{\delta(\mathbf{r}' - \mathbf{r}_0(\tau)) v_0(\tau) dV'}{|\mathbf{r} - \mathbf{r}'|} = \\
 &= \frac{e}{c} \int \frac{\delta\left(\mathbf{r}' - \mathbf{r}_0\left(t - \frac{|\mathbf{r} - \mathbf{r}'|}{c}\right)\right) v_0\left(t - \frac{|\mathbf{r} - \mathbf{r}'|}{c}\right) dV'}{|\mathbf{r} - \mathbf{r}'|}, \quad (25.1)
 \end{aligned}$$

$$\begin{aligned}
 \varphi(\mathbf{r}, t) &= e \int \frac{\delta(\mathbf{r}' - \mathbf{r}_0(\tau)) dV'}{|\mathbf{r} - \mathbf{r}'|} = \\
 &= e \int \frac{\delta\left(\mathbf{r}' - \mathbf{r}_0\left(t - \frac{|\mathbf{r} - \mathbf{r}'|}{c}\right)\right) dV'}{|\mathbf{r} - \mathbf{r}'|}. \quad (25.2)
 \end{aligned}$$

Since \mathbf{r}_0 in the integrand of formulae (25.1) and (25.2) is a function of the delay time $t - |\mathbf{r} - \mathbf{r}'|/c$, one cannot make use of the property of the delta-function directly and assume $\mathbf{r}' = \mathbf{r}_0$. In order to carry out the integration we introduce new variables:

$$l_x = x' - x_0(\tau), \quad l_y = y' - y_0(\tau), \quad l_z = z' - z_0(\tau).$$

The calculation of the Jacobian for the transition to the new variables is in general rather cumbersome. For simplicity we assume that the charge is moving along the axis x_0 , so that $v_x = v_0$. We then have

$$\begin{aligned}
 \frac{\partial l_x}{\partial x'} &= 1 - \frac{\partial x_0}{\partial x'} = 1 - \frac{\partial x_0}{\partial \tau} \frac{\partial \tau}{\partial x'} = \\
 &= 1 - v_0 \frac{\partial}{\partial x'} \left\{ t - \frac{|\mathbf{r} - \mathbf{r}'|}{c} \right\} = 1 - \frac{v_0}{c} \frac{x - x'}{|\mathbf{r} - \mathbf{r}'|};
 \end{aligned}$$

$$\frac{\partial l_x}{\partial y'} = 0; \quad \frac{\partial l_x}{\partial z'} = 0;$$

$$\frac{\partial l_y}{\partial x'} = 0; \quad \frac{\partial l_y}{\partial y'} = 1; \quad \frac{\partial l_y}{\partial z'} = 0;$$

$$\frac{\partial l_z}{\partial x'} = 0; \quad \frac{\partial l_z}{\partial y'} = 0; \quad \frac{\partial l_z}{\partial z'} = 1.$$

Thus, the Jacobian is equal to

$$\frac{\partial(l_x, l_y, l_z)}{\partial(x', y', z')} = 1 - \frac{v_0(x - x')}{c|\mathbf{r} - \mathbf{r}'|}$$

An analogous calculation for an arbitrary orientation of the velocity leads to the expression

$$\frac{\partial(l_x, l_y, l_z)}{\partial(x', y', z')} = 1 - \frac{\mathbf{v}_0 \cdot (\mathbf{r} - \mathbf{r}')}{c|\mathbf{r} - \mathbf{r}'|}.$$

Hence one can write

$$\begin{aligned} dx' dy' dz' &= \frac{\partial(x', y', z')}{\partial(l_x, l_y, l_z)} dl_x dl_y dl_z = \\ &= \frac{dl_x dl_y dl_z}{1 - \frac{\mathbf{v}_0 \cdot (\mathbf{r} - \mathbf{r}')}{c|\mathbf{r} - \mathbf{r}'|}} = \frac{dl}{1 - \frac{\mathbf{v}_0 \cdot (\mathbf{r} - \mathbf{r}')}{c|\mathbf{r} - \mathbf{r}'|}}. \end{aligned}$$

Transforming the expressions (25.1) and (25.2) to new variables, we obtain

$$\begin{aligned} A(\mathbf{r}, t) &= \frac{e}{c} \int \frac{\delta(l) v_0 \left[t - \frac{|\mathbf{r} - \mathbf{l} - \mathbf{r}_0|}{c} \right] dl}{|\mathbf{r} - \mathbf{l} - \mathbf{r}_0| - \frac{(\mathbf{r} - \mathbf{l} - \mathbf{r}_0) \cdot \mathbf{v}_0}{c} \left[t - \frac{|\mathbf{r} - \mathbf{l} - \mathbf{r}_0|}{c} \right]} = \\ &= \frac{e v_0}{c \left[|\mathbf{r} - \mathbf{r}_0| - \frac{\mathbf{v}_0 \cdot (\mathbf{r} - \mathbf{r}_0)}{c} \right]} = \frac{e v_0(\tau)}{c \left[R(\tau) - \frac{\mathbf{v}_0(\tau) \cdot \mathbf{R}(\tau)}{c} \right]}, \end{aligned} \quad (25.3)$$

where $\mathbf{R}(\tau)$ stands for the radius-vector drawn from the instantaneous position of the charge to the point of observation, i.e. $\mathbf{R}(\tau) = \mathbf{r} - \mathbf{r}_0$. The value of the instantaneous position of the charge must be taken at the time τ :

$$\tau = t - \frac{|\mathbf{r} - \mathbf{r}_0|}{c}$$

The value of the instantaneous velocity $\mathbf{v}_0(\tau)$ is also taken at the time τ . Analogously,

$$\begin{aligned}
 \varphi(\mathbf{r}, t) &= e \int \frac{\delta(l) dl}{|\mathbf{r} - \mathbf{l} - \mathbf{r}_0| - \frac{(\mathbf{r} - \mathbf{l} - \mathbf{r}_0) \cdot \mathbf{v}_0}{c} \cdot v_0 \left(t - \frac{|\mathbf{r} - \mathbf{l} - \mathbf{r}_0|}{c} \right)} = \\
 &= \frac{e}{|\mathbf{r} - \mathbf{r}_0| - \frac{\mathbf{v}_0(\tau) \cdot (\mathbf{r} - \mathbf{r}_0)}{c}} = \frac{e}{R(\tau) - \frac{\mathbf{v}_0(\tau) \cdot \mathbf{R}(\tau)}{c}}. \quad (25.4)
 \end{aligned}$$

Between φ and \mathbf{A} there is the relation

$$\mathbf{A} = \mathbf{v}_0 \varphi / c. \quad (25.5)$$

The potentials of the field of an arbitrarily moving point charge (25.3) and (25.4) are called the Liénard-Wiechert potentials. If the abbreviated notation

$$\lambda(\tau) = R(\tau) - \frac{\mathbf{v}_0(\tau) \cdot \mathbf{R}(\tau)}{c}, \quad (25.6)$$

is introduced, then the Liénard-Wiechert potentials assume the form

$$\mathbf{A} = e \mathbf{v}_0 / c \lambda, \quad (25.7)$$

$$\varphi = e / \lambda. \quad (25.8)$$

The importance of the Lienard-Wiechert potentials lies in the fact that they characterize the field of a point charge in the most general form — for an arbitrary value of the velocity and the character of the motion.

It is easy to see that for a velocity of a charge $|\mathbf{v}_0|$ which is very small in comparison with the velocity of light, i.e. for $|\mathbf{v}_0|/c \rightarrow 0$ the expression for the scalar potential φ goes over into formula (20.2), and the vector potential \mathbf{A} turns out to be small. However, in deriving the Liénard-Wiechert potentials we have put no restrictions upon the value of the velocity. Hence the Liénard-Wiechert potentials characterize the field of a point charge in the most general case — for an arbitrary character and velocity of motion.

The field of a charge moving arbitrarily will be discussed in more detail in § 20 of Part II, since a number of inferences from formulae (25.7)–(25.8) can become clear only in the light of the theory of relativity.

Radiation Theory

§ 26. The potentials of the electromagnetic field at a large distance from the emitter in the dipole approximation

The general formulae for retarded potentials obtained in § 23 are very complex. Indeed, since the expressions for the charge density and current density contained in (23.22) and (23.23) are functions of the delay time in the corresponding integrals, it is necessary to take the values of these quantities at different times at each point of the system for the calculation of potentials at time t . Hence, except for the case of a single point charge considered in the preceding paragraph, one is unable to obtain accurate concrete expressions for the potentials by means of the general formulae (23.22) and (23.23).

If, however, the point of observation is located at a sufficiently large distance from the system of moving charges, so that $|\mathbf{r}| \gg L'$, where $L' \sim |V'|^{1/3}$ is the characteristic linear dimension of the system, then the expressions (23.22) and (23.23) allow a simplification. Namely, the expression $1/|\mathbf{r} - \mathbf{r}'|$ figuring in the integrals can be expanded in a series, as was done in calculating the fields of motionless (§ 15) and slowly moving (§ 21) charges. We then obtain

$$\begin{aligned}
 \varphi &= \int \frac{\rho\left(\mathbf{r}', t - \frac{|\mathbf{r} - \mathbf{r}'|}{c}\right) dV'}{|\mathbf{r} - \mathbf{r}'|} \approx \int \left(\frac{1}{r} + \frac{\mathbf{r}' \cdot \mathbf{r}}{r^3}\right) \rho\left(\mathbf{r}', t - \frac{|\mathbf{r} - \mathbf{r}'|}{c}\right) dV' = \\
 &= \int \frac{\rho\left(\mathbf{r}', t - \frac{|\mathbf{r} - \mathbf{r}'|}{c}\right) dV'}{r} \\
 &\quad + \int \frac{\mathbf{r}' \cdot \mathbf{r}}{r^3} \rho\left(\mathbf{r}', t - \frac{|\mathbf{r} - \mathbf{r}'|}{c}\right) dV', \quad (26.1)
 \end{aligned}$$

where r is the distance from the point of observation N to the origin O.

It should be noted that $\int \rho(\mathbf{r}', \tau) dV'$ is by no means the total charge of the system, i.e.

$$e \neq \int \rho(\mathbf{r}', \tau) dV'.$$

Indeed, the value of the density in this integral depends on the argument $\tau = t - |\mathbf{r} - \mathbf{r}'|/c$ and represents a complicated function of coordinates \mathbf{r} , \mathbf{r}' and time. The delay time is different for each point in a volume V' . For this reason the integrals in (26.1) cannot be calculated in a general form.

A further simplification arises in the case where instead of a different delay time for each point of the system one can introduce one general delay time for the entire system. Namely, writing the argument $\tau = t - |\mathbf{r} - \mathbf{r}'|/c$ in the form

$$\tau \approx t - \frac{r}{c} + \frac{\mathbf{r}' \cdot \mathbf{r}}{cr} = \tau_0 + \frac{\mathbf{r}' \cdot \mathbf{r}}{cr}, \quad (26.2)$$

we see that the total delay time $|\mathbf{r} - \mathbf{r}'|/c$ is made up of two parts. The first one, equal to r/c and called the delay time of the system, represents the time needed for the propagation of the electromagnetic field from the origin O to the point of observation N. The second part, equal to $\mathbf{r}' \cdot \mathbf{r}/cr$ and called the proper retardation, also has a simple meaning: it is the time needed for the propagation of the field to the limits of the system. According to the order of magnitude $\mathbf{r}' \cdot \mathbf{r}/cr \sim L'/c$, and for $|\mathbf{r}| \gg L'$ the absolute value of the proper retardation $|\mathbf{r}'|/c$ is small in comparison with $|\mathbf{r}|/c$. However, this does not mean that the charge density can be expanded in a series in the small parameter $\mathbf{r}' \cdot \mathbf{r}/cr$.

$$\begin{aligned}
 \rho(\mathbf{r}', \tau) &= \rho\left(\mathbf{r}', t - \frac{|\mathbf{r} - \mathbf{r}'|}{c}\right) = \\
 &= \rho\left(\mathbf{r}', t - \frac{r}{c} + \frac{\mathbf{r}' \cdot \mathbf{r}}{cr}\right) \approx \rho\left(\mathbf{r}', t - \frac{r}{c}\right) + \frac{\partial \rho}{\partial \tau} \frac{\mathbf{r}' \cdot \mathbf{r}}{cr} = \\
 &= \rho(\mathbf{r}', \tau_0) + \frac{\mathbf{r}' \cdot \mathbf{r}}{cr} \dot{\rho}(\mathbf{r}', \tau_0). \quad (26.3)
 \end{aligned}$$

Indeed, if in a time equal to the proper delay time $\mathbf{r}' \cdot \mathbf{r}/cr$ the configuration of the charges in the system manages to change appreciably, i.e. if in this time the charges manage to be displaced appreciably in the system, then the charge density at a moment $t - r/c$ will differ substantially from the charge density at a moment

$$t - \frac{r}{c} + \frac{\mathbf{r}' \cdot \mathbf{r}}{cr}.$$

In other words, the charge density ρ will be a rapidly varying function of its argument, and it is inadmissible to make use of the equality (26.3). In order that this equality may hold, it is necessary that in the time $\mathbf{r}' \cdot \mathbf{r}/cr$, in the course of which a field propagating with velocity c crosses the system, the charges in the system moving with a velocity v will not be displaced appreciably. During the time $\mathbf{r}' \cdot \mathbf{r}/cr$ the charges traverse a path of the order of

$$v \frac{\mathbf{r}' \cdot \mathbf{r}}{cr} \sim v \frac{L'}{c}.$$

If this path is small in comparison with the dimensions of the system, it can be assumed that during the time of proper retardation the disposition of the charges in the system does not change.

Thus, it can be assumed that for

$$v(L'/c) \ll L',$$

or at the velocities of motion satisfying the inequality

$$v \ll c, \quad (26.4)$$

the change of the configuration in the time of proper retardation is small.

Then $\rho(\mathbf{r}', \tau)$ is a slowly varying function of its argument. This means that to small changes in τ there correspond small changes in ρ , and use can be made of the expansion of ρ in powers of the small retardation. Substituting (26.3) into (26.1) and confining ourselves to the terms of the expansion containing the lowest powers of $1/r$, we find

$$\begin{aligned}\varphi &\approx \int \left(\frac{1}{r} + \frac{\mathbf{r}' \cdot \mathbf{r}}{r^3} \right) \left(\rho(\mathbf{r}', \tau_0) + \frac{\mathbf{r}' \cdot \mathbf{r}}{cr} \dot{\rho}(\mathbf{r}', \tau_0) \right) dV' \approx \\ &\approx \int \left\{ \frac{\rho(\mathbf{r}', \tau_0)}{r} + \frac{\mathbf{r}' \cdot \mathbf{r}}{cr^2} \dot{\rho}(\mathbf{r}', \tau_0) \right\} dV' = \\ &= \int \frac{\rho(\mathbf{r}', \tau_0) dV'}{r} + \frac{\mathbf{n}}{cr} \cdot \int \mathbf{r}' \dot{\rho}(\mathbf{r}', \tau_0) dV',\end{aligned}\quad (26.5)$$

where $\mathbf{n} = \mathbf{r}/r$. The term

$$\frac{\mathbf{r}' \cdot \mathbf{r}}{r^3} \rho(\mathbf{r}', \tau_0)$$

is small in comparison with the term

$$\frac{\mathbf{r}' \cdot \mathbf{r}}{cr^2} \dot{\rho}(\mathbf{r}', \tau_0)$$

at a sufficiently large distance from the system.

In formula (26.5) a very substantial simplification is made in comparison with (26.1), since the charge density at all points of the system is taken at one and the same moment

$$\tau_0 = t - (r/c).$$

The first term in (26.5) has a simple meaning:

$$\rho(\mathbf{r}', \tau_0) = \rho\left(\mathbf{r}', t - \frac{r}{c}\right)$$

represents the charge density in the system at the moment τ_0 . The integral $\int \rho(\mathbf{r}', \tau_0) dV'$ gives the total charge of the system. For an electrically neutral system it is equal to zero. In this case we have

$$\varphi(\mathbf{r}, t) = \frac{n}{cr} \cdot \int \mathbf{r}' \cdot \dot{\rho}(\mathbf{r}', \tau_0) dV' . \quad (26.6)$$

We rewrite the integral on the right-hand side of formula (26.6) by making use of the continuity equation (5.3):

$$\int \mathbf{r}' \cdot \dot{\rho}(\mathbf{r}', \tau_0) dV' = \int \mathbf{r}' \cdot \frac{\partial \rho}{\partial t} \frac{\partial t}{\partial \tau_0} dV' = - \int \mathbf{r}' \cdot [\nabla \cdot \mathbf{j}(\mathbf{r}', \tau_0)] dV' .$$

The above integral is conveniently calculated in the coordinate representation. Namely, we have

$$\int x' \frac{\partial j_{x'}}{\partial x'} dx' = x' j_{x'} \Big|_{x'_1}^{x'_2} - \int j_{x'} dx' ,$$

where x'_1 and x'_2 are the limits of the region of motion of the charges, at which the current density reduces to zero, so that

$$\int x' \frac{\partial j_{x'}}{\partial x'} dx' = - \int j_{x'} dx' .$$

Correspondingly, in the vector form we obtain

$$\int \mathbf{r}' \cdot \dot{\rho}(\mathbf{r}', \tau_0) dV' = \int \mathbf{j} dV' . \quad (26.7)$$

Substituting (26.7) into (26.6), we find the scalar potential as a function of the current density in the system

$$\varphi(\mathbf{r}, t) = \frac{n}{cr} \cdot \int \mathbf{j}(\mathbf{r}', \tau_0) dV' . \quad (26.8)$$

In an analogous way we can obtain the expression for the vector-potential by expanding the expression $1/|\mathbf{r}-\mathbf{r}'|$ in formula (23.23) in a series and disregarding the proper retardation:

$$\mathbf{A}(\mathbf{r}, t) = \frac{1}{cr} \int \mathbf{j}(\mathbf{r}', \tau_0) dV' . \quad (26.9)$$

Comparing (26.8) and (26.9) we find that there is between φ and \mathbf{A} the simple relation:

$$\varphi = \mathbf{A} \cdot \mathbf{n}. \quad (26.10)$$

The integral $\int \mathbf{r}' \dot{\rho}(\mathbf{r}', \tau_0) dV'$ has a simple meaning. Namely, from the definition of the dipole moment (15.14) we see that

$$\int \mathbf{j} dV' = \int \mathbf{r}' \dot{\rho}(\mathbf{r}', \tau_0) dV' = \frac{\partial}{\partial \tau} \int \mathbf{r}' \rho(\mathbf{r}', \tau_0) dV' = \dot{\mathbf{d}}(\tau_0), \quad (26.11)$$

where $\dot{\mathbf{d}}(\tau_0)$ is the derivative of the dipole moment with respect to time, taken at the instant τ_0 . Here we have used the fact that \mathbf{r}' is an independent integration variable which does not depend on τ_0 .

By means of (26.11) the expressions (26.8) and (26.9) can be written in the form

$$\varphi(\mathbf{r}, t) = \frac{\mathbf{n} \cdot \dot{\mathbf{d}}(\tau_0)}{cr} \quad (26.12)$$

$$\mathbf{A}(\mathbf{r}, t) = \frac{\dot{\mathbf{d}}(\tau_0)}{cr} \quad (26.13)$$

We see that in the approximation when the proper retardation can be disregarded the field potentials at a large distance from the system are determined by the value of the derivative of its dipole moment with respect to time. Hence such an approximation in calculating field potentials is called the dipole approximation. The condition of applicability of the dipole approximation is the fulfillment of the inequality (26.4).

In the dipole approximation field potentials at a large distance from an electrically neutral system decrease according to the law $1/r$, whereas the analogous electrostatic potential of an electrically neutral system of charges at rest possessing a dipole moment varies according to the law $1/r^2$.

It is easy to verify that the Lorentz condition is fulfilled for the potentials found in the dipole approximation. We have

$$\begin{aligned} \nabla \cdot \mathbf{A} &= \frac{1}{c} \nabla \cdot \frac{\dot{\mathbf{d}}(\tau_0)}{r} = \\ &= \frac{1}{cr} \nabla \cdot \dot{\mathbf{d}}(\tau_0) + \frac{1}{c} \left(\dot{\mathbf{d}}(\tau_0) \cdot \nabla \frac{1}{r} \right) \approx \frac{1}{cr} \nabla \cdot \dot{\mathbf{d}}(\tau_0). \end{aligned} \quad (26.14)$$

In calculating (26.14), the second term in the sum, which is proportional to

$1/r^2$ is small in comparison with the first which is proportional to $1/r$, and can be discarded. We see that in differentiating with respect to coordinates at a large distance from the emitter the quantity $1/r$ can be considered to be constant. Further, according to formula (I.39) we have

$$\nabla \cdot \dot{\mathbf{d}}(\tau_0) = \frac{\partial \dot{\mathbf{d}}(\tau_0)}{\partial \tau_0} \cdot \nabla \tau_0 = -\ddot{\mathbf{d}} \cdot \frac{\mathbf{r}}{cr} = -\frac{\ddot{\mathbf{d}} \cdot \mathbf{n}}{c}.$$

Thus

$$\nabla \cdot \mathbf{A} = -\frac{1}{c^2 r} \ddot{\mathbf{d}}(\tau_0) \cdot \mathbf{n}.$$

On the other hand,

$$\frac{1}{c} \frac{\partial \varphi}{\partial t} = \frac{1}{c^2} \frac{\partial}{\partial t} \frac{\dot{\mathbf{d}} \cdot \mathbf{n}}{r} \approx \frac{1}{c^2} \frac{\mathbf{n}}{r} \cdot \ddot{\mathbf{d}}(\tau_0),$$

hence

$$\nabla \cdot \mathbf{A} + \frac{1}{c} \frac{\partial \varphi}{\partial t} = 0,$$

as was to be expected.

The results obtained have a simple and very important meaning: when charges in a system are moving (i.e. when the dipole moment of the system changes in time) an electromagnetic field arises in the surrounding space. The potentials of this field decrease relatively slowly (according to the law $1/r$) with increasing distance from the system and depend on time.

A system of non-uniformly moving charges is an emitter of radiation.

In the following paragraphs we shall consider in more detail the radiation field and the properties of systems emitting radiation.

§27. The electromagnetic field of dipole radiation at a large distance from the emitter

Knowing the potential distribution, one can find the values of the magnetic and electric field. We have

$$\mathbf{H} = \nabla \times \mathbf{A} = \frac{1}{c} \nabla \times \frac{\dot{\mathbf{d}}(\tau_0)}{r}.$$

In calculating the curl at a large distance from the emitter the calculation is to be carried out in the same way as for the divergence in formula (26.14): in differentiating with respect to coordinates the factor $1/r$ should be assumed to be constant. Then, according to formula (1.40), we find

$$\mathbf{H} = \frac{1}{cr} \nabla \times \dot{\mathbf{d}}(\tau_0) = \frac{1}{cr} \nabla \tau_0 \times \frac{d\dot{\mathbf{d}}(\tau_0)}{d\tau_0} = \frac{1}{c} \dot{\mathbf{A}} \times \mathbf{n} = \frac{1}{c^2 r} \ddot{\mathbf{d}} \times \mathbf{n}. \quad (27.1)$$

We have omitted writing \mathbf{d} explicitly as a function of τ_0 ; however, here and in all subsequent relations of this section we understand that \mathbf{d} is a function of the argument $\tau_0 = t - r/c$.

For any function of the retarded argument $t - r/c$ we have

$$\nabla f\left(t - \frac{r}{c}\right) = \frac{df}{d\tau_0} \nabla \tau_0 = -\dot{f} \frac{\mathbf{n}}{c},$$

where it is assumed that

$$\frac{\partial f}{\partial t} = \frac{\partial f}{\partial \tau_0} \frac{\partial \tau_0}{\partial t} = \dot{f}.$$

Hence for the electric field

$$\begin{aligned} \mathbf{E} &= -\frac{1}{c} \frac{\partial \mathbf{A}}{\partial t} - \nabla \varphi = -\frac{1}{c} \dot{\mathbf{A}} + \frac{\mathbf{n}}{c} \dot{\varphi} = -\frac{1}{c} \dot{\mathbf{A}} + \frac{\mathbf{n}}{c} (\mathbf{n} \cdot \dot{\mathbf{A}}) = \\ &= \frac{1}{c} \{ \mathbf{n}(\mathbf{n} \cdot \dot{\mathbf{A}}) - \dot{\mathbf{A}} \} = \frac{1}{c} (\dot{\mathbf{A}} \times \mathbf{n}) \times \mathbf{n} = \frac{1}{c^2 r} (\ddot{\mathbf{d}} \times \mathbf{n}) \times \mathbf{n}. \end{aligned} \quad (27.2)$$

Comparing (27.2) with (27.1) we see that the vectors \mathbf{E} and \mathbf{H} are connected by the relation

$$\mathbf{E} = \mathbf{H} \times \mathbf{n}. \quad (27.3)$$

The strengths of the electric and magnetic field depend on coordinates and time according to the law

$$|\mathbf{H}| = |\mathbf{E}| = \frac{f(t - r/c)}{r}.$$

As we have seen in §23, the above formula is an expression for a spherical wave. The amplitude of the wave decreases at a large distance from the emitter according to the law $\sim 1/r$. In this case the vectors of the electric and magnetic field are equal to each other in absolute value, and are perpendicular to each other and to the radius vector \mathbf{r} .

The region at a large distance from the emitter, in which the electromagnetic field is described by spherical waves, is called the radiation zone. Somewhat later we shall define more precisely the notion of the radiation zone.

We introduce the spherical system of coordinates r, θ, ψ (fig. I.10) with the polar axis directed along the vector \mathbf{d} . The direction of the vector \mathbf{H} is determined by the vector $[\mathbf{n} \times \mathbf{d}]$, directed along the tangent to the latitude line on the surface of the sphere and oriented in the direction of decreasing azimuthal angle ψ , so that

$$[\mathbf{n} \times \ddot{\mathbf{d}}]_r = 0, \quad [\mathbf{n} \times \ddot{\mathbf{d}}]_\theta = 0, \quad [\mathbf{n} \times \ddot{\mathbf{d}}]_\psi = -\ddot{d} \sin \theta.$$

Hence the vector \mathbf{H} in spherical coordinates has the following components:

$$H_r = 0, \quad H_\theta = 0, \quad H_\psi = \frac{\ddot{d}}{c^2 r} \sin \theta. \quad (27.4)$$

The vector \mathbf{E} is directed perpendicularly to the vectors \mathbf{H} and \mathbf{n} along the tangent to the line of longitude, and is oriented in the direction of decreasing

Fig. I.10

polar angle θ . Its components are

$$E_r = 0, \quad E_\theta = \frac{\ddot{d}}{c^2 r} \sin \theta, \quad E_\psi = 0. \quad (27.5)$$

Formulae (27.4) and (27.5) show that the field strengths have the largest values at $\theta = \pi/2$ (in the equatorial plane) and decrease down to zero as the distance from the polar axis decreases.

We calculate the Poynting vector of the emitting system:

$$\begin{aligned} \sigma &= \frac{c}{4\pi} \mathbf{E} \times \mathbf{H} = \frac{c}{4\pi} H^2 \mathbf{n} = \frac{c}{8\pi} (E^2 + H^2) \mathbf{n} = \\ &= cu_0 \mathbf{n} = \frac{1}{4\pi c} [\dot{\mathbf{A}} \times \mathbf{n}]^2 \mathbf{n} = \frac{1}{4\pi c^3 r^2} [\mathbf{n} \times \dot{\mathbf{d}}]^2 \mathbf{n}. \end{aligned} \quad (27.6)$$

The Poynting vector turns out to be directed along the radius-vector and is equal in absolute value to

$$\sigma = \frac{1}{4\pi c^3} \frac{\ddot{d}^2}{r^2} \sin^2 \theta. \quad (27.7)$$

The fact that the Poynting vector is different from zero and is always directed away from the emitting system has an obvious meaning: there is a flux of electromagnetic energy emitted by the system into the surrounding space. Formula (27.7) determines the flux density of the emitted energy as a function of the orientation in space (the angle θ) and the distance from the emitting system. The presence of the energy flux justifies the terms "radiation" and "emitter", which we introduced earlier.

We stress that in a factual observation of radiation in a certain direction \mathbf{n} , only the value of the component of the vector of the second derivative of the dipole moment ($\ddot{\mathbf{d}}$) in the plane perpendicular to \mathbf{n} is effective, as is seen from (27.6).

The energy flux through the vector surface $d\Sigma$ enclosing a solid angle $d\Omega$ is the power radiated in the solid angle $d\Omega$. For the power radiated dI

$$\begin{aligned} dI &= \sigma \cdot d\Sigma = \sigma d\Sigma = \sigma r^2 d\Omega = \frac{c}{4\pi} H^2 r^2 d\Omega = \frac{\ddot{d}^2 \sin^2 \theta}{4\pi c^3 r^2} r^2 d\Omega = \\ &= \frac{|\ddot{\mathbf{d}}|^2}{4\pi c^3} \sin^3 \theta d\theta d\psi = \frac{[\mathbf{n} \times \ddot{\mathbf{d}}]^2}{4\pi c^3} d\Omega. \end{aligned} \quad (27.8)$$

The total flux of energy emitted by the system, usually called the total radiated power, is equal to

$$-\frac{dE}{dt} = I = \int \sigma \cdot d\Sigma = \frac{\ddot{d}^2}{4\pi c^3} \int_0^\pi \sin^3 \theta \, d\theta \int_0^{2\pi} d\psi = \frac{2}{3} \frac{\ddot{d}^2}{c^3} \quad (27.9)$$

Here $(-dE/dt)$ is the decrease in the energy of the emitting system per second.

The power radiated in the dipole approximation is determined only by the value of $\ddot{d}(t-r/c)$. In other words, at a time t the value of I at a given point depends on the value of \ddot{d} at the preceding time $t-r/c$. But in other respects the power radiated does not depend on the distance from the emitting system, as is to be expected on the basis of the energy conservation law: the energy flux passing per unit time through any closed surface surrounding the emitting system has one and the same value.

In conclusion we point to the relation holding for the density of the energy and momentum of the radiation. By virtue of formulae (27.6) and (13.11) we can write

$$\mathbf{g} = \frac{1}{c^2} \boldsymbol{\sigma} = \frac{u_0}{c} \mathbf{n}. \quad (27.10)$$

We shall often encounter this important relation later.

We see that in emitting radiation the emitting system loses both energy and momentum, which become the energy and momentum of the radiation.

§ 28. Dipole radiation of simple systems

As an example of the use of dipole radiation formulae we shall consider several simple systems.

For a single charge, accelerated by a force \mathbf{F} , we can write

$$\left. \begin{aligned} \mathbf{d} &= e\mathbf{r}, \\ \ddot{\mathbf{d}} &= e\ddot{\mathbf{r}} = e \frac{\mathbf{F}}{m}, \end{aligned} \right\} \quad (28.1)$$

where $\mathbf{r} = \mathbf{r}$ is the acceleration of the charge. Hence

$$\sigma = \frac{c}{4\pi} H^2 \mathbf{n} = \frac{e^2 w^2 \sin^2 \theta}{4\pi c^3 r^2} \mathbf{n}. \quad (28.2)$$

Energy flux is absent in the direction of the acceleration vector ($\theta = 0$) and has its largest value in the direction perpendicular to the acceleration vector ($\theta = \pi/2$). The total energy emitted per unit time in the solid angle $d\Omega$ (total power of radiation in the angle $d\Omega$) is equal to

$$dI = \frac{e^2 w^2}{4\pi c^3} \sin^2 \theta d\Omega \quad (28.3)$$

and is proportional to the square of the acceleration. The total radiated power emitted by a single charge in all directions is equal to (see (27.9))

$$I = \frac{2}{3} \frac{e^2 w^2}{c^3}. \quad (28.4)$$

It is determined by the value of the square of the acceleration and the square of the charge.

We see that every charge moving with an acceleration emits energy in the form of electromagnetic waves.

The application of (28.2) to a single charge needs some explanation. In deriving formula (27.6) the expansion was carried out with respect to a small parameter — the proper time of retardation — which loses its meaning in the case of a system consisting of one charge.

However, in §25 we found the expressions for the field potentials of an arbitrarily moving point charge. If one substitutes in (25.7)

$$e\mathbf{v}_0 = \int \rho \mathbf{v}_0 dV = \int \mathbf{j} dV = \dot{\mathbf{d}},$$

and considers the case of motion with a velocity which is small in comparison with the velocity of light, so that $\lambda(\tau) \approx r$, then the expression for the vector-potential of the point charge is the same as formula (26.13).

Thus, at a large distance from a slowly moving charge its field will be the same as that of a system of charges in the dipole approximation.

Let us also calculate the loss of momentum of the emitting particle. By virtue of formulae (13.11) and (27.10) we see that the rate of loss of momentum of the charge while emitting is

$$-\frac{d\mathbf{P}}{dt} = \int \mathbf{g} d\Omega = \frac{1}{c^2} \int \sigma d\Omega = 0. \quad (28.5)$$

The meaning of this result lies in the fact that the emission by the charge at angles θ , $\pi - \theta$ is the same. The momenta in opposite directions are mutually compensated. It should be stressed that formulae (28.4) and (28.5) refer to a charge which was at rest at the moment of emission. It is only for such a charge that the relation (28.1) holds.

Let us consider several simple examples of the calculation of radiation from a moving point charge.

Let, for instance, the charge move in a uniform magnetic field. For simplicity we assume that the initial velocity of the charge \mathbf{v}_0 is perpendicular to the vector \mathbf{H} . The charge moving in the magnetic field has the acceleration

$$\mathbf{w} = \frac{\mathbf{F}}{m} = \frac{e}{mc} \mathbf{v} \times \mathbf{H}$$

and, correspondingly, continually emits electromagnetic waves. The total intensity of the radiation is equal to

$$I = \frac{2}{3} \frac{e^4}{m^2 c^5} [\mathbf{v} \times \mathbf{H}]^2 \quad (28.6)$$

If the energy loss is assumed to be small, then the velocity of the charge can be considered as approximately constant: $\mathbf{v} \approx \mathbf{v}_0$. In this case $\mathbf{v} \times \mathbf{H} \approx \mathbf{v}_0 \times \mathbf{H} = v_0 \mathbf{H}$. Hence

$$I = \frac{2}{3} \frac{e^4 v^2 H^2}{m^2 c^5} = \frac{4}{3} \frac{e^4 H^2}{m^3 c^5} \left(\frac{mv^2}{2} \right). \quad (28.6')$$

The energy emitted is inversely proportional to c^5 and is very small. However, it increases with charged particle energy and the effect of emission becomes substantial at very high particle energies, for example, for cosmic-ray particles in the Earth's magnetic field, or for fast electrons moving in the magnetic fields of contemporary betatrons. Calculations have shown that it is the energy losses due to radiation in a magnetic field which are the main losses limiting the energies attainable by particles in a betatron. However, it should be borne in mind that formula (28.6) is applicable only at velocities $v \ll c$. The case $v \sim c$ is discussed in §26 of Part II.

As another example, let us consider the radiation by a charge oscillating according to the harmonic law:

$$\mathbf{r} = \mathbf{r}_0 \cos(\omega_0 t + \alpha). \quad (28.7)$$

The acceleration of the charge is equal to

$$\ddot{\mathbf{r}} = -\omega_0^2 \mathbf{r} = -\omega_0^2 \mathbf{r}_0 \cos(\omega t + \alpha), \quad (28.8)$$

so that the corresponding dipole moment is expressed by $\mathbf{d} = \mathbf{d}_0(\cos \omega_0 t + \alpha)$. Hence the radiation power emitted in the solid angle $d\Omega$ is equal to

$$dI = \frac{e^2 \omega_0^4}{4\pi c^3} [\mathbf{n} \times \mathbf{r}_0]^2 \cos^2(\omega t + \alpha) d\Omega.$$

The mean (over one period) intensity of radiation in the angle $d\Omega$ is

$$d\bar{I} = \frac{1}{T} \int_0^T dI = \frac{e^2 \omega_0^4}{8\pi c^3} [\mathbf{n} \times \mathbf{r}_0]^2 d\Omega. \quad (28.9)$$

Formula (28.9) determines, in particular, the angular distribution of the radiation emitted. The total intensity of the radiation emitted by the oscillator is, according to (27.13), given by the formula

$$\bar{I} = \int d\bar{I} = \frac{e^2 \omega_0^4 r_0^2}{3c^3}. \quad (28.10)$$

The oscillator emits electromagnetic waves whose frequency is the same as its natural frequency ω_0 . The intensity of radiation is proportional to the square of the amplitude of motion and the fourth power of the frequency. The particular importance of this example is in the following.

At the beginning of the development of electron theory the well-known Thomson atomic model was proposed. It was assumed that the electron was located in the centre of a sphere formed by continuously distributed positive charge. The radiation by an atom in Thomson's model was associated with small oscillations of the electron about its equilibrium position in the centre of the atom. Thus, the atom as a radiating system was reduced to an emitting oscillator, and formula (28.10) gave the intensity of atomic radiation. In 1911 Rutherford's experiments showed Thomson's model to be incorrect, and it was abandoned. However, it turned out that the harmonic oscillator as a model of a radiating atomic system led in a number of cases to quite correct results which found experimental confirmation. The most important of these is the existence of definite frequencies ω_0 of radiation, characteristic of a given atom. Hence the oscillator remained in classical physics as a model of

a radiating atomic system, although it could not be understood within the framework of classical theory why such a model, so far from reality, could give correctly the most important properties of atomic emitters. The situation was elucidated by the appearance of the quantum theory of radiation. In quantum mechanics we shall see that the quantum theory of radiation leads, in a number of cases, to relations which are formally the same as the expressions obtained for the classical model of the emitter. This results, roughly speaking, from the following. A number of properties of atomic emitters is determined not by some concrete law of the motion of the emitting particles, but simply by the periodicity of the process. On the other hand, the circular periodic motion of an electron with a constant angular velocity corresponds to the oscillation of a plane oscillator

$$x = a \cos(\omega_0 t + \alpha), \quad y = a \sin(\omega_0 t + \alpha).$$

Hence the model of the oscillator oscillating with the frequency ω_0 yields some characteristic features of the atomic emitter. We shall take into account this fact and, later on, discuss in detail the properties of the oscillator as a classical model of an atomic radiating system. On the other hand, we shall see in a number of examples that classical electrodynamics is not directly applicable to intraatomic processes and that it leads to relations which are quantitatively, and even qualitatively, in contradiction with experimental data.

Let us now consider a system consisting of two particles with charges e_1 and e_2 and masses m_1 and m_2 . For such a system

$$\ddot{\mathbf{d}} = e_1 \ddot{\mathbf{r}}_1 + e_2 \ddot{\mathbf{r}}_2 = e_1 \mathbf{w}_1 + e_2 \mathbf{w}_2.$$

If the system of two particles is closed, the accelerations can be written in the form

$$\mathbf{w}_1 = \mathbf{F}/m_1, \quad \mathbf{w}_2 = -\mathbf{F}/m_2,$$

where \mathbf{F} is the force of interaction between the particles. Hence

$$\ddot{\mathbf{d}} = \left(\frac{e_1}{m_1} - \frac{e_2}{m_2} \right) \mathbf{F}$$

and the power of radiation in the angle $d\Omega$ is

$$dI = \frac{1}{4\pi c^3} \left(\frac{e_1}{m_1} - \frac{e_2}{m_2} \right)^2 [\mathbf{F} \times \mathbf{n}]^2 d\Omega. \quad (28.11)$$

The most important consequence of formula (28.11) is the statement that a closed system consisting of identical particles, or a closed system of different particles which have the same ratio e/m , cannot emit radiation in the dipole approximation. In order to find the radiation of such systems it is necessary to take into account effects of higher order (see §32).

§ 29. Radiation reaction

We have seen in preceding paragraphs that a single charge, moving with an acceleration, loses energy by radiation. In making the energy balance of a particle moving under the action of external forces it is necessary to take into account radiation losses.

We have also seen that the radiation field possesses not only energy but also momentum. Owing to this the emission of radiation is accompanied by a reaction force of the field on the particle. This action of the radiation field on the motion of the particle is called radiation reaction.

The balance of forces taking into account the radiation effect must be written in the form

$$m\mathbf{w} = \mathbf{F} + \mathbf{F}_s = \int \rho \left(\mathbf{E} + \frac{\mathbf{v} \times \mathbf{H}}{c} \right) dV + \mathbf{F}_s.$$

The first term represents the external force acting on the particle, and \mathbf{F}_s represents the radiation reaction force, called also the Lorentz deceleration force.

To calculate the radiation reaction force \mathbf{F}_s we can, in principle, proceed in the following way. We assume that the radiating charge is distributed in space. Dividing it into elements δe and $\delta e'$ we can calculate the action of the field emitted by an element $\delta e'$ on an element δe . Summing then over all elements $\delta e'$ and δe we find the total self-force sought. The calculation described appears to be rather cumbersome*. Moreover, it can be carried out only in the case of a model whose validity is, from the standpoint of contemporary quantum theory, rather weak. Therefore we shall concentrate on a different line of reasoning leading to the same expression for the force \mathbf{F}_s .

We assume that the Lorentz deceleration force \mathbf{F}_s is small in comparison with external forces. The meaning of such an assumption will be discussed in detail below, when we find \mathbf{F}_s . If this assumption is fulfilled, then in the first

* W.Heitler, *Quantum theory of radiation* (Clarendon Press, Oxford, 1954).

approximation the charge performs its motion under the action of external field forces \mathbf{F} . During this motion it radiates energy as given by formula (27.9).

In addition, we assume that the charge performs a periodic motion or, more generally, that at a certain time t_1 it comes back to the initial state of motion which it was in at the initial time t_0 . We balance the energy for a system consisting of a charge performing such a motion and an external electromagnetic field. It is obvious that, if the charge emitted nothing, then upon

its coming back into the initial state the total work $W = \int_{t_0}^{t_1} \mathbf{F} \cdot \mathbf{v} dt$ done on it

by the external field would be equal to zero. Also the change $\Delta E_{\text{ext. field}}$ in the energy of the external field would be equal to zero.

If in the next approximation we take into account that the total force acting on the charge is made up of the forces \mathbf{F} and \mathbf{F}_s , then the energy balance can be written in the form

$$\int_{t_0}^{t_1} (\mathbf{F} + \mathbf{F}_s) \cdot \mathbf{v} dt = \Delta E + \Delta E_{\text{ext. field}},$$

where ΔE is the energy emitted by the charge during the time $(t_1 - t_0)$. Taking into account that

$$\Delta E_{\text{ext. field}} = \int_{t_0}^{t_1} \mathbf{F} \cdot \mathbf{v} dt = 0,$$

it can be written that

$$\int_{t_0}^{t_1} \mathbf{F}_s \cdot \mathbf{v} dt = \Delta E = -\frac{2}{3} \frac{e^2}{c^3} \int_{t_0}^{t_1} w^2 dt. \quad (29.1)$$

Integrating the right-hand side by parts, we obtain

$$\int_{t_0}^{t_1} \mathbf{F}_s \cdot \mathbf{v} dt = -\frac{2}{3} \frac{e^2}{c^3} \mathbf{w} \cdot \mathbf{v} \Big|_{t_0}^{t_1} + \frac{2}{3} \frac{e^2}{c^3} \int_{t_0}^{t_1} \mathbf{v} \cdot \ddot{\mathbf{v}} dt.$$

Since at time t_1 the state of motion is the same as that at time t_0 , so that $\mathbf{v}_{t_0} = \mathbf{v}_{t_1}$, $\mathbf{w}_{t_0} = \mathbf{w}_{t_1}$, we have

$$\int_{t_0}^{t_1} \mathbf{F}_s \cdot \mathbf{v} dt = \frac{2}{3} \frac{e^2}{c^3} \int_{t_0}^{t_1} \mathbf{v} \cdot \ddot{\mathbf{v}} dt.$$

Equating the integrands, we find

$$\mathbf{F}_s = \frac{2}{3} \frac{e^2}{c^3} \ddot{\mathbf{v}} = \frac{2}{3} \frac{e^2}{c^3} \mathbf{w}. \quad (29.2)$$

The radiation reaction force turns out to be dependent on the derivative of the acceleration of the particle. According to the assumption made that the radiation reaction force \mathbf{F}_s is small in comparison with the external force acting on the particle, the \mathbf{w} in (29.1) should be understood to be the acceleration of the particle in the external force field. If it were not so, i.e. if, for example, the reverse inequality $\mathbf{F}_s \gg \mathbf{F}$ were fulfilled, then the equation of motion would have the form

$$m\mathbf{w} \approx \mathbf{F}_s = \frac{2}{3} \frac{e^2}{c^3} \dot{\mathbf{w}}.$$

Its solution is

$$\mathbf{w} = \mathbf{w}_0 \exp \frac{3mc^3}{2e^2} t.$$

This last formula shows that under the action of the reverse radiation reaction the acceleration increases exponentially in time — the particle is self-accelerated. Such a self-acceleration contradicts the laws of classical mechanics as well as all experimental data.

Thus, the assumption that $|\mathbf{F}_s| \gg |\mathbf{F}|$ leads to a physically senseless result. On the contrary, for $|\mathbf{F}_s| \ll |\mathbf{F}|$ the quantity \mathbf{w} can, with a sufficient degree of accuracy, be considered as equal to the acceleration acquired by the particle in the external field under the action of the Lorentz force \mathbf{F} . Assuming the latter to be a periodic function of time with a frequency ω we can, obviously, write the following expression for the amplitude of \mathbf{F}_s :

$$|\mathbf{F}_s| = \frac{2}{3} \frac{e^2}{c^3} |\dot{\mathbf{w}}| = \frac{2}{3} \frac{e^2}{c^3} \left| \frac{\dot{\mathbf{F}}}{m} \right| = \frac{2}{3} \frac{e^2}{c^3} \frac{\omega}{m} |\mathbf{F}|. \quad (29.3)$$

Hence the condition of applicability of expression (29.3) for the radiation reaction $|F_s| \ll |F|$ assumes the following form:

$$e^2 \omega / mc^3 \ll 1 \quad (29.4)$$

Violation of the inequality (29.4) means that the radiation reaction is not small, and the latter leads to a physically incorrect result. Thus, the inequality (29.4) is of fundamental importance for the applicability of radiation theory and the laws of classical field theory in general. The classical field theory only leads to reasonable results which agree with experimental data for the frequencies

$$\omega \ll mc^3 / e^2 \quad (29.5)$$

If m is understood to be the mass of the elementary charge — an electron — then the condition (29.5) turns out to be fulfilled at all optical and X-ray frequencies and even for not too high-energy γ -rays. However, as will be explained in more detail in §17 of Part II, in the case of hard γ -rays the laws of classical electrodynamics turn out to be inapplicable and quantum effects play the basic role.

It is of interest to rewrite the inequality (29.5), introducing the wavelength $\lambda = 2\pi c / \omega$ into it. Then instead of (29.5) we have

$$\lambda \gg e^2 / mc^2 = r_0 \quad (29.6)$$

For reasons which will be explained in §13 of Part II, the quantity $r_0 \approx 2.5 \times 10^{-13}$ cm is called the classical radius of the electron.

The inequality (29.6) can be interpreted as follows. For electromagnetic phenomena on the scale $\sim r_0$ the radiation reaction is not small in comparison with other forces. In this case the relations of classical field theory turn out to be inapplicable. Thus, in classical field theory there is an intrinsic limit of applicability; it is suitable for the consideration of phenomena taking place in a region of space greater than the order of the classical radius of the electron. In what follows we shall see that the actual region of applicability of classical field theory does not extend to such small dimensions. It turns out that quantum effects, which impose a limit upon the applicability of classical concepts to microparticles, begin to play a role at distances $\sim \Lambda = \hbar / mc$, where \hbar is the Planck constant equal to 1.05×10^{-27} erg·sec. The quantity Λ , equal to 2×10^{-10} cm for the electron, is called the Compton wavelength. We shall encounter this quantity in §17 of Part II, where the so-called Compton effect will be considered.

In quantum mechanics we shall discuss in detail the question of the range of applicability of the relations of classical theory, and give the proof of the statement presented.

§30. Line width of emitted radiation

The radiation reaction has a fundamental effect on the properties of the field emitted. We shall show that an emitter which in the absence of the reaction force would emit monochromatic electromagnetic waves with a frequency ω_0 in reality emits a range of frequencies in the region of ω_0 .

In other words, because of the damping effect the monochromatic radiation becomes radiation with a continuous spectrum of waves of all possible frequencies.

We shall present the proof of this statement for the simplest model of an emitting system — the linear harmonic oscillator. Let a charged particle move under the action of a quasi-elastic force $(-kx)$ along the x -axis, so that its equation of motion has the form

$$\ddot{x} = -\omega_0^2 x + \frac{F_s}{m},$$

or

$$\ddot{x} = -\omega_0^2 x + \frac{2}{3} \frac{e^2 \dot{w}}{mc^3},$$

where $\omega_0 = \sqrt{k/m}$ is the frequency of the oscillator in the absence of the force F_s .

Considering F_s to be small in comparison with the quasi-elastic force $(-kx)$, the acceleration can be assumed to be equal to the acceleration of the harmonic oscillator without radiation reaction, i.e.

$$\dot{w} = -\omega_0^2 x, \quad \dot{w} = -\omega_0^2 \dot{x},$$

and it can be written that

$$\ddot{x} + \gamma \dot{x} + \omega_0^2 x = 0, \quad (30.1)$$

where

$$\gamma = \frac{2}{3} \frac{e^2 \omega_0^2}{mc^3}. \quad (30.2)$$

The expression

$$x \approx x_0 e^{-\frac{1}{2}\gamma t} e^{i\omega_0 t} \quad (30.3)$$

serves as the solution of eq. (30.1) for $\gamma \ll \omega_0$. In this case it is to be understood that in (30.3) and subsequent formulae containing complex expressions one has to take the real part. The solution (30.3) corresponds to the initial conditions

$$x(0) = x_0, \quad \dot{x}(0) = 0.$$

Formula (30.3) shows that, because of the radiation reaction determined by the quantity γ , the oscillations are damped. The damping coefficient $\frac{1}{2}\gamma$ is analogous to the damping coefficient of the mechanical oscillator in the presence of a frictional force. This justifies the second name of the force F_s — the Lorentz friction force.

To find the radiation of a damped oscillator we write its acceleration in the form

$$w = \ddot{x} = A e^{-\frac{1}{2}\gamma t} e^{i\omega_0 t},$$

where A is a constant (in the same approximation ($\gamma \ll \omega_0$), $A \approx -x_0\omega_0^2$).

The acceleration of a damped oscillator is not a periodic function of time. Hence electromagnetic waves emitted by such an oscillator have no definite frequency. On the contrary, all frequencies $0 \leq \omega < \infty$ will be present in the radiation. This means that a damped oscillator emits a continuous spectrum of frequencies.

In what follows we shall be interested in the energy distribution in this spectrum, i.e. in the fraction of the total energy emitted by the oscillator per frequency interval $\omega, \omega + d\omega$. This function $I(\omega)$, called the Lorentz spectral distribution function, is related to the total energy I_0 emitted by the oscillator:

$$I_0 = \int_0^\infty I(\omega) d\omega. \quad (30.4)$$

The total energy emitted by the oscillator is

$$I_0 = \int_0^\infty I dt = \frac{2}{3} \frac{e^2}{c^3} \int_0^\infty w^2 dt = \frac{2}{3} \frac{e^2}{c^3} \int_{-\infty}^\infty w^2 dt \quad (30.5)$$

Here we extend the integration range to the region of negative times, since at $t < 0$ the oscillator was at rest and the integrand is identically equal to zero.

We expand the acceleration in a Fourier integral:

$$w(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} W(\omega) e^{i\omega t} d\omega,$$

where the Fourier component $W(\omega)$ is equal to

$$\begin{aligned} W(\omega) &= \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} w(t) e^{-i\omega t} dt = \frac{1}{\sqrt{2\pi}} \int_0^{\infty} w(t) e^{-i\omega t} dt = \\ &= \frac{A}{\sqrt{2\pi}} \frac{1}{[\frac{1}{2}\gamma - i(\omega_0 - \omega)]}. \end{aligned}$$

According to formula (II.9) we have

$$\int_{-\infty}^{\infty} w^2 dt = \int_{-\infty}^{\infty} |W(\omega)|^2 d\omega = \frac{A^2}{2\pi} \int_{-\infty}^{\infty} \frac{d\omega}{(\omega_0 - \omega)^2 + \frac{1}{4}\gamma^2} = \frac{A^2}{\gamma} \quad (30.6)$$

Substituting formula (30.6) into (30.5), we find

$$I_0 = \frac{1}{3\pi} \frac{e^2}{c^3} A^2 \int_{-\infty}^{\infty} \frac{d\omega}{(\omega_0 - \omega)^2 + \frac{1}{4}\gamma^2} = \frac{2}{3} \frac{e^2}{c^3} \frac{A^2}{\gamma}, \quad (30.7)$$

whence

$$A^2 = \frac{3c^3\gamma}{2e^2} I_0. \quad (30.8)$$

On the other hand, comparing (30.7) and (30.4) and taking into account that the spectral distribution is determined only for essentially positive values of the frequencies, we find

$$I(\omega) = \frac{I_0}{2\pi} \frac{\gamma}{[(\omega_0 - \omega)^2 + \frac{1}{4}\gamma^2]}. \quad (30.9)$$

Fig. 1.11

The spectral distribution functions for different values of $\omega_0/2\gamma$ are shown in fig. 1.11. They have a sharp maximum for $\omega \approx \omega_0$, i.e. for the frequency which would be emitted by the oscillator in the absence of damping,

$$I(\omega_0) = 2I_0/\pi\gamma.$$

For $\omega = \omega_0 \pm \frac{1}{2}\gamma$ the emitted intensity is equal to

$$I(\omega_0 \pm \frac{1}{2}\gamma) = \frac{1}{2}I(\omega_0),$$

i.e. is lower by a factor of two than the intensity in the maximum. For this reason the quantity $\frac{1}{2}\gamma$ is called the half-width of the emitted line. According to (30.2), there corresponds to the line half-width $\frac{1}{2}\gamma$, the wavelength interval

$$\begin{aligned}
 |\Delta\lambda| &= 2\pi \left| \Delta \frac{c}{\omega_0} \right| = \frac{2\pi c \Delta\omega}{\omega_0^2} = \frac{2\pi c}{\omega_0^2} \frac{\gamma}{2} \\
 &= \frac{\pi c}{\omega_0^2} \frac{2}{3} \frac{e^2}{c^3 m} \omega_0^2 = \frac{2\pi}{3} \frac{e^2}{mc^2} = \frac{2\pi}{3} r_0,
 \end{aligned}$$

which does not depend on the wavelength and whose order of magnitude is equal to that of the classical radius of the electron.

§31. Quadrupole and magnetic dipole radiation

We have already seen above that in certain cases a system of charges cannot emit radiation in the dipole approximation. This does not mean, of course, that such a system cannot emit radiation at all.

If there is no radiation in the dipole approximation, one has to look for higher terms of the expansion in powers of the proper retardation in the system, which will determine a radiation of higher order — quadrupole radiation, octupole radiation and so on. We shall restrict ourselves to finding the radiation of the next order beyond the dipole approximation.

We write the vector potential of the emitting system, at a large distance from the system, in a form analogous to (26.5):

$$\begin{aligned}
 \mathbf{A}(\mathbf{r}, t) &= \frac{1}{c} \int \frac{1}{r} \left[\mathbf{j}(\mathbf{r}', \tau_0) + \frac{\mathbf{r}' \cdot \mathbf{r}}{cr} \frac{\partial \mathbf{j}}{\partial \tau_0} \right] dV' = \\
 &= \frac{1}{cr} \int \mathbf{j}(\mathbf{r}', \tau_0) dV' + \frac{1}{c^2 r} \int \frac{\partial \mathbf{j}}{\partial \tau_0} (\mathbf{n} \cdot \mathbf{r}') dV' = \mathbf{A}_1 + \mathbf{A}_2.
 \end{aligned} \tag{31.1}$$

According to (26.9), the first term of (31.1) describes the dipole radiation. Hence we shall be interested only in the second term:

$$\mathbf{A}_2 = \frac{1}{c^2 r} \int \frac{\partial \mathbf{j}(\mathbf{r}', \tau_0)}{\partial \tau_0} (\mathbf{n} \cdot \mathbf{r}') dV' = \frac{1}{c^2 r} \frac{\partial}{\partial \tau_0} \int \mathbf{j}(\mathbf{n} \cdot \mathbf{r}') dV' \tag{31.2}$$

Here we have made use of the fact that the constant vector \mathbf{n} and the integration constant \mathbf{r}' do not depend on time, and we have changed the order of the differentiation and integration. The value of the integral is taken at time τ_0 .

We transform the integrand, symmetrizing it by means of formula (1.6).

We then obtain

$$\begin{aligned} \mathbf{A}_2 = & \frac{1}{2c^2 r} \frac{\partial}{\partial \tau_0} \left\{ \int (\mathbf{r}' \times \mathbf{j}) \times \mathbf{n} dV' \right\} \\ & + \frac{1}{2c^2 r} \frac{\partial}{\partial \tau_0} \int \{ \mathbf{j}(\mathbf{r}' \cdot \mathbf{n}) + \mathbf{r}'(\mathbf{j} \cdot \mathbf{n}) \} dV'. \end{aligned} \quad (31.3)$$

From the definition of the magnetic moment (22.1) it follows that the first integral can be written in the form

$$\frac{1}{2c} \int (\mathbf{r}' \times \mathbf{j}) \times \mathbf{n} dV' = \mathbf{M} \times \mathbf{n}.$$

In order to find the meaning of the second integral, it is convenient to go over from integration to summation *, projecting the vector expression onto a particular axis α in the Cartesian coordinate frame:

$$\begin{aligned} \int \{ \mathbf{j}(\mathbf{r}' \cdot \mathbf{n}) + \mathbf{r}'(\mathbf{j} \cdot \mathbf{n}) \} \alpha dV' &= \sum_i \{ e_i \mathbf{v}_i (\mathbf{r}'_i \cdot \mathbf{n}) + e_i \mathbf{r}'_i (\mathbf{v}_i \cdot \mathbf{n}) \} \alpha = \\ &= \frac{\partial}{\partial \tau_0} \left\{ \sum e \mathbf{r}'_i (\mathbf{r}'_i \cdot \mathbf{n}) \right\} \alpha = \frac{1}{3} \frac{\partial}{\partial \tau_0} \{ D_{\alpha\beta} n_\beta \}, \end{aligned}$$

where $D_{\alpha\beta}$ is the quadrupole moment of the system, determined by formula (16.3). The summation is carried out with respect to the index β ($\beta = x, y, z$). Going over to the vector expression, we can write

* We draw attention to the transition from integration to summation. For a simpler expression it can be written in more detail:

$$\begin{aligned} \int \mathbf{r}' \cdot \frac{\partial \mathbf{j}}{\partial t} dV' &= \frac{\partial}{\partial t} \int \mathbf{r}' \cdot \mathbf{j} dV' = \frac{\partial}{\partial t} \int \mathbf{r}' \cdot \sum e \mathbf{v}_i \delta(\mathbf{r}' - \mathbf{r}_i) dV' = \\ &= \frac{\partial}{\partial t} \sum e_i \mathbf{v}_i \cdot \mathbf{r}_i = \sum e_i \left(\frac{d\mathbf{v}_i}{dt} \cdot \mathbf{r}_i + \mathbf{v}_i \cdot \frac{d\mathbf{r}_i}{dt} \right). \end{aligned}$$

The integration variable \mathbf{r}' is a constant in the differentiation. Only the coordinate of the i th charge \mathbf{r}_i depends on time. Hence the order of the differentiation with respect to t and integration with respect to \mathbf{r}' can be changed. However, after going over to the summation it is necessary to differentiate \mathbf{r}_i .

$$\int \{ \mathbf{j}(\mathbf{r}' \cdot \mathbf{n}) + \mathbf{r}'(\mathbf{j} \cdot \mathbf{n}) \} dV' = \frac{\partial}{\partial \tau_0} \mathbf{D}, \quad (31.4)$$

where the vector \mathbf{D} is defined by

$$D_\alpha = D_{\alpha\beta} n_\beta. \quad (31.5)$$

Then, finally, we find for the vector potential

$$\mathbf{A} = \frac{\dot{\mathbf{d}}}{cr} + \frac{\dot{\mathbf{M}} \times \mathbf{n}}{cr} + \frac{\ddot{\mathbf{D}}}{6c^2 r} = \mathbf{A}_{\text{dip}} + \mathbf{A}_{\text{magn. dip}} + \mathbf{A}_{\text{quadr}}, \quad (31.6)$$

where the dot denotes the differentiation with respect to the argument τ_0 on which the vectors \mathbf{d} , \mathbf{M} and \mathbf{D} depend.

In the expression (31.6) the first term describes dipole radiation. The second term is determined by the derivative with respect to time of the magnetic moment and, naturally, is called magnetic dipole radiation. The last term contains the second derivative of the quadrupole moment. It determines the quadrupole radiation.

We estimate the order of magnitude of the terms of (31.6):

$$\dot{\mathbf{d}} \sim eL'\omega, \quad \dot{\mathbf{M}} \sim \frac{e}{c} vL'\omega \approx \frac{eL'^2\omega^2}{c}, \quad \ddot{\mathbf{D}} \sim eL'^2\omega^2.$$

Hence

$$\frac{|\dot{\mathbf{M}} \times \mathbf{n}|}{|\dot{\mathbf{d}}|} \sim \frac{evL'}{ecL'} \sim \frac{v}{c},$$

$$\frac{1}{c} \frac{|\ddot{\mathbf{D}}_{\alpha\beta} n_\beta|}{|\dot{\mathbf{d}}|} \sim \frac{e\omega^2 L'^2}{ec\omega L'} \sim \frac{L'\omega}{c} \sim \frac{L'}{\lambda},$$

where L' is the characteristic dimension of the system, and λ is the wavelength of the radiation.

Since according to our assumptions $v \ll c$ and $L' \ll \lambda$, the terms corresponding to magnetic dipole radiation and quadrupole radiation are very small in comparison with the first term describing dipole radiation. This means that magnetic dipole radiation and quadrupole radiation are significant only for systems for which the electric dipole radiation is absent. In general it cannot be said which of these two terms then gives the main contribution to the radiation.

We shall calculate separately the intensity of the magnetic dipole radiation and the quadrupole radiation.

According to formulae (27.8) and (27.1), the intensity of the magnetic dipole radiation is

$$\begin{aligned} dI_m &= \frac{c}{4\pi} H^2 r^2 d\Omega = \frac{1}{4\pi c} [\dot{\mathbf{A}} \times \mathbf{n}]^2 r^2 d\Omega = \\ &= \frac{1}{4\pi c^3} [(\ddot{\mathbf{M}} \times \mathbf{n}) \times \mathbf{n}]^2 d\Omega = \frac{1}{4\pi c^3} \ddot{M}^2 \sin^2 \theta d\theta d\psi. \quad (31.7) \end{aligned}$$

The intensity of the magnetic dipole radiation has exactly the same form as the intensity of the electric dipole radiation (27.8), but in (31.7) we have $\ddot{\mathbf{M}}$ instead of $\ddot{\mathbf{d}}$.

The total intensity of the magnetic dipole radiation is obtained by integrating (31.7) over all angles:

$$I_m = \frac{2}{3} \frac{(\ddot{\mathbf{M}})^2}{c^3}. \quad (31.8)$$

The intensity of the magnetic dipole radiation is smaller than that of the electric dipole radiation by the ratio $(v/c)^2$.

It should be stressed that magnetic dipole radiation is absent for systems whose magnetic moment is proportional to the angular momentum. According to what was said in §22, this holds for systems with a constant value of the ratio e/m , and also for systems of two arbitrary particles. Because of this, magnetic dipole radiation is absent in collisions between two particles.

We now go on to the calculation of the intensity of the quadrupole radiation. Substituting the value of $\mathbf{A}_{\text{quadr}}$ into the general formula (27.6) and reproducing the calculations of §27, we find

$$\begin{aligned} dI_{\text{quadr}} &= \frac{c}{4\pi} H^2 r^2 d\Omega = \frac{1}{4\pi c} [\dot{\mathbf{A}}_{\text{quadr}} \times \mathbf{n}]^2 r^2 d\Omega = \\ &= \frac{1}{4\pi c} \frac{1}{36c^4} [\ddot{\mathbf{D}} \times \mathbf{n}]^2 d\Omega. \quad (31.9) \end{aligned}$$

We transform the square of the vector product according to formula (I.5) taking into account the definition (31.5):

$$[\ddot{\mathbf{D}} \times \mathbf{n}]^2 = (\ddot{\mathbf{D}})^2 - (\mathbf{n} \cdot \ddot{\mathbf{D}})^2 = \ddot{D}_{\alpha\beta} \ddot{D}_{\alpha\gamma} n_\beta n_\gamma - \ddot{D}_{\alpha\beta} \ddot{D}_{\lambda\mu} n_\alpha n_\beta n_\lambda n_\mu. \quad (31.10)$$

Summation over repeated indices is implied.

The angular dependence of dI_{quadr} turns out to be very complex. However, the total radiation per unit time can be calculated relatively simply. Integrating (31.9), taking into account (31.10), we obtain

$$I_{\text{quadr}} = \frac{1}{4\pi c} \frac{1}{36c^4} \left\{ \ddot{D}_{\alpha\beta} \ddot{D}_{\alpha\gamma} \int n_\beta n_\gamma d\Omega - \ddot{D}_{\alpha\beta} \ddot{D}_{\lambda\mu} \int n_\alpha n_\beta n_\lambda n_\mu d\Omega \right\} \quad (31.11)$$

The calculation gives:

$$\int n_\beta n_\gamma d\Omega = \frac{4}{3} \pi \delta_{\beta\gamma}, \quad (31.12)$$

$$\int n_\alpha n_\beta n_\lambda n_\mu d\Omega = \frac{4}{15} \pi (\delta_{\alpha\beta} \delta_{\lambda\mu} + \delta_{\alpha\lambda} \delta_{\beta\mu} + \delta_{\alpha\mu} \delta_{\beta\lambda}). \quad (31.13)$$

Hence for I we find

$$\begin{aligned} I_{\text{quadr}} &= \frac{1}{36c^5} \left\{ \frac{1}{3} (\ddot{D}_{\alpha\beta})^2 - \frac{1}{15} (\ddot{D}_{\alpha\alpha} \ddot{D}_{\beta\beta} + 2\ddot{D}_{\alpha\beta}^2) \right\} = \\ &= \frac{1}{180c^5} (\ddot{D}_{\alpha\beta})^2, \end{aligned} \quad (31.14)$$

since, according to (16.6), the sum of the diagonal elements $\ddot{D}_{\alpha\alpha}$ is always equal to zero. When the quadrupole moment varies periodically, the quadrupole radiation turns out to be proportional to ω^6 . The factor $1/c^5$ in (31.14) makes its intensity very small. Nevertheless, there are important examples of systems for which quadrupole radiation plays the basic role. These are, first of all, some atomic nuclei emitting no electric dipole radiation (this is due to the law of conservation of angular momentum; for a justification of this assertion see Part V, §106).

A closed system consisting of particles with the same values of e/m could serve as another example (see eq. (28.11)).

§32*. General case of electromagnetic radiation. The spectral decomposition of fields. The radiation zone and induction zone. Effect of the proper retardation

We shall now consider a somewhat more general case of radiation emitted by a system of moving charges.

Without restricting the general character of the treatment it can be assumed that the current density in the system and the charge density may be expanded in Fourier integrals, so that they can be written

$$\mathbf{j}(\mathbf{r}', t) = \int \mathbf{j}(\mathbf{r}', \omega) e^{i\omega t} d\omega, \quad (32.1)$$

$$\rho(\mathbf{r}', t) = \int \rho(\mathbf{r}', \omega) e^{i\omega t} d\omega. \quad (32.2)$$

In these expansions we make use of the normalization (II.1) and assume formally that the frequency may be negative as well as positive. In reality the frequency ω is a quantity which is essentially positive, so that this representation should be supplemented by the condition $\mathbf{j}(\mathbf{r}', \omega) = \mathbf{j}(\mathbf{r}', -\omega)$. The quantity $\mathbf{j}(\mathbf{r}', t)$ will have a real value. Then, expanding the field potential in a Fourier integral

$$A(\mathbf{r}, t) = \int A(\mathbf{r}, \omega) e^{i\omega t} d\omega, \quad (32.3)$$

and substituting the expansions (32.1)–(32.3) into eq. (23.23) for the vector potential, we find

$$\int A(\mathbf{r}, \omega) e^{i\omega t} d\omega = \frac{1}{c} \int \frac{\mathbf{j}(\mathbf{r}', \omega)}{|\mathbf{r} - \mathbf{r}'|} \exp \left\{ i\omega \left(t - \frac{|\mathbf{r} - \mathbf{r}'|}{c} \right) \right\} d\omega dV$$

Whence, for the Fourier component of the vector potential, we obtain

$$A(\mathbf{r}, \omega) = \frac{1}{c} \int \frac{\mathbf{j}(\mathbf{r}', \omega)}{|\mathbf{r} - \mathbf{r}'|} \exp \left\{ -i \frac{\omega}{c} |\mathbf{r} - \mathbf{r}'| \right\} dV' \quad (32.4)$$

Analogously,

$$\varphi(\mathbf{r}, \omega) = \int \frac{\rho(\mathbf{r}', \omega)}{|\mathbf{r} - \mathbf{r}'|} \exp \left\{ -i \frac{\omega}{c} |\mathbf{r} - \mathbf{r}'| \right\} dV' \quad (32.5)$$

If the current density and charge density are given as functions of coordinates, then from formulae (32.4) and (32.5) one can find the Fourier components

of the field potentials accurately, without disregarding the proper retardation in the system.

Hence the expressions for the potentials themselves can be found directly from the formula (II.2) of the Fourier transform.

Thus, it is in principle possible to find the field of an emitting system without disregarding the proper retardation, and at any distance from the emitting system. Below we shall present a simple example of such a calculation.

If we are interested in the field at large distances from the emitting system, then, assuming

$$|\mathbf{r} - \mathbf{r}'| \approx r - \frac{\mathbf{r} \cdot \mathbf{r}'}{r} = \frac{\mathbf{r}}{r} \cdot (\mathbf{r} - \mathbf{r}'),$$

where $|\mathbf{r}| \gg |\mathbf{r}'|$, and introducing a quantity called the wave vector,

$$\mathbf{k} = \frac{\omega}{c} \frac{\mathbf{r}}{r} = \frac{\omega}{c} \mathbf{n} = k \mathbf{n}, \quad (32.6)$$

where k is the wave number

$$k = \frac{\omega}{c} = \frac{2\pi}{\lambda} \quad (32.7)$$

and \mathbf{n} is a unit vector, we have

$$\mathbf{A}(\mathbf{r}, \omega) = \frac{e^{-ikr}}{cr} \int \mathbf{j}(\mathbf{r}', \omega) e^{i\mathbf{k} \cdot \mathbf{r}'} dV', \quad (32.8)$$

$$\varphi(\mathbf{r}, \omega) = \frac{e^{-ikr}}{r} \int \rho(\mathbf{r}', \omega) e^{i\mathbf{k} \cdot \mathbf{r}'} dV', \quad (32.9)$$

when in the denominator the approximation $|\mathbf{r} - \mathbf{r}'| \approx r$ is made. The formulae of spectral decomposition are often applied to the determination of the field of a single charge. In this case one can obtain a useful representation of $\mathbf{A}(\mathbf{r}, \omega)$ by substituting for the Fourier component of the current density the current density itself according to the formula

$$\mathbf{j}(\mathbf{r}', \omega) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} \mathbf{j}(\mathbf{r}', t) e^{-i\omega t} dt,$$

and assuming

$$\mathbf{j}(\mathbf{r}', t) = e\mathbf{v}\delta(\mathbf{r}' - \mathbf{R}_0(t)) ,$$

where $\mathbf{R}_0(t)$ is the instantaneous position of the charge at time t , and $\mathbf{v} = d\mathbf{R}_0/dt$. This gives

$$\mathbf{A}(\mathbf{r}, \omega) = \frac{e^{-ikr}}{2\pi cr} \int_{-\infty}^{+\infty} e\mathbf{v}(t) e^{-i[\omega t - \mathbf{k} \cdot \mathbf{R}_0(t)]} dt . \quad (32.10)$$

The above formula allows one to find the Fourier components of the vector potential from the trajectory of the particle — the dependence of \mathbf{R}_0 on time. The quantity r represents the absolute value of \mathbf{r} — the distance from the origin to the point of observation at time t . If the Fourier components of the vector potential at a large distance from the system of charges are known, then the Fourier components of the field can be found from formulae (27.1) and (27.3). Namely, we have

$$\begin{aligned} \mathbf{H}(\mathbf{r}, t) &= \int \mathbf{H}(\mathbf{r}, \omega) e^{i\omega t} d\omega = \nabla \times \mathbf{A}(\mathbf{r}, t) = \\ &= \frac{1}{c} \dot{\mathbf{A}} \times \mathbf{n} = \frac{1}{c} \int i\omega [\mathbf{A}(\mathbf{r}, \omega) \times \mathbf{n}] e^{i\omega t} d\omega . \end{aligned}$$

Whence

$$\mathbf{H}(\mathbf{r}, \omega) = i[\mathbf{A}(\mathbf{r}, \omega) \times \mathbf{k}] . \quad (32.11)$$

Analogously,

$$\mathbf{E} = \frac{i}{k} [(\mathbf{A}(\mathbf{r}, \omega) \times \mathbf{k}) \times \mathbf{k}] . \quad (32.12)$$

In general a radiating system emits all possible frequencies or, as is usually said, a frequency spectrum $-\infty < \omega < \infty$.

It is often of interest to find the weight of different frequencies in a spectrum, i.e. the relative fraction of energy for a given frequency (or, more precisely, for a frequency lying in an interval $\omega, \omega + d\omega$). We write the total energy radiated into a solid angle $d\Omega$ in a time dt in the form

$$\Delta E = \int I dt = \frac{c}{4\pi} \int H^2 r^2 d\Omega dt = d\Omega \int J_\omega d\omega dt , \quad (32.13)$$

where $J_\omega d\omega d\Omega$ is the power radiated into a solid angle $d\Omega$ in a frequency interval $d\omega$.

Expanding \mathbf{H} in a Fourier integral and making use of the Parseval equality (II.9), we have

$$\int (H(\mathbf{r}, t))^2 dt = 4\pi \int (H(\mathbf{r}, \omega))^2 d\omega.$$

Then for the power (energy per unit time) of the radiation in a solid angle $d\Omega$ in a frequency interval $d\omega$ we obtain the expression

$$\begin{aligned} J_\omega d\Omega d\omega &= c |\mathbf{H}(\mathbf{r}, \omega)|^2 r^2 d\Omega d\omega = \\ &= \frac{1}{c} \left| [\mathbf{k} \times \int \mathbf{j}(\mathbf{r}', \omega) e^{i\mathbf{k} \cdot \mathbf{r}'} dV'] \right|^2 d\Omega d\omega. \end{aligned} \quad (32.14)$$

The actual spectral distribution of the emitted energy is, naturally, determined by the law of motion of the charges $\mathbf{j}(\mathbf{r}', t)$.

The above formulae are simplified if the current density and charge density vary at a single frequency ω according to the simple harmonic law:

$$\begin{aligned} \mathbf{j}(\mathbf{r}', t) &= \mathbf{j}_0(\mathbf{r}') e^{i\omega t}, \\ \rho(\mathbf{r}', t) &= \rho_0(\mathbf{r}') e^{i\omega t} \end{aligned} \quad (32.15)$$

In this case the system, naturally, emits only one frequency ω , and the vector potential is given using the general formula (24.16) with $d\mathbf{r}' = dV'$

$$\mathbf{A}(\mathbf{r}, t) = \frac{e^{i\omega t}}{c} \int \frac{\mathbf{j}_0(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} \exp \left\{ -i \frac{\omega}{c} |\mathbf{r} - \mathbf{r}'| \right\} dV' = \mathbf{A}_0(\mathbf{r}) e^{i\omega t}, \quad (32.16)$$

where the amplitude of the potential $\mathbf{A}_0(\mathbf{r})$ is, obviously, equal to

$$\mathbf{A}_0(\mathbf{r}) = \frac{1}{c} \int \frac{\mathbf{j}_0(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} \exp \{ -ik |\mathbf{r} - \mathbf{r}'| \} dV'. \quad (32.17)$$

At a large distance from the emitting system,

$$\mathbf{A}(\mathbf{r}, t) \approx \frac{e^{-i(kr - \omega t)}}{cr} \int \mathbf{j}_0(\mathbf{r}') e^{i\mathbf{k} \cdot \mathbf{r}'} dV' \quad (32.18)$$

The quantity $\mathbf{k} \cdot \mathbf{r}'$ obviously determines the retardation inside the system (the proper retardation).

Now consider the case when the proper retardation can be disregarded. For this it is necessary that the inequality

$$\mathbf{k} \cdot \mathbf{r}' \ll 1$$

or

$$L' \ll \lambda \quad (32.19)$$

be satisfied. We see that the condition for disregarding the proper retardation is the smallness of the geometrical dimensions of the emitting system in comparison with the wavelength of the radiation.

Assuming that the condition (32.19) is fulfilled, we have, by virtue of (26.11),

$$\mathbf{A}(\mathbf{r}, t) = \frac{e^{-i(kr - \omega t)}}{cr} \int \mathbf{j}_0(\mathbf{r}') dV' = \frac{\dot{\mathbf{d}}(\tau_0)}{cr}, \quad (32.20)$$

which is in agreement with (26.13).

Let us also find the scalar potential, assuming, however, that the distance to the point of observation is not large in comparison with the wavelength. In order not to repeat the calculations of §26, we write the expression for the scalar potential making use of the Lorentz condition:

$$\begin{aligned} \varphi &= -c \int \nabla \cdot \mathbf{A} dt = -c \nabla \cdot \frac{\dot{\mathbf{d}}(\tau_0)}{cr} = \\ &= \frac{\mathbf{n} \cdot \dot{\mathbf{d}}(\tau_0)}{r} \left(ik + \frac{1}{r} \right). \end{aligned} \quad (32.21)$$

We see that two limiting cases can be realized:

$$\mathbf{k} \cdot \mathbf{r} \sim r/\lambda \gg 1,$$

$$\mathbf{k} \cdot \mathbf{r} \sim r/\lambda \ll 1.$$

In the first case, when the distance from the emitter is large in comparison with its dimensions, we obtain

$$\varphi(\mathbf{r}, t) = ik \frac{\mathbf{n} \cdot \mathbf{d}(\tau_0)}{r}. \quad (32.22)$$

which is in agreement with (26.12). It should be recalled that in formula (32.22) the real part of the corresponding expression is implied, and the factor i plays no role. Thus, in the range

$$r \gg \lambda \gg L'$$

all the formulae of §26 are valid. This is the region of large distances or the radiation zone.

In the range of distances

$$r \ll \lambda \ll L'$$

we can write

$$\varphi(\mathbf{r}, t) \approx \frac{\mathbf{n} \cdot \mathbf{d}(\tau_0)}{r^2} = \frac{\mathbf{n} \cdot \mathbf{d}_0 e^{i\omega\tau_0}}{r^2}. \quad (32.23)$$

In this region, called the neighbouring or induction zone, the scalar potential φ is the same as the potential of a dipole electrostatic field, whose value varies according to a harmonic law. The vector potential \mathbf{A} in this zone is small in comparison with the scalar potential by the ratio r/λ . This means that in the induction zone the field has, basically, the character of the electric field. The strength of the electric field varies in the entire induction zone in phase with the variation of the dipole moment of the system of charges, and the field does not have a wave character.

The magnetic field is smaller than the electric field by the ratio $|\mathbf{H}|/|\mathbf{E}| \approx r/\lambda$ in contrast to the radiation zone, where the relation (27.3) is fulfilled. We see that in emitting long waves ($\lambda \gg L'$) the field of the emitting system has an induction character in the region $r \ll \lambda$, and a wave character for $r \gg \lambda$. The angular distribution of the electric field in the two regions is different. In the induction zone the energy flux averaged over the time, characterized by the Poynting vector, is equal to zero. Thus, the induction zone gives no contribution to the radiation.

We also write the expressions for the fields in monochromatic waves at a large distance from the emitting system:

$$\mathbf{H} = \frac{k^2}{r} \mathbf{n} \times \mathbf{d}_0 e^{i(\omega t - kr)}, \quad (32.24)$$

$$\mathbf{E} = \frac{k^2}{r} (\mathbf{n} \times \mathbf{d}_0) \times \mathbf{n} e^{i(\omega t - kr)}, \quad (32.25)$$

and in the vicinity of the emitting system:

$$\mathbf{E} = \frac{3\mathbf{n}(\mathbf{d}_0 \cdot \mathbf{n}) - \mathbf{d}_0}{r^3} e^{i\omega t}, \quad (32.26)$$

$$\mathbf{H} \cong 0$$

In the radiation zone the Poynting vector is determined by formula (27.6). Hence the emitted power averaged over the time is equal to

$$I = \frac{\omega^4 d_0^2}{3c^3} = \frac{cd_0^2}{3} \left(\frac{2\pi}{\lambda} \right)^4 \quad (32.27)$$

It turns out to be inversely proportional to the fourth power of the wavelength and directly proportional to the square of the amplitude of the dipole moment d_0 . Finally, we shall discuss an example of the calculation of the field of the emitter taking into account the retardation in the system. We consider a system in which the current density is expressed by the formula

$$\mathbf{j}(\mathbf{r}') = j_0 \mathbf{k}_1 \sin\left(\frac{1}{2}kL - k|z|\right) \delta(x) \delta(y) e^{i\omega t} \quad (32.28)$$

Here \mathbf{k}_1 is the unit vector along the z -axis.

Formula (32.28) has a simple meaning. In an infinitely thin line of length L , directed along the z -axis, a current having the character of a standing wave is produced. At the ends of the line at $z = \pm \frac{1}{2}L$ the current density reduces to zero. Such a system is called a linear radiator and is often used for emitting radiowaves.

Substituting (32.28) into (32.18), we obtain for the vector \mathbf{A}

$$\mathbf{A}(\mathbf{r}, t) = j_0 \frac{\mathbf{k}_1}{cr} \int_{-\frac{1}{2}L}^{+\frac{1}{2}L} \sin\left(\frac{1}{2}kL - k|z|\right) e^{ikz \cos \theta} e^{i(\omega t - \mathbf{k} \cdot \mathbf{r})} dz,$$

where $\theta = (\mathbf{n} \cdot \mathbf{k}_1)$. On integrating we obtain

$$\mathbf{A} = \left\{ \mathbf{k}_1 j_0 \frac{kL^2}{4} \frac{e^{i(\omega t - \mathbf{k} \cdot \mathbf{r})}}{cr} \right\} F(\theta, k), \quad (32.29)$$

where the factor $F(\theta, k)$ is equal to

$$F(\theta, k) = \frac{8}{k^2 L^2} \frac{\cos(\frac{1}{2} kL \cos \theta) - \cos \frac{1}{2} kL}{\sin^2 \theta}. \quad (32.30)$$

The factor in the brackets corresponds to the emission of waves whose wavelength is $\lambda \gg \frac{1}{2} L$ (very long waves) and for which the proper retardation can be disregarded. It is obtained directly from (32.20) upon substituting formula (32.28), in which it is assumed that $\frac{1}{2} kL \rightarrow 0$.

The factor $F(\theta, k)$ characterizes the proper retardation in the system. It tends to one as $\frac{1}{2} kL \rightarrow 0$. For a finite value of kL it corresponds to a substantial change in the angular distribution of the radiation.

For $kL = \pi$ (i.e. $L = \frac{1}{2}\lambda$) the angular distribution of the radiation differs relatively little from that of a simple dipole. For $kL = m\pi$, where m is the integer number of half-wavelengths within the length of the linear emitter, there arise distributions within values of θ at which the radiation has a maximum value, the most intense maxima being nearest the polar axis.

With increasing m these intense maxima progressively approach the axis of the emitter. In the limit, as $m \rightarrow \infty$, the radiation turns out to be directed along the axis.

Electromagnetic Field in a Vacuum and Electromagnetic Wave Scattering

§33. The propagation of electromagnetic waves at a large distance from the emitter

In the preceding paragraphs the phenomenon of emission of electromagnetic waves has been studied. We can now analyse the mechanism of propagation of electromagnetic waves in a space free of charges (in vacuum).

We have seen in the preceding chapter that radiating systems emit electromagnetic waves for which the equal-phase surfaces are spheres of radius r .

We now pass over in formulae (32.24) and (32.25) to the limit, assuming the distance from the system of charges to be so large that one may disregard the difference in the direction of the vector \mathbf{r}_0 and \mathbf{n} , where \mathbf{r}_0 is the unit vector directed from the origin to the point of observation, and \mathbf{n} is, as before, the unit vector directed from the emitter to the observation point.

We can then write

$$r = \mathbf{r} \cdot \mathbf{r}_0 \approx \mathbf{r} \cdot \mathbf{n}$$

and make this substitution in the phase factor, after which formulae (32.24) and (32.25) will take the form

$$\mathbf{H} = \frac{\omega^2}{c^2} \frac{1}{r} \mathbf{n} \times \mathbf{d}_0 \exp i\omega \left(t - \frac{\mathbf{r} \cdot \mathbf{n}}{c} \right), \quad (33.1)$$

$$\mathbf{E} = \frac{\omega^2}{c^2} \frac{1}{r} (\mathbf{n} \times \mathbf{d}_0) \times \mathbf{n} \exp i\omega \left(t - \frac{\mathbf{r} \cdot \mathbf{n}}{c} \right). \quad (33.2)$$

In formulae (33.1) and (33.2) the distance from the point of observation to the origin enters in the amplitude in the form of the factor $1/r$. However, it is clear that at an infinitely large distance from the origin the variation of the function $1/r$ can be assumed to be very slow and we can set $1/r \approx \text{const}$. In this case the variation of the fields with distance is determined solely by the phase factor. Then (33.1) and (33.2) can be written in the form

$$\mathbf{E} = \mathbf{E}_0 \exp i\omega \left(t - \frac{\mathbf{r} \cdot \mathbf{n}}{c} \right), \quad (33.3)$$

$$\mathbf{H} = \mathbf{H}_0 \exp i\omega \left(t - \frac{\mathbf{r} \cdot \mathbf{n}}{c} \right), \quad (33.4)$$

where \mathbf{E}_0 and \mathbf{H}_0 are quantities which are constant in space and time.

We introduce the vector $\mathbf{k} = \omega \mathbf{n}/c$, called the wave vector. In absolute value $k = \omega/c = 2\pi/\lambda$, where λ is the wavelength, and is oriented in the direction of propagation of the electromagnetic wave. Then

$$\mathbf{E} = \mathbf{E}_0 e^{i(\omega t - \mathbf{k} \cdot \mathbf{r})}, \quad (33.5)$$

$$\mathbf{H} = \mathbf{H}_0 e^{i(\omega t - \mathbf{k} \cdot \mathbf{r})}. \quad (33.6)$$

In formulae (33.5) and (33.6) it is implied that in the final expressions the real part is to be taken. According to (27.3), the amplitudes \mathbf{E}_0 and \mathbf{H}_0 are perpendicular to each other and to the vector \mathbf{k} :

$$\mathbf{E}_0 = \mathbf{H}_0 \times \mathbf{n}. \quad (33.7)$$

The vectors \mathbf{E} and \mathbf{H} represent plane monochromatic waves: the planes $\mathbf{k} \cdot \mathbf{r} = \text{const}$ are equal-phase surfaces (surfaces of equal values of the strengths \mathbf{E} and \mathbf{H}) (fig. I.12).

Thus, we arrive at a natural result. At sufficiently large distances from the emitter spherical waves approximate to plane waves. This can be pictured in an obvious way as follows. If the emitting system is sufficiently distant, the radius of curvature of the spherical equal-phase surface of the electromagnetic wave is very large in comparison with the dimensions of that region of space in which the field is considered. Hence in the limits of this region the sphere can be assumed with a sufficient degree of accuracy to be a flat surface.

Fig. I.12

If the direction of propagation is chosen to be the x -axis, then formulae (33.5) and (33.6) can be written in the form

$$\mathbf{E} = \mathbf{E}_0 e^{i(\omega t - kx)}, \quad (33.8)$$

$$\mathbf{H} = \mathbf{H}_0 e^{i(\omega t - kx)}. \quad (33.9)$$

Formulae (33.7)–(33.9) describe plane waves propagating in the positive direction of the x -axis with a velocity

$$v = \omega/k = c. \quad (33.10)$$

Clearly at time $(t + 1)$ the phase factor at point $(x + c)$ has the same value as it had at time t at point x . Thus, v represents the velocity of propagation of the equal-phase surface and for this reason it is called the phase velocity.

The propagation of plane waves, in contrast to spherical waves, is not accompanied by a decrease in their amplitude.

We calculate the Poynting vector in a plane wave:

$$\boldsymbol{\sigma} = \frac{c}{4\pi} \mathbf{E} \times \mathbf{H} = \frac{c}{4\pi} (\mathbf{H} \times \mathbf{n}) \times \mathbf{H} = nc \frac{H^2}{4\pi} = nc \frac{E^2 + H^2}{8\pi} = nc u_0 \quad (33.11)$$

It turns out to be constant and equal to the energy flux moving with the velocity of light. The momentum of a plane electromagnetic wave is equal to

$$\mathbf{g} = \sigma/c^2 = \mathbf{n}u_0/c. \quad (33.12)$$

The expressions we have found for the field in a plane wave can also be obtained directly from the solution of the field equations in a region of space free of charges.

Since the charge density and current density in the part of space considered are equal to zero, the equations for the electromagnetic field potentials assume the following form:

$$\nabla^2 \mathbf{A} - \frac{1}{c^2} \frac{\partial^2 \mathbf{A}}{\partial t^2} = 0,$$

$$\nabla^2 \varphi - \frac{1}{c^2} \frac{\partial^2 \varphi}{\partial t^2} = 0,$$

$$\nabla \cdot \mathbf{A} + \frac{1}{c} \frac{\partial \varphi}{\partial t} = 0.$$

For simplicity we consider first the case where the field potentials depend only on the x coordinate, so that the equations for the potentials have the form

$$\frac{\partial^2 \mathbf{A}(x, t)}{\partial x^2} - \frac{1}{c^2} \frac{\partial^2 \mathbf{A}(x, t)}{\partial t^2} = 0, \quad (33.13)$$

$$\frac{\partial^2 \varphi(x, t)}{\partial x^2} - \frac{1}{c^2} \frac{\partial^2 \varphi}{\partial t^2} = 0, \quad (33.14)$$

$$\frac{\partial \mathbf{A}_x(x, t)}{\partial x} + \frac{1}{c} \frac{\partial \varphi}{\partial t} = 0. \quad (33.15)$$

Moreover, we assume that the field depends on time according to a simple harmonic law. We then look for the solutions of eqs. (33.13)–(33.15) in the form

$$\mathbf{A}(x, t) = \mathbf{A}_0(x) e^{i\omega t}, \quad (33.16)$$

$$\varphi(x, t) = \varphi_0(x) e^{i\omega t}. \quad (33.17)$$

The substitution of (33.16) and (33.17) into (33.13) and (33.14) gives for \mathbf{A}_0 and φ_0

$$\frac{d^2 A_0(x)}{dx^2} + \frac{\omega^2}{c^2} A_0 = 0,$$

$$\frac{d^2 \varphi_0(x)}{dx^2} + \frac{\omega^2}{c^2} \varphi_0 = 0.$$

Whence

$$A_0 = l e^{-ikx} + l' e^{+ikx},$$

$$\varphi_0 = \alpha e^{-ikx} + \alpha' e^{+ikx},$$

where $k = \omega/c$, and l, l', α, α' are constants. In this case we find for the potentials

$$A(x, t) = l e^{i(\omega t - kx)} + l' e^{i(\omega t + kx)}, \quad (33.18)$$

$$\varphi = \alpha e^{i(\omega t - kx)} + \alpha' e^{i(\omega t + kx)}. \quad (33.19)$$

The first terms in (33.18) and (33.19) represent a monochromatic plane wave propagating in the positive direction of the x -axis, while the second terms represent the same wave propagating in the negative direction of the x -axis. Which one of these waves is actually excited depends on the arrangement of the emitting system. Without restricting the general character of the treatment one can consider one of these waves, for example the first one.

The amplitudes l and α are not arbitrary, but are related by the Lorentz condition (33.15), which by substitution of (33.18) and (33.19) into it gives

$$\alpha = l_x$$

The field potentials are then written finally in the form

$$A = l e^{i(\omega t - kx)} = l e^{i\psi}, \quad (33.20)$$

$$\varphi = l_x e^{i(\omega t - kx)} = \mathbf{A} \cdot \mathbf{i} = l \cdot \mathbf{i} e^{i\psi}, \quad (33.21)$$

where \mathbf{i} is the unit vector along the x -axis, and $\psi = \omega t - kx$.

The field strengths in the plane wave have the form

$$\begin{aligned}
 \mathbf{E} &= -\frac{1}{c} \frac{\partial \mathbf{A}}{\partial t} - \nabla \varphi = -\frac{1}{c} \frac{\partial \mathbf{A}}{\partial \psi} \frac{\partial \psi}{\partial t} - \frac{\partial \varphi}{\partial \psi} \nabla \psi = \\
 &= -\frac{\omega}{c} \dot{\mathbf{A}} - \dot{\varphi} \nabla \psi = -k \dot{\mathbf{A}} + k \dot{\varphi} \mathbf{i} = k \{ \mathbf{i} (\dot{\mathbf{A}} \cdot \mathbf{i}) - \dot{\mathbf{A}} \} = \\
 &= k (\mathbf{A} \times \mathbf{i}) \times \mathbf{i} = \mathbf{E}_0 e^{i\psi} = \mathbf{E}_0 e^{i(\omega t - kx)}, \quad (33.22)
 \end{aligned}$$

$$\mathbf{H} = \nabla \times \mathbf{A} = (\nabla \psi) \times \dot{\mathbf{A}} = k \dot{\mathbf{A}} \times \mathbf{i} = \mathbf{H}_0 e^{i(\omega t - kx)}, \quad (33.23)$$

where differentiation with respect to the argument ψ is denoted by a dot, and \mathbf{E}_0 and \mathbf{H}_0 are the amplitudes of the field strengths whose moduli are obviously $|\mathbf{E}_0| = |\mathbf{H}_0| = k|1|$. The vectors \mathbf{E}_0 and \mathbf{H}_0 are perpendicular to each other.

We write the expressions for the field components:

$$\begin{aligned}
 E_x &= 0, & H_x &= 0, \\
 E_y &= -k \dot{A}_y = H_z, & H_y &= k \dot{A}_z = -E_z, \\
 E_z &= -k \dot{A}_z = -H_y; & H_z &= -k \dot{A}_y = E_y.
 \end{aligned} \quad (33.24)$$

In these formulae, as well as in the preceding ones, the real part of the complex expressions written for the potentials and fields is implied.

In the general case, when the direction of propagation of waves does not coincide with the x -axis, the unit vector \mathbf{i} should be replaced by the unit vector in the direction of propagation \mathbf{n} (fig. 1.12), and the relations (33.22) and (33.23) are the same as (33.5) and (33.6). The values of the wave amplitudes $|\mathbf{E}_0| = |\mathbf{H}_0|$ remain completely arbitrary. They are connected with the amplitude of the waves radiated by the emitter.

It is useful to compare the expressions which we have obtained with analogous formulae obtained for another potential gauge, which is often used in the literature*.

As we have seen in § 11, field potentials allow the gauge transformation (11.1) and (11.2). We perform the transition from φ to the new value φ' ,

$$\varphi' = \varphi - \frac{1}{c} \frac{\partial \psi}{\partial t},$$

* L. D. Landau and E. M. Lifshitz, *The classical theory of fields* (Pergamon Press, London, 1962).

and choose the function $\psi = c \int \varphi dt$. Then $\varphi' = 0$, i.e. in the representation considered the field is described only by the vector potential $A'(x, t) = A + \nabla \psi$. Such a choice of ψ is not always possible but can only be made in vacuum, when $\rho = 0$ and the equation for φ allows a zero solution.

The Lorentz condition is then written in the form

$$\frac{\partial A_x}{\partial x} = 0, \quad \text{i.e.} \quad A_x = 0.$$

The solution $A_x = \text{const} \neq 0$ does not differ from $A_x = 0$, since it leads to the same values of field strengths. It is easy to see that for such a gauge we again obtain for the field components the values (33.24).

If the wave process does not have a simple periodic character, i.e. is not described by a monochromatic wave, one can easily obtain the general form of solution of the equation for the potentials φ and A . The solution is obtained in a way analogous to that in §23.

Introducing the new variables

$$\xi = x - ct, \quad \eta = x + ct,$$

we reduce the equations for the potentials to the form

$$\frac{\partial^2 A}{\partial \xi \partial \eta} = 0, \quad \frac{\partial^2 \varphi}{\partial \xi \partial \eta} = 0.$$

As the solution of the equation for the vector potential we can write

$$A = A(ct - x) + A'(ct + x),$$

where A and A' are arbitrary functions of the arguments $ct - x$ and $ct + x$, respectively. The first of these represents a general expression for a plane wave propagating with velocity c in the positive direction of the x -axis. The second one represents a wave propagating in the negative direction of the x -axis. An analogous expression is also obtained for the scalar potential.

The Lorentz condition leads to the equality

$$\varphi = A_x = A \cdot i,$$

which is valid for an arbitrary form of the functions A and φ .

Finally, it should be noted that in a vacuum one can obtain wave equations for the field vectors \mathbf{E} and \mathbf{H} directly. For this one has to take the curl of the Maxwell equation

$$\nabla \times (\nabla \times \mathbf{H}) = \nabla (\nabla \cdot \mathbf{H}) - \nabla^2 \mathbf{H} = -\nabla^2 \mathbf{H} = \frac{1}{c} \nabla \times \frac{\partial \mathbf{E}}{\partial t},$$

so that

$$\nabla^2 \mathbf{H} - \frac{1}{c^2} \frac{\partial^2 \mathbf{H}}{\partial t^2} = 0.$$

The wave equation for \mathbf{E} can be obtained analogously.

§ 34. Plane wave polarization

Let us consider in somewhat more detail how the changes in the field vectors of a plane monochromatic wave take place. To do this we pass over from the complex to real expressions.

In formula (33.22) we write the complex amplitude \mathbf{E}_0 in the form

$$\mathbf{E}_0 = \mathbf{g}_1 + i\mathbf{g}_2,$$

where \mathbf{g}_1 and \mathbf{g}_2 are real vectors. We then have

$$\begin{aligned} \mathbf{E} &= \text{Re} \{ (\mathbf{g}_1 + i\mathbf{g}_2) [\cos(\omega t - \mathbf{k} \cdot \mathbf{r}) + i \sin(\omega t - \mathbf{k} \cdot \mathbf{r})] \} = \\ &= \text{Re} \{ [\mathbf{g}_1 \cos(\omega t - \mathbf{k} \cdot \mathbf{r}) - \mathbf{g}_2 \sin(\omega t - \mathbf{k} \cdot \mathbf{r})] + \\ &\quad + i[\mathbf{g}_1 \sin(\omega t - \mathbf{k} \cdot \mathbf{r}) + \mathbf{g}_2 \cos(\omega t - \mathbf{k} \cdot \mathbf{r})] \} = \\ &= \mathbf{g}_1 \cos(\omega t - \mathbf{k} \cdot \mathbf{r}) - \mathbf{g}_2 \sin(\omega t - \mathbf{k} \cdot \mathbf{r}). \end{aligned} \quad (34.1)$$

We now transform from the vectors \mathbf{g}_1 and \mathbf{g}_2 , orientated at an arbitrary angle to each other, to mutually perpendicular vectors \mathbf{E}_1 and \mathbf{E}_2 (fig. I.13). Let

$$\mathbf{E}_1 = \mathbf{g}_1 \cos \alpha + \mathbf{g}_2 \sin \alpha, \quad (34.2)$$

$$\mathbf{E}_2 = \mathbf{g}_1 \sin \alpha - \mathbf{g}_2 \cos \alpha, \quad (34.3)$$

Fig. 1.13

where α is an unknown angle which is to be found. Taking the scalar product of the expressions (34.2) and (34.3), we find

$$\mathbf{E}_1 \cdot \mathbf{E}_2 = 0 = (g_1^2 - g_2^2) \sin \alpha \cos \alpha - \mathbf{g}_1 \cdot \mathbf{g}_2 (\cos^2 \alpha - \sin^2 \alpha),$$

whence

$$\tan 2\alpha = \frac{2\mathbf{g}_1 \cdot \mathbf{g}_2}{g_1^2 - g_2^2}$$

Writing

$$\mathbf{g}_1 = \mathbf{E}_1 \cos \alpha + \mathbf{E}_2 \sin \alpha,$$

$$\mathbf{g}_2 = \mathbf{E}_1 \sin \alpha - \mathbf{E}_2 \cos \alpha,$$

and substituting into (34.1), we find

$$\mathbf{E} = \mathbf{E}_1 \cos(\omega t - \mathbf{k} \cdot \mathbf{r} + \alpha) + \mathbf{E}_2 \sin(\omega t - \mathbf{k} \cdot \mathbf{r} + \alpha).$$

Let the x -axis be chosen as the direction of propagation of the waves. If the vector \mathbf{E}_1 is taken in the y -direction then the vector \mathbf{E}_2 will be in the z -direction (in the positive or negative sense). Then

$$E_y = E_1 \cos(\omega t - kx + \alpha), \quad (34.4)$$

$$E_z = E_2 \sin(\omega t - kx + \alpha). \quad (34.5)$$

The quantities E_1 and E_2 are called amplitudes, while the quantity $\psi = \omega t - kx + \alpha$ is called the phase of the wave.

From formulae (34.4) and (34.5) it is easy to eliminate the phase by writing

$$\frac{E_y^2}{E_1^2} + \frac{E_z^2}{E_2^2} = 1. \quad (34.6)$$

The expression (34.6) relates the values of the components of the vector \mathbf{E} in the plane wave. It is obvious that in a given plane $x = \text{const}$, the vector \mathbf{E} rotates in the (yz) plane in such a way that its end describes an ellipse (fig. I.14).

Fig. I.14

Formula (34.6) represents the equation of this ellipse. If, in particular, the amplitudes E_1 and E_2 are equal in absolute value, the vector \mathbf{E} rotates on a circle.

Since the propagation of the electromagnetic wave takes place in the direction \mathbf{n} , one can picture the change of the vector \mathbf{E} in space and time in an obvious way as the motion of its end on an elliptical (or circular) helix drawn about the line \mathbf{n} . The pitch of the helix is equal to the wavelength $\lambda = 2\pi/k$.

By virtue of eqs. (33.24) the following expressions can be written for the components of the magnetic field strength:

$$H_y = -E_2 \sin(\omega t - kx + \alpha), \quad (34.7)$$

$$H_z = E_1 \cos(\omega t - kx + \alpha). \quad (34.8)$$

Waves in which the vectors \mathbf{E} and \mathbf{H} rotate on an ellipse are called elliptically polarized, and those in which the vectors rotate on a circle are called circularly polarized.

The direction of rotation of the vector \mathbf{E} is determined by the phase α . If the rotation is clockwise for the observed looking in the direction of propagation of the wave, then such a wave is said to have left-handed polarization or positive helicity (so for example for $\alpha = \pm \frac{1}{2}\pi$ provided that \mathbf{g}_1 and \mathbf{g}_2 are directed along the positive axes).

If one of the vectors \mathbf{E}_1 or \mathbf{E}_2 is equal to zero, the change of \mathbf{E} and \mathbf{H} takes place in mutually perpendicular directions. Such waves are called plane polarized waves. According to historical tradition, the direction in which the vector \mathbf{H} oscillates is called the polarization direction. Thus, for example, a wave polarized in the z -direction has a component H_z different from zero, and a component E_y of the same magnitude, oscillating in the y -direction.

§35. Interference and the formation of wave packets

The monochromatic plane wave considered above appears to be only an idealization of real electromagnetic waves. On the one hand, the monochromatic plane wave, which is a process strictly periodic in space and time, should obviously have an infinitely large extension in space and an infinitely long duration. On the other hand, there are no strictly monochromatic emitters. As we have seen in §30, the effect of damping shows itself in the emission of frequencies differing from the natural frequency ω_0 (even if close to it). Hence to describe real wave processes it is necessary to consider the result of superposition and interference of different monochromatic plane waves.

Let us consider the superposition of an infinitely large number of monochromatic plane waves whose frequencies are continuously distributed in a narrow interval $\omega_0 - \Delta\omega \leq \omega \leq \omega_0 + \Delta\omega$, where ω_0 , called the carrier frequency, satisfies the condition $\omega_0 \gg \Delta\omega$.

We consider the amplitude of all the waves to be constant. For the strength of the electric (or magnetic) field we can write

$$\mathbf{E} = \int_{\omega_0 - \Delta\omega}^{\omega_0 + \Delta\omega} \mathbf{E}_0 e^{i(\omega t - kx)} d\omega = \mathbf{E}_0 \int_{\omega_0 - \Delta\omega}^{\omega_0 + \Delta\omega} e^{i(\omega t - kx)} d\omega.$$

For the general character of the results, which we shall need later, we assume that the wave number k is a function of the frequency ω not necessarily corresponding to the relation $k = \omega/c$ valid for electromagnetic waves in vacuum.

Setting

$$\omega = \omega_0 + (\omega - \omega_0),$$

$$k \approx k_0 + \left(\frac{dk}{d\omega}\right)_{\omega=\omega_0} (\omega - \omega_0) \equiv k_0 + \left(\frac{dk}{d\omega}\right)_0 (\omega - \omega_0),$$

we find

$$\begin{aligned} E &= E_0 \int_{\omega_0 - \Delta\omega}^{\omega_0 + \Delta\omega} e^{i(\omega_0 t - k_0 x)} \exp i(\omega - \omega_0) \left[t - \left(\frac{dk}{d\omega}\right)_0 x \right] d\omega = \\ &= E_0 e^{i(\omega_0 t - k_0 x)} \int_{-\Delta\omega}^{\Delta\omega} \exp iu \left[t - \left(\frac{dk}{d\omega}\right)_0 x \right] du = \\ &= 2E_0 \frac{\sin \Delta\omega \left[t - \left(\frac{dk}{d\omega}\right)_0 x \right]}{t - \left(\frac{dk}{d\omega}\right)_0 x} e^{i(\omega_0 t - k_0 x)} \end{aligned} \quad (35.1)$$

where the integration variable $u = \omega - \omega_0$ is introduced. We arrive in principle at the following result: the superposition of waves with a spectrum with frequencies lying in a narrow interval $2\Delta\omega$ about the carrier frequency ω_0 leads to the appearance of a wave with frequency ω_0 and wave number k_0 but with a modulated amplitude

$$A = \frac{2E_0 \sin \{ \Delta\omega / v_g (x - v_g t) \}}{v_g^{-1} (x - v_g t)}, \quad (35.2)$$

$$v_g = \left(\frac{d\omega}{dk} \right)_0. \quad (35.3)$$

The modulated amplitude has a very sharp principal maximum (fig. 1.15 where the dependence of A on $\frac{1}{2} (\Delta\omega / v_g)(x - v_g t)$ is given) at the point

$$x_m = v_g t,$$

where it is equal to

$$A_{\max} = 2\Delta\omega E_0.$$

Fig. 1.15

In both directions away from the position of the maximum the value of the modulated amplitude decreases, and at points where

$$\frac{\Delta\omega}{v_g} (x - v_g t) = \pm \pi$$

the modulated amplitude reduces to zero. In addition to the principal maximum, the modulated amplitude has a number of subsidiary maxima in which, however, the amplitudes are very small in comparison with that in the principal maximum, and the heights of which decrease rapidly with increasing argument (see fig. 1.15). In practice, it can be assumed that the electromagnetic field is excited only near the principal maximum, while elsewhere in space the superposition of the waves leads to their complete mutual cancellation.

The group of waves form a wave packet. The wave packet moves in space with a velocity v_g , maintaining a limited extension in space. Hence the quantity v_g is called the group velocity of motion of the packet, as distinct from the phase velocity

$$v = \frac{\omega}{2\pi} \lambda ,$$

with which the equal-phase surface of a single monochromatic wave moves in space. It is obvious that the energy of the wave packet travels with its amplitude, i.e. with a velocity v_g . The dimensions of the wave packet are determined by the relation

$$\Delta\omega \left[t - \left(\frac{dk}{d\omega} \right)_0 x \right] \approx 2\pi . \quad (35.4)$$

For a more obvious explanation of the meaning of the equality (35.4) let us find the spatial dimensions of the packet. At a fixed moment t the field differs from zero between the points x_1 and x_2 which are a distance

$$x_1 - x_2 = \Delta x = \frac{2\pi}{\Delta\omega(dk/d\omega)_0} = \frac{2\pi}{\Delta k} \quad (35.5)$$

apart. Outside this region the field has a value close to zero.

If now a certain location $x = \text{const}$ is considered, then the duration of the time interval during which the field of the wave packet differs from zero is equal to

$$\Delta t \approx 2\pi/\Delta\omega. \quad (35.6)$$

After the lapse of time Δt the field will reduce to zero at the given location.

Thus, the wave packet has a limited spatial extension and duration, satisfying the conditions

$$\Delta t \Delta\omega \approx 2\pi, \quad \Delta x \Delta k \approx 2\pi. \quad (35.7)$$

Now the statement of the problem can be modified. Suppose we want to obtain a wave field different from zero in a certain region of space Δx . To obtain such a field from monochromatic waves it is necessary to form a wave packet.

If the dimensions of the packet are given by our condition, then according to (35.7) the superposition of monochromatic waves with wave numbers lying in an interval Δk must be carried out. The narrower the wave packet, i.e. the smaller its spatial dimensions, the larger Δk , i.e. the larger the interval of the wavelengths which must take part in the formation of the packet.

A wave packet existing for a limited time at a certain location can be considered in a completely analogous way. The shorter the required duration Δt of the packet, the larger the frequency interval $\Delta\omega$ of those monochromatic waves which must form it.

The relations found for waves propagating along the x -axis can easily be generalized to the case of waves propagating in an arbitrary direction in space. One then obtains the relations

$$\Delta x \Delta k_x \approx 2\pi, \quad \Delta y \Delta k_y \approx 2\pi, \quad \Delta z \Delta k_z \approx 2\pi, \quad \Delta t \Delta\omega \approx 2\pi. \quad (35.8)$$

The results obtained are of a great theoretical and practical significance.

A monochromatic wave completely homogeneous and infinitely extended in space and time, cannot, as was pointed out before, be realized in practice. However, by making use of an emitter with sufficiently weak damping, radiating for a sufficiently long time, one can produce in space waves whose properties are sufficiently close to those of monochromatic waves. It is clear that monochromatic waves of infinite extent cannot be used for the transmission of signals.

We understand by signals electromagnetic perturbations which in principle can be detected by means of suitable devices and which can provide information about physical events. Thus, for example, the fact of emission of radiation, beginning at a certain instant of time, is a signal. The detection of a system of charges producing the scattering of electromagnetic waves is another example of a signal.

From the above it is clear that electromagnetic waves can be used for producing signals only in the case where wave packets are formed by them. The relations (35.8) are used for the analysis of the properties required of the signal. Let, for example, a recording device need for its operation a signal whose duration is not shorter than a certain value Δt . Then the signal will be recorded only in the case where it represents a wave packet formed of monochromatic waves with frequencies distributed within an interval $\Delta\omega \geq 2\pi/\Delta t$.

We shall not dwell on other examples of the application of the relations (35.8). They play an important role in quantum mechanics.

In conclusion we stress that the expression which we obtained for the wave packet is only of an approximate character. It is valid if:

- 1) the amplitudes of all monochromatic waves forming the packet have one and the same value;
- 2) in the expansion of $k(\omega)$ in a series in $\Delta\omega$ one can restrict oneself to the first term.

The first restriction has no great significance, and finding wave packets formed by waves with different amplitudes does not present any particular difficulty.

The second requirement is fulfilled automatically for electromagnetic waves in a vacuum:

$$k = \frac{\omega}{c} = \frac{\omega_0}{c} + \frac{\Delta\omega}{c} = k_0 + \frac{1}{c} \Delta\omega.$$

However, as we shall see in quantum mechanics, in cases where the requirement 2) is not fulfilled, important consequences follow from taking into account further terms of the expansion: the form of the packet, which, in

the first approximation, is constant in time and space, turns out to be variable when further terms are taken into account. The wave packet progressively deforms and diffuses.

§ 36. Scattering of the electromagnetic waves by a free charge and by a bound electron

Let us now consider the effects arising when an electromagnetic wave is incident on a system of charged particles.

The electromagnetic field of the wave acts on the particles of the system with the Lorentz force

$$\mathbf{F} = e \left(\mathbf{E} + \frac{\mathbf{v} \times \mathbf{H}}{c} \right) \approx e\mathbf{E}.$$

Since in the electromagnetic wave $|\mathbf{H}| = |\mathbf{E}|$, the magnetic part of the Lorentz force is smaller than the electric part by the ratio v/c . Each particle of the system acquires an acceleration $\mathbf{w} = \mathbf{F}/m$, and becomes in its turn an emitter. Since each particle emits spherical electromagnetic waves, the direction of emission of these waves is not dependent upon the direction of propagation of the incident wave. Hence it is said that the initial wave is scattered. The frequencies of the emitted waves are the same as that of the incident wave. The scattering taking place without a change in the frequency is called coherent scattering. In addition to coherent scattering, in some cases there may occur scattering with a change in frequency — incoherent scattering (see Part V).

The scattering of electromagnetic waves by a bound charge can be considered as an example of the linear harmonic oscillator. Let a plane polarized, monochromatic plane wave be incident on the oscillator. The equation of motion will have the form

$$\ddot{\mathbf{r}} + \omega_0^2 \mathbf{r} = \frac{2}{3} \frac{e^2}{mc^3} \ddot{\mathbf{r}} + \frac{e\mathbf{E}_0 e^{i\omega t}}{m}$$

Assuming the damping to be weak, we can write $\ddot{\mathbf{r}} \approx -\omega_0^2 \dot{\mathbf{r}}$, so that

$$\ddot{\mathbf{r}} + \omega_0^2 \mathbf{r} + \gamma \dot{\mathbf{r}} = \frac{e}{m} \mathbf{E}_0 e^{i\omega t}, \quad (36.1)$$

where γ , as in §30, is equal to $\frac{2}{3} e^2 \omega_0^2 / mc^3$. The particular solution of eq. (36.1) which interests us is

$$\mathbf{r} = \frac{(e/m) E_0 e^{i\omega t}}{\omega_0^2 - \omega^2 + i\omega\gamma}. \quad (36.2)$$

Formula (36.2) describes the motion of the oscillator under the action of an external force.

For the power of the radiation scattered into a solid angle $d\Omega$ we find, according to formula (27.8),

$$\begin{aligned} dI &= \frac{e^2}{4\pi c^3} [\ddot{\mathbf{r}} \times \mathbf{n}]^2 d\Omega = \\ &= \frac{e^4 \omega^4 E_0^2}{4\pi m^2 c^3} \times \frac{\sin^2 \vartheta}{(\omega_0^2 - \omega^2)^2 + \omega^2 \gamma^2} \cos^2(\omega t - \delta) d\Omega. \end{aligned} \quad (36.3)$$

The scattered radiation has the same frequency as the incident radiation, but is shifted in phase by an amount

$$\delta = \arctan \frac{\gamma\omega}{\omega_0^2 - \omega^2}.$$

Introducing the incident intensity $\bar{I}_0 = cE_0^2/8\pi$ and averaging over the period $T = 2\pi/\omega$, we find

$$\overline{dI} = \frac{1}{T} \int_0^T dI dt = r_0^2 \bar{I}_0 \frac{\omega^4 \sin^2 \vartheta d\Omega}{(\omega_0^2 - \omega^2)^2 + \omega^2 \gamma^2}, \quad (36.4)$$

where r_0 is the classical electron radius (29.6). Here ϑ stands for the angle between the direction of observation \mathbf{n} and the direction of the vector of polarization \mathbf{E}_0 (fig. 1.16).

The process of scattering of electromagnetic waves is characterized by the differential cross section. By definition the differential cross section for scattering into a solid angle $d\Omega$ is the ratio of the intensity of the radiation scattered into the angle $d\Omega$ to the intensity of the incident radiation:

$$d\sigma = \frac{\overline{dI}}{\bar{I}_0}. \quad (36.5)$$

Fig. I.16

From (36.4) we find for the differential scattering cross section

$$d\sigma = \frac{r_0^2 \omega^4 \sin^2 \vartheta}{(\omega_0^2 - \omega^2)^2 + \omega^2 \gamma^2} d\Omega. \quad (36.6)$$

As is seen from formula (36.5) the differential scattering cross section has the dimensions of cm^2 (it is this which accounts for the term “cross section”). Formula (36.5) gives the cross section for the scattering of plane polarized light. The angle ϑ and the polar angles θ and ψ are mutually connected by a relation which is easily established from fig. I.16. In this drawing the polar axis z is directed along the wave vector \mathbf{k} of the incident wave, while the axis x is directed along its vector of polarization. Projecting the unit vector in the direction of observation \mathbf{n} onto the axis x , we find

$$\cos \vartheta = \sin \theta \cos \psi,$$

or

$$\sin^2 \vartheta = 1 - \sin^2 \theta \cos^2 \psi. \quad (36.7)$$

In practice it is often important to know the scattering cross section for unpolarized radiation. In order to find it, it is necessary to average the cross section (36.5) over all possible polarizations, i.e. over all possible orientations of the vector \mathbf{E}_0 in the plane (xy) . This means that it is necessary to average the expression (36.7) over all possible values of the azimuthal angle ψ , i.e. to assume

$$\sin^2 \vartheta = 1 - \sin^2 \theta \overline{\cos^2 \psi} = 1 - \frac{1}{2} \sin^2 \theta = \frac{1}{2} + \frac{1}{2} \cos^2 \theta.$$

We then obtain

$$d\sigma = \frac{r_0^2 \omega^4}{(\omega_0^2 - \omega^2)^2 + \omega^2 \gamma^2} \frac{1 + \cos^2 \theta}{2} d\Omega \quad (36.8)$$

The angular dependence in formula (36.8) shows that the strongest scattering takes place in the direction of the incident radiation ($\theta = 0$) and in the opposite direction ($\theta = \pi$).

Integrating (36.8) over the entire solid angle we obtain the total scattering cross section for unpolarized radiation

$$\sigma = \frac{8}{3} \pi \frac{r_0^2 \omega^4}{(\omega_0^2 - \omega^2)^2 + \omega^2 \gamma^2} \quad (36.9)$$

This expression is called the dispersion formula of classical electrodynamics.

The dependence of the total cross section on frequency is expressed by a curve similar to that shown in fig. I.11, with a strongly pronounced maximum for $\omega \approx \omega_0$, i.e. for the frequency of the incident radiation close to the natural frequency of the oscillator. Assuming in formula (36.9) that $\omega \approx \omega_0$, we obtain near the resonance

$$\sigma \approx \frac{8}{3} \pi \frac{r_0^2 \omega_0^2}{(\omega_0 - \omega)^2 + (\frac{1}{2} \gamma)^2} \quad (36.10)$$

The quantity γ characterizes the width of the resonance region. In particular, for exact resonance $\omega = \omega_0$, the cross section in the maximum is equal to

$$\sigma_{\max} = \frac{8}{3} \pi r_0^2 \frac{\omega_0^2}{\gamma^2} \quad (36.11)$$

Since $\gamma \ll \omega_0$, the cross section for the resonance frequency attains very large values. This phenomenon plays an important role in the optics of material media. It is called resonance fluorescence*.

The dispersion formula, obtained in the example of the scattering of radiation by a harmonic oscillator, has in reality a very general character. It is of the same form as the corresponding formula for the scattering of light by atoms obtained in quantum mechanics (Part V). We shall see that in quantum mechanics the region of applicability of the dispersion formula is not re-

* Comparing (36.10) with formula (III.4') we see that for $\gamma \rightarrow 0$ the cross section behaves as a δ -function.

stricted to the scattering of light, but also extends to a number of other systems.

Let us consider the two relations obtained from (36.9) in the limiting case of low and high frequencies. For low frequencies $\omega \ll \omega_0$

$$\sigma \approx \frac{8}{3} \pi r_0^2 \frac{\omega^4}{\omega_0^4}, \quad (36.12)$$

i.e. the cross section is proportional to the fourth power of the frequency or inversely proportional to the fourth power of the wavelength of the incident radiation.

This law of scattering is of a very general character. It is applicable when the wavelength of the light scattered is large in comparison with the dimensions of the scattering object. This case is often called Rayleigh scattering.

For high frequencies $\omega \gg \omega_0$ formula (36.9) is again simplified:

$$\sigma \approx \frac{8\pi r_0^2}{3} = \frac{8\pi e^4}{3m^2 c^4}. \quad (36.13)$$

This is called the Thomson formula.

The cross section turns out to be constant, depending neither on the frequency of the radiation scattered nor on the properties of the oscillator. This fact has a simple meaning. At high frequencies the force acting on the charge due to the field is very large in comparison with the quasi-elastic force. The electron scatters as a free particle. According to the Thomson formula, the cross section σ is a universal constant determined by the classical radius of the electron. It is clear that the Thomson formula describes the scattering by electrons belonging to any system, for example atoms, if one can disregard the forces binding the electrons in the atoms and consider the electrons to be free. The scattering of radiation by heavy nuclei can be disregarded, since the cross section is inversely proportional to the square of the mass of the scatterer.

The universal character of formula (36.13) makes it one of the fundamental relations of classical electrodynamics. It has been put to a thorough experimental test, the results of which are shown in fig. 1.17.

We see that the ratio $\sigma_{\text{exp}}/\sigma_{\text{Thom}} = 1$ only for wavelengths larger than about 2 \AA .

For smaller wavelengths the classical treatment of scattering processes turns out to be inapplicable. Here we encounter the fact mentioned in §28. Although the limit of applicability of classical electrodynamics, inherent in

Fig. 1.17

the theory, occurs at the scale of wavelengths $\lambda \approx r_0 \approx 10^{-5}$ Å, actually it already appears at a scale 10^5 times larger. This is associated, as we have already stressed, with the manifestation of quantum effects. The trend of the cross section in fig. 1.17 is in excellent agreement with the predictions of the quantum theory of radiation (Part V, the Klein-Nishina formula).

§37. Absorption of radiation

In addition to scattering, the radiation interacting with matter undergoes absorption. In classical electrodynamics this effect can be calculated for the oscillator model. We shall restrict ourselves to the case where the frequency of the incident radiation is close to the resonance frequency, when the absorption is greatest. However, the frequency of the radiation cannot then be assumed to be exactly equal to the natural frequency of the oscillator. From what follows it can be seen that in such a case the calculation would not lead to a well defined result. Hence it should be assumed that the incident radiation has a continuous frequency distribution.

We can expand the incident field in a Fourier integral, writing

$$\mathbf{E}(t) = \int \mathbf{E}(\omega) e^{i\omega t} d\omega.$$

Substituting this into the equation of motion of the oscillator (36.1) and expanding the displacement of the latter in a Fourier integral,

$$\mathbf{r}(t) = \int \mathbf{r}(\omega) e^{i\omega t} d\omega,$$

it is easy to find that

$$\mathbf{r}(\omega) = \frac{e}{m} \frac{\mathbf{E}(\omega)}{\omega_0^2 - \omega^2 + i\omega\gamma}. \quad (37.1)$$

The energy loss is obviously equal to the total work done by the field on the oscillator. The latter can be calculated from the formula

$$-\Delta E = W = \int \mathbf{F} \cdot \mathbf{v} dt = e \int \mathbf{E}(t) \cdot \dot{\mathbf{r}}(t) dt. \quad (37.2)$$

Proceeding in an analogous way as in deriving the Parseval formula (II.9) we find, using $\mathbf{E}^*(\omega) = \mathbf{E}(-\omega)$, $\mathbf{r}^*(\omega) = \mathbf{r}(-\omega)$ and eq. (37.1):

$$\begin{aligned} -\Delta E &= \frac{1}{2} e \left[\int_{-\infty}^{+\infty} dt \mathbf{E}(t) \cdot \int_{-\infty}^{+\infty} i\omega \mathbf{r}(\omega) e^{i\omega t} d\omega + \int_{-\infty}^{+\infty} dt \dot{\mathbf{r}}(t) \cdot \int_{-\infty}^{+\infty} \mathbf{E}(\omega) e^{i\omega t} d\omega \right] \\ &= \frac{2\pi e}{2} \int_{-\infty}^{+\infty} i\omega [\mathbf{E}^*(\omega) \cdot \mathbf{r}(\omega) - \mathbf{E}(\omega) \cdot \mathbf{r}^*(\omega)] d\omega = \\ &= \frac{4\pi e^2}{m} \int_0^{\infty} \frac{\omega^2 \gamma |\mathbf{E}(\omega)|^2 d\omega}{(\omega_0^2 - \omega^2)^2 + \omega^2 \gamma^2} \approx \frac{\pi e^2}{m} \int_0^{\infty} \frac{\gamma |\mathbf{E}(\omega)|^2 d\omega}{(\omega_0 - \omega)^2 + (\frac{1}{2}\gamma)^2}. \end{aligned} \quad (37.3)$$

The integrand has a sharp maximum in the region of resonance. We assume that the spectral distribution of the radiation absorbed in the region of resonance varies slowly in comparison with the resonance factor. Then the integral can be calculated approximately. Substituting $\omega = \omega_0 + \frac{1}{2}\gamma x$ we get

$$\begin{aligned} \int_0^{\infty} \frac{\gamma |\mathbf{E}(\omega)|^2 d\omega}{(\omega_0 - \omega)^2 + (\frac{1}{2}\gamma)^2} &= \int_{-2\omega_0/\gamma}^{\infty} \frac{\frac{1}{2}\gamma^2 |\mathbf{E}(\omega_0 + \frac{1}{2}\gamma x)|^2 dx}{(\frac{1}{2}\gamma x)^2 + (\frac{1}{2}\gamma)^2} \approx \\ &\approx 2 \int_{-\infty}^{+\infty} |\mathbf{E}(\omega_0 + \frac{1}{2}\gamma x)|^2 \frac{dx}{x^2 + 1} \approx 2\pi |\mathbf{E}(\omega_0)|^2 \end{aligned} \quad (37.4)$$

We have replaced the lower limit of the integration by infinity, since $\gamma \ll \omega_0$. Substituting (37.4) into (37.3), we find

$$-\Delta E = \frac{2\pi^2 e^2}{m} |E(\omega_0)|^2 = 2\pi^2 c^2 r_0 |E(\omega_0)|^2. \quad (37.5)$$

The energy absorbed turns out to be independent of the physical properties of the absorbing system, and depends only on the position of the resonance frequency ω_0 . Hence the expression obtained is of a very general character as in the case of the dispersion formula. Very similar expressions for absorption are also obtained in the quantum theory of radiation (see Part V).

§38*. Canonical form of the field equations

In passing over to the quantum theory of the electromagnetic field it is convenient to give to the electromagnetic field equations a form very similar to that of the equations of mechanics. It turns out that the electromagnetic field can be compared with a certain mechanical system, and that D'Alembert's equations can take the form of Hamilton's equations describing the motion of this mechanical system. We shall confine ourselves to the case of the electromagnetic field in vacuum.

Making use of the Coulomb potential gauge described in §11, for which $\varphi = 0$, we write the field equations in the form

$$\nabla^2 \mathbf{A} - \frac{1}{c^2} \frac{\partial^2 \mathbf{A}}{\partial t^2} = 0, \quad (38.1)$$

$$\nabla \cdot \mathbf{A} = 0. \quad (38.2)$$

The region in which these field equations are valid is the space which is free of charges and currents. At the limit of this region a boundary condition must be given. Such a condition may take, for example, the expression for \mathbf{A} in the form of a retarded potential. However, we shall not be interested in the amplitude of electromagnetic waves, and shall confine ourselves to the consideration of the field in vacuum at a large distance from currents and charges. We divide the entire region of space which is free of charge into a set of cubes (we shall call them the normalization cubes) of edge L , and consider the field inside one of the cubes. Then the boundary condition must be given at the surface of the normalization cube.

As we know, the electromagnetic field in a vacuum represents a set of travelling waves. The solution in the form of travelling waves is obtained if it is assumed that the vector potential \mathbf{A} and its derivatives have equal values at opposite faces of the cube. This is equivalent to the requirement: \mathbf{A} is a periodic function of the variables x, y, z with a period L :

$$\mathbf{A}(x, y, z) = \mathbf{A}(x + L, y + L, z + L). \quad (38.3)$$

Having obtained the solution of eqs. (38.1) and (38.2) in a normalization cube with edge L with the boundary condition (38.3), we can write the solution in the entire space by simply repeating the solution in the initial normalization cube. The final results will not depend on the choice of L .

We look for the solution of (38.1) and (38.2) in a normalization cube in the form of a set of expressions of the form $q_i(t) \mathbf{A}_i(\mathbf{r})$, where $q_i(t)$ depends only on time, and $\mathbf{A}_i(\mathbf{r})$ depends only on coordinates.

Each of the vector functions $\mathbf{A}_i(\mathbf{r})$ represents a wave in the normalization cube. Since the volume of the latter is finite, it can contain a denumerably great number of standing or travelling waves. Thus, we set

$$\mathbf{A}(\mathbf{r}, t) = \sum_i q_i(t) \mathbf{A}_i(\mathbf{r}), \quad (38.4)$$

where the index i runs over an infinite but discrete number of values. This means that the vector potential of the field in the normalization cube can be expanded in a Fourier series. The number of terms in the sum (38.4), i.e. the number of waves in the normalization cube, is infinitely large.

Substituting (38.4) into (38.1), we find

$$\sum_i \left(q_i(t) \nabla^2 \mathbf{A}_i(\mathbf{r}) - \frac{1}{c^2} \ddot{q}_i(t) \mathbf{A}_i(\mathbf{r}) \right) = 0. \quad (38.5)$$

Since all waves forming the superposition (38.4) are independent, the equality (38.5) must hold for each of the waves, i.e.

$$q_i(t) \nabla^2 \mathbf{A}_i(\mathbf{r}) - \frac{1}{c^2} \ddot{q}_i(t) \mathbf{A}_i(\mathbf{r}) = 0. \quad (38.6)$$

We rewrite (38.6) in the form

$$\frac{c^2 \nabla^2 [\mathbf{A}_i(\mathbf{r})]_k}{[\mathbf{A}_i(\mathbf{r})]_k} = \frac{\ddot{q}_i(t)}{q_i(t)}, \quad k = x, y, z. \quad (38.7)$$

Since $[A_i(\mathbf{r})]_k$ and $q_i(t)$ are functions of different variables, the equality (38.7) can hold only if its right-hand side and left-hand side are separately equal to a constant, called the separation constant. For reasons which will be clear from what follows, this constant must be an essentially negative quantity. Denoting it by $(-\omega_i^2)$, we find

$$\nabla^2 A_i(\mathbf{r}) + \frac{\omega_i^2}{c^2} A_i(\mathbf{r}) = 0 \quad (38.8)$$

$$\ddot{q}_i(t) + \omega_i^2 q_i(t) = 0. \quad (38.9)$$

Expressions of the type

$$A_i \sim \mathbf{e}_j \sin \mathbf{k}_i \cdot \mathbf{r}, \quad (38.10)$$

$$A_i \sim \mathbf{e}_j \cos \mathbf{k}_i \cdot \mathbf{r},$$

serve as the solutions of eq. (38.8) satisfying the conditions of periodicity (38.3).

The components of the vector \mathbf{k}_i must assume a discrete number of values

$$k_{ix} = \frac{2\pi n_{i1}}{L}, \quad k_{iy} = \frac{2\pi n_{i2}}{L}, \quad k_{iz} = \frac{2\pi n_{i3}}{L}, \quad (38.11)$$

where n_{i1} , n_{i2} and n_{i3} are positive integers. The whole set of such values of the components of \mathbf{k}_i ensures the presence of nodes or antinodes at the faces of the normalization cube. The absolute value of the vector \mathbf{k} is by definition equal to $|\mathbf{k}_i| = \omega_i/c$. The vector \mathbf{e}_j is the unit polarization vector, which can assume two values ($j = 1, 2$) for a given \mathbf{k}_i .

Instead of sines and cosines in formula (38.10) we could take their arbitrary linear combination.

Eq. (38.2) leads to the requirement

$$\mathbf{e}_j \cdot \mathbf{k}_i = 0, \quad (38.12)$$

meaning (see §33) that the waves are transverse.

The whole set of functions A_i is given completely by eqs. (38.1) and (38.2) and the boundary condition (38.3). It appears to be the same for any fields in the normalization cube.

For the actual determination of the vector potential at a given point of

space at a definite instant of time it is necessary to give the set of all time amplitudes $q_i(t)$. This means that the state of the field is characterized by defining an infinite set of amplitudes $q_i(t)$.

The latter are determined by eq. (38.9), which is the same as the equation of motion of the linear harmonic oscillator. The quantity ω_i represents the frequency of this oscillator. The value of $q_i(t)$ determines the state of the i th oscillator at any moment t . The definition of the whole set of the variable amplitudes $q_i(t)$ is equivalent to the definition of the state of a whole set of an infinitely large number of oscillators with frequencies ω_i . If the state of all the oscillators at given moment t is known, then the field is also known at this moment. Thus, the electromagnetic field can formally be replaced by a mechanical system with an infinitely large number of degrees of freedom — a set of an infinitely large number of oscillators usually called field oscillators. The whole set of states of the field oscillators $q_i(t)$ characterizes the state of this mechanical system and, at the same time, the state of the field.

The quantities $q_i(t)$ can be considered as the set of coordinates of a mechanical system whose equations of motion can be written in the form of Hamilton's equations. One can ascribe to this system the Hamiltonian function (which is the same as its energy):

$$H = \frac{1}{2} \sum (p_i^2 + \omega_i^2 q_i^2), \quad (38.13)$$

where p_i is the momentum conjugate to the coordinate q_i . The mass of all field oscillators is assumed to be equal to unity.

Indeed, Hamilton's equations for the i th degree of freedom (i.e. the i th oscillator) read:

$$\dot{q}_i = \partial H / \partial p_i = p_i, \quad \dot{p}_i = -\partial H / \partial q_i = -\omega_i^2 q_i,$$

whence the eq. (38.9) for the quantity q_i follows directly.

A particular solution of the field eqs. (38.1) and (38.2) can be written in the form

$$A_{ij} \sim C_{1i} \mathbf{e}_j \cos \omega_i t \sin \mathbf{k}_i \cdot \mathbf{r} + C_{2i} \mathbf{e}_j \sin \omega_i t \cos \mathbf{k}_i \cdot \mathbf{r}. \quad (38.14)$$

If one chooses properly the normalization of the linear combination of solutions of the type (38.14), from which the general solution (38.4) of the field equations (38.1) and (38.2) is formed, one can make the energy of the field in the normalization cube equal to the energy of the system of field oscillators (38.13). For such a normalization of the vector potential we can

assume that the system of field oscillators is completely equivalent to the electromagnetic field. The state of the set of oscillators is uniquely related to the state of the field.

The necessary linear combination of solutions of the type (38.14) has the following form:

$$\begin{aligned} A &= \sqrt{\frac{4\pi}{L^3}} \sum_i \sum_{j=1}^2 \mathbf{e}_j \frac{1}{k_i} (-\dot{q}_i(t) \sin \mathbf{k}_i \cdot \mathbf{r} + \omega_i q_i \cos \mathbf{k}_i \cdot \mathbf{r}) = \\ &= \sqrt{\frac{4\pi}{L^3}} \sum_i \sum_{j=1}^2 \mathbf{e}_j \frac{1}{k_i} (-p_i \sin \mathbf{k}_i \cdot \mathbf{r} + \omega_i q_i \cos \mathbf{k}_i \cdot \mathbf{r}). \end{aligned} \quad (38.15)$$

Indeed, we shall verify the fact that the energy of the field in the normalization cube satisfies the requirement

$$E = \int \frac{\mathbf{E}^2 + \mathbf{H}^2}{8\pi} dV = \frac{1}{2} \sum_i \sum_{j=1}^2 (p_i^2 + \omega_i^2 q_i^2) \quad (38.16)$$

Oscillators with different polarizations are considered to be different. The total number of field oscillators is obtained by summing over i and j . This amounts to doubling the result.

From (38.15) it follows that

$$\begin{aligned} \mathbf{E} &= -\frac{1}{c} \frac{\partial A}{\partial t} = \\ &= -\frac{1}{c} \sqrt{\frac{4\pi}{L^3}} \sum_i \sum_{j=1}^2 \mathbf{e}_j \frac{1}{k_i} (-\ddot{q}_i \sin \mathbf{k}_i \cdot \mathbf{r} + \omega_i \dot{q}_i \cos \mathbf{k}_i \cdot \mathbf{r}) = \\ &= -\sqrt{\frac{4\pi}{L^3}} \sum_i \sum_j \mathbf{e}_j \frac{1}{ck_i} (\omega_i^2 q_i \sin \mathbf{k}_i \cdot \mathbf{r} + \omega_i p_i \cos \mathbf{k}_i \cdot \mathbf{r}) = \\ &= -\sqrt{\frac{4\pi}{L^3}} \sum_i \sum_j \mathbf{e}_j (\omega_i q_i \sin \mathbf{k}_i \cdot \mathbf{r} + p_i \cos \mathbf{k}_i \cdot \mathbf{r}) = \\ &= \sum_i \mathbf{E}_i, \end{aligned} \quad (38.17)$$

$$\begin{aligned}
\mathbf{H} &= \nabla \times \mathbf{A} = \sqrt{\frac{4\pi}{L^3}} \sum_i \sum_{j=1}^2 \frac{1}{k_i} \{ -q_i \nabla \times (\mathbf{e}_j \sin \mathbf{k}_i \cdot \mathbf{r}) + \\
&\quad + \omega_i q_i \nabla \times (\mathbf{e}_j \cos \mathbf{k}_i \cdot \mathbf{r}) \} = \\
&= -\sqrt{\frac{4\pi}{L^3}} \sum_i \sum_j \frac{1}{k_i} (p_i \mathbf{k}_i \times \mathbf{e}_j \cos \mathbf{k}_i \cdot \mathbf{r} + \omega_i q_i \mathbf{k}_i \times \mathbf{e}_j \sin \mathbf{k}_i \cdot \mathbf{r}) = \\
&= -\sqrt{\frac{4\pi}{L^3}} \sum_i \sum_j \frac{\mathbf{k}_i \times \mathbf{e}_j}{k_i} (p_i \cos \mathbf{k}_i \cdot \mathbf{r} + \omega_i q_i \sin \mathbf{k}_i \cdot \mathbf{r}) = \\
&= \sum_i \frac{\mathbf{k}_i \times \mathbf{E}_i}{k_i}. \tag{38.18}
\end{aligned}$$

Let us work out the expression for the integrals $(1/8\pi) \int \mathbf{E}^2 dV$ and $(1/8\pi) \int \mathbf{H}^2 dV$. From (38.17) it follows that

$$\frac{1}{8\pi} \int \mathbf{E}^2 dV = \frac{1}{2L^3} \int \left\{ \sum_i \sum_j \mathbf{e}_j (\omega_i q_i \sin \mathbf{k}_i \cdot \mathbf{r} + p_i \cos \mathbf{k}_i \cdot \mathbf{r}) \right\}^2 dV$$

In calculating the integrals we make use of the obvious relations

$$\begin{aligned}
\int \sin \mathbf{k}_i \cdot \mathbf{r} \sin \mathbf{k}_{i'} \cdot \mathbf{r} dV &= \int \sin \mathbf{k}_i \cdot \mathbf{r} \cos \mathbf{k}_{i'} \cdot \mathbf{r} dV = \\
&= \int \cos \mathbf{k}_i \cdot \mathbf{r} \cos \mathbf{k}_{i'} \cdot \mathbf{r} dV = \\
&= \int \sin \mathbf{k}_i \cdot \mathbf{r} \cos \mathbf{k}_{i'} \cdot \mathbf{r} dV = 0. \\
\int \sin^2 \mathbf{k}_i \cdot \mathbf{r} dV &= \int \cos^2 \mathbf{k}_i \cdot \mathbf{r} dV = \frac{1}{2} V = \frac{1}{2} L^3.
\end{aligned}$$

Hence it is easy to obtain the expression

$$\frac{1}{8\pi} \int \mathbf{E}^2 dV = \frac{1}{4} \sum_i \sum_j (p_i^2 + \omega_i^2 q_i^2).$$

Quite analogously one obtains from (38.18):

$$\begin{aligned} \frac{1}{8\pi} \int H^2 dV &= \frac{1}{2L^3} \int \left\{ \sum_i \sum_j \mathbf{e}_j \frac{1}{k_i} (p_i \mathbf{k}_i \times \mathbf{e}_j \cos \mathbf{k}_i \cdot \mathbf{r} + \right. \\ &\quad \left. + \omega_i q_i \mathbf{k}_i \times \mathbf{e}_j \sin \mathbf{k}_i \cdot \mathbf{r}) \right\}^2 dV = \\ &= \frac{1}{4} \sum_i \sum_j (p_i^2 + \omega_i^2 q_i^2). \end{aligned}$$

Adding the two expressions, we arrive at the equality (38.16).

For the normalization method which we have chosen — i.e. the selection of the factors before $\sin \mathbf{k}_i \cdot \mathbf{r}$ and $\cos \mathbf{k}_i \cdot \mathbf{r}$ — the field in the normalization volume can be compared with a set of field oscillators whose energy is the same as that of the field. The state of the oscillators — the set of the quantities $q_i(t)$ at a moment t — determines the value of the vector potential $\mathbf{A}(\mathbf{r}, t)$.

Thus, the electromagnetic field in a finite volume is formally equivalent to a mechanical system with an infinitely large but denumerable number of degrees of freedom — a set of field oscillators — while the field equations are formally equivalent to Hamilton's equations of motion of the field oscillators. The Hamiltonian function of the equivalent system of oscillators is often called simply the Hamiltonian field function, while the expansion of the vector potential (38.15) is called the expansion of the field into oscillators. It should be stressed that within the framework of classical electrodynamics the expansion of the field into oscillators is a mathematical device. Field oscillators cannot be associated with the oscillations of any real particles. However, this expansion plays a most important role in the quantum theory of the electromagnetic field (see Part V).

In the quantum theory of the electromagnetic field the expansion (38.15) is often expressed in terms of exponential functions. Later, in Part V, we shall need such a representation. We write the expression for the vector potential $\mathbf{A}(\mathbf{r}, t)$ in the form

$$\mathbf{A}(\mathbf{r}, t) = \sum_{\lambda} (b_{\lambda} \mathbf{A}_{\lambda} + b_{\lambda}^* \mathbf{A}_{\lambda}^*). \quad (38.19)$$

Here the following notations are introduced:

$$\begin{aligned} \mathbf{A}_{\lambda} &= \mathbf{e}_{\lambda} \sqrt{\frac{4\pi c^2}{L^3}} e^{i\mathbf{k}_{\lambda} \cdot \mathbf{r}}, \\ \mathbf{A}_{\lambda}^* &= \mathbf{e}_{\lambda} \sqrt{\frac{4\pi c^2}{L^3}} e^{-i\mathbf{k}_{\lambda} \cdot \mathbf{r}}. \end{aligned}$$

The index λ , over which the summation in (38.19) is carried out, replaces the indices i and j in (38.15), i.e. it runs over a double (in comparison with i) series of values, corresponding to the two directions of the polarization vector (\mathbf{e}_1 and \mathbf{e}_2). The term $b_\lambda \mathbf{A}_\lambda$ characterizes the wave propagating (travelling) in the positive direction of the vector \mathbf{k}_λ . The second term $b_\lambda^* \mathbf{A}_\lambda^*$ represents the wave propagating in the opposite direction ($-\mathbf{k}_\lambda$). Thus, the waves having the wave vectors (\mathbf{k}_λ) and ($-\mathbf{k}_\lambda$) are considered to be different waves. The components of the vectors (\mathbf{k}_λ) and ($-\mathbf{k}_\lambda$) assume the values given by (38.11), but with both positive and negative values of the integers n_{i1} , n_{i2} , n_{i3} . This means that to one standing wave there correspond two travelling waves — in the positive and negative directions.

Substituting \mathbf{A}_λ and \mathbf{A}_λ^* into (38.19), we rewrite this formula in the form

$$\mathbf{A}(\mathbf{r}, t) = \sqrt{\frac{4\pi c^2}{L^3}} \sum_{\lambda} \mathbf{e}_{\lambda} (b_{\lambda} e^{i\mathbf{k}_{\lambda} \cdot \mathbf{r}} + b_{\lambda}^* e^{-i\mathbf{k}_{\lambda} \cdot \mathbf{r}}).$$

Comparing the above expression with (38.15) and equating coefficients of $e^{i\mathbf{k}_{\lambda} \cdot \mathbf{r}}$ and $e^{-i\mathbf{k}_{\lambda} \cdot \mathbf{r}}$, we find

$$\begin{aligned} b_{\lambda} &= \frac{1}{2\omega_{\lambda}} (ip_{\lambda} + \omega_{\lambda} q_{\lambda}), \\ b_{\lambda}^* &= \frac{1}{2\omega_{\lambda}} (-ip_{\lambda} + \omega_{\lambda} q_{\lambda}). \end{aligned} \tag{38.20}$$

In this notation the field energy is written in the form

$$E = \frac{1}{2} \sum_i \sum_j (p_i^2 + \omega_i^2 q_i^2) = \frac{1}{2} \sum_{\lambda} (p_{\lambda}^2 + \omega_{\lambda}^2 q_{\lambda}^2) = 2 \sum_{\lambda} b_{\lambda} b_{\lambda}^* \omega_{\lambda}^2. \tag{38.21}$$

Later we shall also need to calculate the number of field oscillators with given frequency and given polarization. It is obviously equal to the number of travelling waves in the volume $V = L^3$. In order to find the number of oscillators it is convenient to make use of a simple geometrical construction. We choose n_1 , n_2 and n_3 in formula (38.11) to be the coordinates in an imaginary space of the numbers (n_1, n_2, n_3) , omitting the suffixes i for clarity.

Fig. 1.18 presents a part of this space. To each possible value of n_1 and n_2 in this drawing there corresponds a point. We introduce the quantity

$$n = \sqrt{n_1^2 + n_2^2 + n_3^2}.$$

Fig. 1.18

If the numbers n_1, n_2, n_3 are sufficiently large, then the points representing them lie very close to each other and fill the entire space in an almost continuous way. The quantity n , as a function of n_1, n_2, n_3 , will vary almost continuously, and in fig. 1.18 will be represented by a radius vector.

Since to each set of three numbers n_1, n_2, n_3 there corresponds a definite value of k given by

$$k = |\mathbf{k}| = \frac{2\pi}{L} \sqrt{n_1^2 + n_2^2 + n_3^2} = n \frac{2\pi}{L},$$

the number of waves with a k lying in the interval between k and $k + dk$ is equal to the number of the values of n lying in the interval between n and $n + dn$. The latter is equal to the number of representative points within a spherical layer lying between spherical surfaces with radii $n, n + dn$. For this number we have, obviously, the value

$$g(n) dn = 4\pi n^2 dn.$$

Thus, the number of travelling waves or the number of field oscillators with $|\mathbf{k}|$ lying in the interval $k, k + dk$ and with a given polarization in a volume $V = L^3$ is equal to

$$g(k) dk = 4\pi n^2 dn = \frac{4\pi k^2 dk}{(2\pi)^3} L^3$$

The number of oscillators with a given polarization and a frequency lying in the interval $\omega, \omega + d\omega$ is

$$g(\omega) d\omega = \frac{4\pi\omega^2 d\omega}{(2\pi c)^3} L^3 \quad (38.22)$$

Hence one has to make use of the formula for the number of field oscillators with given frequency, given polarization and a direction of the vector \mathbf{k} lying within a solid angle $d\Omega$. The number of such oscillators is equal to

$$g(\omega) d\omega \frac{d\Omega}{4\pi} = \frac{\omega^2 d\omega L^3 d\Omega}{(2\pi c)^3}. \quad (38.23)$$

We shall need the expression for the momentum of radiation in a volume L^3 . Writing it on the basis of (13.11), (38.17) and (38.18) in the form

$$\begin{aligned} \mathbf{G} &= \frac{1}{4\pi c} \int \mathbf{E} \times \mathbf{H} dV = \frac{1}{4\pi c} \int \left[\sum_{\lambda} \mathbf{E}_{\lambda} \times \sum_{\mu} \frac{\mathbf{k}_{\mu} \times \mathbf{E}_{\mu}}{k_{\mu}} \right] dV = \\ &= \frac{1}{4\pi c} \sum_{\lambda} \frac{\mathbf{k}_{\lambda}}{k_{\lambda}} \int E_{\lambda}^2 dV = \int \sum_{\lambda} \frac{\mathbf{k}_{\lambda} E_{\lambda}^2}{4\pi c k_{\lambda}} dV = \sum_{\lambda} \mathbf{g}_{\lambda}, \end{aligned}$$

we can ascribe to each oscillator an energy

$$\epsilon_{\lambda} = 2b_{\lambda} b_{\lambda}^* \omega_{\lambda}^2 = p_{\lambda}^2 + \omega_{\lambda}^2 q_{\lambda}^2, \quad (38.24)$$

and a momentum

$$\mathbf{p}_{\lambda} = \mathbf{k}_{\lambda} \epsilon_{\lambda} / c k_{\lambda} = \mathbf{g}_{\lambda}, \quad (38.25)$$

so that

$$E = \sum \epsilon_{\lambda}, \quad \mathbf{G} = \sum \mathbf{p}_{\lambda}.$$

The Motion of Particles in Electromagnetic Fields

§39. The motion of charged particles in constant electric and magnetic fields

One of the branches of electrodynamics which is important from the practical point of view is the theory of motion of charged particles in electric and magnetic fields. The theory of the motion of charged particles in electromagnetic fields is at the basis of electronics, accelerator technology, electron and proton microscopy, mass-spectrography, investigation of reactions in plasma, and experimental facilities for the investigation of thermonuclear phenomena. It is very important for a number of other fields of physics — astrophysics, physics of cosmic rays and so on.

In this book we shall restrict ourselves to the consideration of the simplest problems. We shall assume that the field in which a particle is placed has a strength which is very large compared with that of the particle itself. In other words, we consider the particle whose motion interests us as a test particle which does not distort the given external field.

We begin with the motion of a charged particle in a uniform electric field constant in time. The equations of motion have the form

$$m \frac{d^2 \mathbf{r}}{dt^2} = e \mathbf{E}.$$

If at the initial instant $t = 0$ the charged particle was at rest, then, taking the direction of the field along the x -axis we have

$$m\ddot{x} = eE,$$

$$m\ddot{y} = 0;$$

it can be shown that

$$v \equiv \dot{x} = \pm \sqrt{2eV/m + v_0^2} = \pm \sqrt{2eV/m}, \quad (39.1)$$

where $V = (\varphi_2 - \varphi_1)$ is the accelerating (or decelerating) potential difference traversed by the particle. Here it is assumed that $v_0 = 0$.

If the particle at the initial instant was at the origin and had a velocity v_0 directed at an angle θ to the y -axis, then the double integration of the equations of motion gives:

$$\dot{x} = \frac{etE}{m} + v_0 \sin \theta,$$

$$x = \frac{et^2E}{2m} + (v_0 \sin \theta)t,$$

$$\dot{y} = v_0 \cos \theta,$$

$$y = (v_0 \cos \theta)t.$$

Eliminating t from the expressions written for y and x , we find the equation of the trajectory:

$$x = (\tan \theta)y + \frac{eEy^2}{2m(v_0 \cos \theta)^2}. \quad (39.2)$$

As was to be expected, the particle moves in a parabola.

Let us now consider the motion of a particle in a constant uniform magnetic field. We orientate the z -axis along the direction of the field. The equations of motion have the form

$$m\ddot{\mathbf{r}} = \frac{e}{c} \mathbf{v} \times \mathbf{H}, \quad (39.3)$$

or, taking the components,

$$\ddot{x} = \frac{e}{mc} yH, \quad (39.4)$$

$$\ddot{y} = -\frac{e}{mc} xH, \quad (39.5)$$

$$\ddot{z} = 0. \quad (39.6)$$

Eq. (39.6) means that the magnetic field directed along the z -axis has no effect on the component of the motion of a particle in this direction. We look for the solution of eqs. (39.4) and (39.5) in the form

$$\dot{x} = A \cos(\omega_C t + \alpha),$$

$$y = B \sin(\omega_C t + \alpha).$$

We then have

$$-\omega_C A = \frac{eH}{mc} B,$$

$$-\frac{eH}{mc} A = \omega_C B,$$

from which we find

$$\omega_C = eH/mc, \quad A = -B. \quad (39.7)$$

Thus, we can write

$$\begin{aligned}\dot{x} &= A \cos(\omega_C t + \alpha) = A \cos\left(\frac{eH}{mc} t + \alpha\right), \\ \dot{y} &= -A \sin(\omega_C t + \alpha) = -A \sin\left(\frac{eH}{mc} t + \alpha\right).\end{aligned}\tag{39.8}$$

It is obvious that

$$A^2 = v_x^2 + v_y^2 = v_{\perp}^{(0)2},$$

where $v_{\perp}^{(0)}$ is the initial velocity in the plane (xy).

Integrating the expressions obtained once more, we have

$$\begin{aligned}x &= x_0 + \frac{v_{\perp}^{(0)}}{\omega_C} \sin(\omega_C t + \alpha), \\ y &= y_0 + \frac{v_{\perp}^{(0)}}{\omega_C} \cos(\omega_C t + \alpha).\end{aligned}$$

Eliminating the time from the above relations, we find that the particle moves in a circle

$$(x - x_0)^2 + (y - y_0)^2 = \frac{v_{\perp}^{(0)2}}{\omega_C^2} = R_C^2.$$

The frequency of rotation of the particle, given by formula (39.7), is called the cyclotron frequency. The cyclotron frequency, equal to double the Larmor frequency, does not depend on the initial velocity of the particle and is determined by the ratio e/m . The radius of the circle

$$R_C = \frac{v_{\perp}^{(0)}}{\omega_C} = \frac{mc v_{\perp}^{(0)}}{eH}\tag{39.9}$$

has the following simple meaning: on a circle of radius R_C the centrifugal force and the Lorentz force are balanced,

$$\frac{m(v_{\perp}^{(0)})^2}{R_C} = \frac{e}{c} v_{\perp}^{(0)} H.$$

If at the initial moment the particle had a velocity component $v_z^{(0)}$ along

the z -axis in addition to its velocity in the plane (xy), then it would move uniformly along the direction of the magnetic field. The superposition of the two motions, the uniform one along the z -axis and the rotation in the plane (xy), leads to a helical trajectory of the particle in the longitudinal field. The turns of the helix lie on a cylindrical surface of radius R_C with its axis parallel to the z -axis.

For the motion in a constant magnetic field \mathbf{H} the following conservation laws hold:

1. The total energy of the particle is conserved:

$$\epsilon = \frac{1}{2} m \{ (v_{\perp}^{(0)})^2 + (v_z^{(0)})^2 \} = \text{const.}$$

2. The projection of the angular momentum onto the z -axis is conserved, i.e.

$$L_z = m R_C^2 \dot{\varphi} = m R_C^2 \omega_C = \text{const.}$$

From formula (22.4) it follows that the magnetic moment produced by the particle moving in a circle is also conserved:

$$\mu = \frac{e}{2mc} L_z = \frac{e R_C^2 \omega_C}{2c} = \frac{1}{2} (m v_{\perp}^2) \frac{1}{H} = \frac{\epsilon_{\perp}}{H} = \text{const.}, \quad (39.10)$$

where $\epsilon_{\perp} = \frac{1}{2} m v_{\perp}^2$ is the kinetic energy of motion in the plane (xy). We shall make use of this important result in the next paragraph.

A constant uniform magnetic field possesses the property of focussing. Let a beam of particles emerge in different directions from a certain point with different initial velocities lying in the plane (xy). Since the cyclotron frequency does not depend on the initial velocity, the particles, having performed one revolution, will again come together at one point after the lapse of a time interval $T_C = 2\pi/\omega_C$.

If one now considers a beam of particles emerging in different directions, but having the same values of the initial velocity component $|v_{\perp}^{(0)}|$, then it can be seen that during a time T_C they will all traverse one turn of a helix. Its pitch, equal to $l = v_z^{(0)} T_C = v^{(0)} T_C \cos \alpha$, will in each case be different. Here α is the angle between the direction of the initial velocity and the z -axis. Hence the particles emerging from the initial point will not come together again at one point. If, however, the angle α is small, so that $\cos \alpha \approx 1$, then the pitch of the helix turns out to be the same for all the particles, and the beam is focussed.

Finally, let us consider the general case of the motion of a particle in electric and magnetic fields which are uniform and constant in time. We write the equation of motion in this case in the form

$$m \frac{d\mathbf{v}}{dt} = e\mathbf{E} + \frac{e}{c} \mathbf{v} \times \mathbf{H}.$$

We introduce a new unknown quantity \mathbf{V} , determined by the relation

$$\mathbf{V} = \mathbf{v} - \frac{c \mathbf{E} \times \mathbf{H}}{H^2}. \quad (39.11)$$

Substituting \mathbf{V} into the equation of motion, we find

$$\frac{d\mathbf{V}}{dt} = \frac{e}{m} \left(\mathbf{E} + \frac{1}{c} \mathbf{V} \times \mathbf{H} + \frac{(\mathbf{E} \times \mathbf{H}) \times \mathbf{H}}{H^2} \right).$$

Evaluating the vector product

$$(\mathbf{E} \times \mathbf{H}) \times \mathbf{H} = \mathbf{H}(\mathbf{H} \cdot \mathbf{E}) - E H^2,$$

we obtain

$$\frac{d\mathbf{V}}{dt} = \frac{e}{m} \frac{\mathbf{H}(\mathbf{H} \cdot \mathbf{E})}{H^2} + \frac{e}{mc} \mathbf{V} \times \mathbf{H}. \quad (39.12)$$

If the electric field is perpendicular to the magnetic field, so that $\mathbf{H} \cdot \mathbf{E} = 0$, then

$$\frac{d\mathbf{V}}{dt} = \frac{e}{mc} \mathbf{V} \times \mathbf{H}.$$

The above equation is the same as (39.3). Consequently, \mathbf{V} represents the velocity of motion of a particle in a circle in the plane perpendicular to the magnetic field \mathbf{H} with the cyclotron frequency. The components of the velocity \mathbf{V} are given by formulae analogous to (39.8), in which we assume that $\alpha = 0$.

In this case the total velocity of the particle is equal to

$$\mathbf{v} = \mathbf{V} + c \frac{\mathbf{E} \times \mathbf{H}}{H^2}$$

or, in the components,

$$v_x = V_x + cE_y/H = v_{\perp}^{(0)} \cos \omega_C t + cE_y/H, \quad (39.13)$$

$$v_y = V_y = -v_{\perp}^{(0)} \sin \omega_C t, \quad (39.14)$$

where $v_{\perp}^{(0)}$ is the initial value of the velocity in the plane perpendicular to the direction of the magnetic field \mathbf{H} . For the constant α equal to zero, the corresponding initial velocity of the particle is directed along the x -axis. From (39.13) it follows that v_x remains small in comparison with the velocity of light c , if the inequality $E_y \ll H$ holds.

The component of the velocity of the particle

$$v_D = c \frac{\mathbf{E} \times \mathbf{H}}{H^2} \quad (39.15)$$

is directed perpendicularly to both of the fields. Its absolute value is equal to

$$|v_D| = cE/H \quad (39.16)$$

and depends neither on the charge nor on the mass of the particle.

The motion of a particle in the direction of v_D is called "drift".

An obvious interpretation of the phenomenon of drift can be obtained from the following reasoning. Let a positively charged particle move on a circle in the plane (xy) perpendicular to the direction of the magnetic field \mathbf{H} ,

Fig. I.19

chosen to be the z -axis (in fig. I.19). The magnetic field is directed upward perpendicular to the plane of the drawing. Let, in addition, the electric field be directed along the y -axis. Then the electric field will accelerate the particle as it moves on the left semicircle, and decelerate it as it moves on the right semicircle. The circular trajectory will be distorted. The particle traverses the upper part of the circle with a larger velocity than the lower part. The magnetic field will bend the trajectory of the particle more in the lower part of the circle than in the upper one. Hence the projection of the path traversed by the particle onto the x -axis will be smaller in the lower part of the circle than in the upper one. As a result, after each revolution there arises a certain shift of the particle along the x -axis in its positive direction (in fig. I.19 from the left to the right), and the particle begins to move in the positive direction of the x -axis.

Similar reasoning for a negative particle leads to the same direction of drift.

Integrating the expressions (39.13) and (39.14) once more, we find the equations of the trajectory of the particle in parametric form:

$$x = \frac{v_{\perp}^{(0)}}{\omega_C} \sin \omega_C t + \frac{cEt}{H} + x_0, \quad (39.17)$$

$$y = \frac{v_{\perp}^{(0)}}{\omega_C} \cos \omega_C t + y_0. \quad (39.18)$$

The curve described by the particle is called a trochoid. The fixed parameters of the trochoid depend on the initial conditions. If it is assumed that at $t = 0$ the charged particle was at the origin, then $x_0 = 0$, $y_0 = -v_{\perp}^{(0)}/\omega_C$. In this case the form of the curve is determined only by the value of the initial velocity $v_{\perp}^{(0)}$. For $|v_{\perp}^{(0)}| > cE/H$ the upper curve of fig. I.20 is obtained, while for $|v_{\perp}^{(0)}| < cE/H$ the middle curve is obtained. The lower curve, a cycloid, corresponds to the case $v_{\perp}^{(0)} = -cE/H$.

If \mathbf{E} is not perpendicular to \mathbf{H} , then eq. (39.12) can be projected onto the plane perpendicular to \mathbf{H} and onto the z -axis. Then we find:

$$\frac{d\mathbf{V}_{\perp}}{dt} = \frac{e}{mc} \mathbf{V}_{\perp} \times \mathbf{H}, \quad \frac{dV_z}{dt} = \frac{e}{m} E_{\parallel},$$

where E_{\parallel} is the component of the electric field parallel to the magnetic field. In this case one has to write E instead of E_{\perp} in the drift velocity. The uniformly accelerated motion along the magnetic field under the action of the force eE_{\parallel} is superposed on the drift of the particle.

Fig. 1.20

§40. The motion of charged particles in slowly varying magnetic fields

Now we apply ourselves to the very important case of the motion of charged particles in magnetic fields varying in space and time. In the general case of varying fields the integration of the equations of motion turns out to be a very difficult problem. Hence we restrict ourselves to the case of fields varying slowly in time and space.

Consider the case where the magnetic field varies slowly in time, remaining uniform in space. Let a particle rotate with a cyclotron frequency ω_C in the plane perpendicular to the magnetic field. We assume that the change in the field per revolution is sufficiently small, i.e. that

$$T_C \left| \frac{\partial H}{\partial t} \right| \ll |H|, \quad (40.1)$$

where $T_C = 2\pi/\omega_C$.

For a time-varying field

$$\oint \mathbf{E} \cdot d\mathbf{l} = -\frac{1}{c} \int \frac{\partial \mathbf{H}}{\partial t} \cdot d\mathbf{S}, \quad (40.2)$$

where the trajectory of the particle can be taken as the integration path. Multiplying (40.2) by the charge of the particle and assuming that during one revolution $\partial \mathbf{H} / \partial t$ remains constant, we can write:

$$e \oint \mathbf{E} \cdot d\mathbf{l} = -\frac{e}{c} \left| \frac{\partial \mathbf{H}}{\partial t} \right| S = -\frac{e}{c} \left| \frac{\partial \mathbf{H}}{\partial t} \right| \pi R_C^2. \quad (40.3)$$

The integral on the left of (40.3) represents the work done on the charge per revolution. It is equal to the increase of the kinetic energy of motion in the plane (xy), which we shall denote by $\Delta \epsilon_{\perp}$. Thus

$$\Delta \epsilon_{\perp} = -\frac{e}{c} \pi R_C^2 \left| \frac{\partial \mathbf{H}}{\partial t} \right| = \frac{|e| \pi R_C^2}{c} \left| \frac{\partial \mathbf{H}}{\partial t} \right| \quad (40.4)$$

The minus sign means that a particle with a negative charge moves in a direction opposite to the positive direction of the integration path.

Let us find the derivative $d\epsilon_{\perp}/dt$. On the basis of (40.4) and (39.10) we have

$$\begin{aligned} \frac{d\epsilon_{\perp}}{dt} &= \frac{\Delta \epsilon_{\perp}}{T_C} = \frac{|e| \pi R_C^2}{c T_C} \left| \frac{\partial \mathbf{H}}{\partial t} \right| = \frac{|e| \pi \omega_C R_C^2}{2\pi c} \left| \frac{\partial \mathbf{H}}{\partial t} \right| = \\ &= \mu \left| \frac{\partial \mathbf{H}}{\partial t} \right| = \mu \left| \frac{\partial H}{\partial t} \right| \end{aligned} \quad (40.5)$$

According to definition (39.10),

$$\frac{d\epsilon_{\perp}}{dt} = \mu \frac{\partial H}{\partial t} + H \frac{\partial \mu}{\partial t}. \quad (40.6)$$

Comparing eqs. (40.5) and (40.6) we see that, when the magnetic field varies slowly, the magnetic moment of the particle remains constant:

$$\frac{\partial \mu}{\partial t} = 0. \quad (40.7)$$

We can obtain the same result by considering the motion of a particle in a stationary magnetic field which varies slowly from point to point.

Fig. I.21

Let a magnetic field be symmetric about the z -axis and let its strength increase with increasing z . The field lines converge, as shown in fig. I.21. We shall assume that in a distance $\approx R_C$ the variation of the magnetic field is small, i.e.

$$R_C \left| \frac{\partial \mathbf{H}}{\partial z} \right| \ll |\mathbf{H}|. \quad (40.8)$$

Since the magnetic field varies along the z -axis, the radial component H_r of the field also differs from zero. From the continuity equation in cylindrical coordinates

$$\nabla \cdot \mathbf{H} = \frac{1}{r} \frac{\partial}{\partial r} (r H_r) + \frac{\partial H_z}{\partial z} = 0,$$

we have

$$\frac{\partial}{\partial r} (r H_r) = -r \frac{\partial H_z}{\partial z}.$$

Integrating, and disregarding the dependence of $\partial H_z / \partial z$ on the coordinate r on a circle of radius $r \sim R_C$, we find

$$H_r \approx -\frac{1}{2} r \frac{\partial H_z}{\partial z}.$$

Since, if the condition (40.8) is fulfilled, the component H_r is small in comparison with the component H_z for all $r < R_C$, it can be assumed that $|\mathbf{H}| \approx H_z$, i.e. that the field is directed at a small angle to the z -axis, and

$$H_r \approx -\frac{1}{2} r \frac{\partial |\mathbf{H}|}{\partial z}. \quad (40.9)$$

If the component of the magnetic field $H_z \neq 0$, then a particle moving in a circle in the (xy) plane with a cyclotron frequency is acted upon by a force in the direction of the z -axis. The particle will drift in this direction. Then the component v_z satisfies the equation of motion

$$m \frac{dv_z}{dt} = \frac{e}{c} v_{\perp} H_r = -\frac{e}{2c} v_{\perp} R_C \frac{\partial H}{\partial z} = -\frac{e}{2c} R_C^2 \omega_C \frac{\partial H}{\partial z} = -\mu \frac{\partial H}{\partial z}. \quad (40.10)$$

Whence in the usual way, multiplying (40.10) by v_z , we find

$$\frac{d}{dt} \left(\frac{1}{2} m v_z^2 \right) = -\mu \frac{\partial H}{\partial t}.$$

Since the total energy of the particle is conserved, we have

$$\frac{d}{dt} \left(\frac{1}{2} m v_z^2 + \frac{1}{2} m v_{\perp}^2 \right) = 0,$$

from which we obtain

$$\frac{d\epsilon_{\perp}}{dt} = \frac{d}{dt} \left(\frac{1}{2} m v_{\perp}^2 \right) = \mu \frac{\partial H}{\partial t}. \quad (40.11)$$

Comparing (40.11) with (40.6), we again arrive at the conclusion that the magnetic moment of the particle is conserved:

$$\frac{\partial \mu}{\partial t} = 0.$$

The conservation of the magnetic moment in a slowly varying non-uniform magnetic field leads to very important consequences. Since

$$\mu = \frac{\epsilon_{\perp}}{H}, \text{ and } R_C = \frac{cmv_{\perp}}{eH} = \frac{c}{eH} \sqrt{2m\epsilon_{\perp}} \sim \frac{1}{H},$$

the radii of the circles on which the particle moves decrease in the direction of increasing values of z (see fig. 1.21).

Let θ_0 be the angle formed by the velocity vector of the particle with the z -axis at a point z_0 , and let θ be the same angle at an arbitrary point. Then at the point $z = z_0$

$$\epsilon_{\perp} = \frac{1}{2} m v_{\perp}^2 = \frac{1}{2} m v_0^2 \sin^2 \theta_0 = \mu H(z_0),$$

where $H(z_0)$ is the value of the magnetic field at the point z_0 . At a certain point z the field strength is equal to $H(z)$, and

$$\epsilon_{\perp} = \mu H(z) = \frac{1}{2} m v_0^2 \sin^2 \theta.$$

Hence we have

$$\sin \theta = \sin \theta_0 \sqrt{\frac{H(z)}{H(z_0)}}.$$

As the particle moves along the z -axis and the field strength increases the angle increases. At a point z^* , where

$$\sqrt{\frac{H(z^*)}{H(z_0)}} \approx \frac{1}{\sin \theta_0},$$

$\sin \theta = 1$ and $v_{\perp} = v_0$. This means that the velocity component v_z of the particle reduces to zero. The particle cannot move farther than the point z^* , but is then reflected into the region $z < z^*$. The region $z \geq z^*$, which is impenetrable for particles with an initial velocity $v_{\perp} = v_0 \sin \theta_0$, is called a magnetic mirror.

The reflection of particles from the magnetic mirror plays a fundamental role in various electronic devices. E. Fermi put forward the idea of the acceleration of particles in cosmic rays as a result of reflection from magnetic mirrors. The role of the latter can be played by clouds of interstellar matter. If it is assumed that in the clouds of interstellar matter the magnetic field strength is larger than in the space separating them, then all particles confined between the clouds will be reflected from them as from magnetic mirrors. Assume that the clouds are moving towards each other with velocities v . Charged particles, colliding with the moving clouds and reflecting from them, change their velocity by $2v$ for each reflection. Calculations show that in cosmic conditions the velocities of the particles could reach enormous values.

In conclusion it should be stressed that all of the results obtained refer only to the motion of particles with velocities small in comparison with the velocity of light c . The motion with velocities comparable with the velocity of light c will be considered in Part II.

§41. The Lagrangian and Hamiltonian for a particle moving in an electromagnetic field

The equations of motion of a particle in an electromagnetic field

$$m \frac{d\mathbf{v}}{dt} = e \left(\mathbf{E} + \frac{1}{c} \mathbf{v} \times \mathbf{H} \right) \quad (41.1)$$

can be written in the form of Lagrange's equations, if the Lagrangian is introduced by the relation

$$L = \frac{1}{2} m v^2 - e\varphi + \frac{e}{c} \mathbf{A} \cdot \mathbf{v}. \quad (41.2)$$

We derive the Lagrange equations:

$$\frac{d}{dt} \frac{\partial L}{\partial \mathbf{v}} - \frac{\partial L}{\partial \mathbf{r}} = 0.$$

Clearly, for the generalized momentum we have

$$\mathbf{P} = \frac{\partial L}{\partial \mathbf{v}} = m \mathbf{v} + \frac{e}{c} \mathbf{A} = \mathbf{p} + \frac{e}{c} \mathbf{A}. \quad (41.3)$$

Correspondingly, the generalized force is

$$\begin{aligned} \left(\frac{\partial L}{\partial \mathbf{r}} \right)_{\mathbf{v}} &= -e \nabla \varphi + \frac{e}{c} \nabla (\mathbf{A} \cdot \mathbf{v}) = \\ &= -e \nabla \varphi + \frac{e}{c} \{ (\mathbf{v} \cdot \nabla) \mathbf{A} + \mathbf{v} \times (\nabla \times \mathbf{A}) \}. \end{aligned}$$

In calculating the partial derivative with respect to coordinates, \mathbf{v} was assumed to be constant.

Substituting these expressions into the Lagrange equations, we find

$$\frac{d}{dt} \left(\mathbf{p} + \frac{e}{c} \mathbf{A} \right) = -e \nabla \varphi + \frac{e}{c} (\mathbf{v} \cdot \nabla) \mathbf{A} + \frac{e}{c} \mathbf{v} \times (\nabla \times \mathbf{A}),$$

or

$$\frac{d\mathbf{p}}{dt} = -\frac{e}{c} \frac{d\mathbf{A}}{dt} + \frac{e}{c} (\mathbf{v} \cdot \nabla) \mathbf{A} + \frac{e}{c} \mathbf{v} \times (\nabla \times \mathbf{A}) - e \nabla \varphi.$$

However, according to (I.18) the total derivative with respect to time will be

$$\frac{d\mathbf{A}}{dt} = \frac{\partial \mathbf{A}}{\partial t} + (\mathbf{v} \cdot \nabla) \mathbf{A},$$

whence

$$\frac{d\mathbf{p}}{dt} = e \left\{ -\frac{1}{c} \frac{\partial \mathbf{A}}{\partial t} - \nabla \varphi \right\} + \frac{e}{c} \mathbf{v} \times (\nabla \times \mathbf{A}),$$

or

$$\frac{d\mathbf{p}}{dt} = e \left(\mathbf{E} + \frac{1}{c} \mathbf{v} \times \mathbf{H} \right),$$

which is the same as (41.1).

We can also write the Hamiltonian for a particle:

$$\begin{aligned} H = \mathbf{P} \cdot \mathbf{v} - L &= \frac{\mathbf{P}}{m} \cdot \left(\mathbf{P} - \frac{e}{c} \mathbf{A} \right) - \frac{1}{2m} \left(\mathbf{P} - \frac{e}{c} \mathbf{A} \right)^2 + \\ &+ e\varphi - \frac{e\mathbf{A}}{mc} \cdot \left(\mathbf{P} - \frac{e}{c} \mathbf{A} \right) = \frac{1}{2m} \left(\mathbf{P} - \frac{e}{c} \mathbf{A} \right)^2 + e\varphi. \end{aligned} \quad (41.4)$$

In the case of a system of independent particles the Lagrangian and the Hamiltonian can be written in the form

$$\begin{aligned} L &= \sum \frac{1}{2} m_i v_i^2 - \sum e_i \varphi_i + \sum \frac{e_i}{c} \mathbf{A}_i \cdot \mathbf{v}_i = \\ &= \sum \frac{1}{2} m_i v_i^2 - \sum e_i \varphi_i + \frac{1}{c} \sum \mathbf{j}_i \cdot \mathbf{A}_i, \end{aligned} \quad (41.5)$$

and, correspondingly,

$$H = \sum \frac{1}{2m_i} \left(\mathbf{P}_i - \frac{e_i}{c} \mathbf{A}_i \right)^2 + \sum e_i \varphi_i, \quad (41.6)$$

where A_i and φ_i are the values of field potentials at the position of the i th particle. The summation is carried out over all particles of the system.

Later we shall need these expressions for the Lagrangian and the Hamiltonian.

It should be noted that, if one introduces the vector potential for a constant uniform magnetic field given by formula (19.16) into the expression for the generalized momentum P_i , then

$$P_i = p_i + \frac{e}{2c} \mathbf{H} \times \mathbf{r}, \quad (41.7)$$

and, consequently,

$$H = \sum \frac{1}{2m_i} \left(P_i - \frac{e_i}{2c} \mathbf{H} \times \mathbf{r} \right)^2 + \sum e_i \varphi_i \quad (41.8)$$

§42. The motion of a system of two charged particles and the radiation from them

Up to now we have considered the motion of particles in external fields. Now we shall discuss the problem of the motion of charged particles in the field produced by other particles.

Let us now consider the problem of the motion of two interacting charged particles*.

This problem can be solved by making use of the method of successive approximations. Namely, assuming the energy losses of the particles due to radiation to be small, the trajectories of the particles can be calculated in the first approximation. Knowing them, one can then find the radiation of the system.

Let the charged particles have masses m_1 and m_2 , and charges e_1 and e_2 . The potential energy of the system can be written in the form

$$U = e_1 \varphi(r),$$

* In what follows we shall confine ourselves to a brief exposition of the problem, since it appears to be a particular case of the two-body problem considered in detail in courses in classical mechanics. A detailed exposition of this and other problems touched upon in this paragraph can be found in: L.D. Landau and E.M. Lifshitz, *Mechanics* (Pergamon, Oxford, 1960), and H. Goldstein, *Classical mechanics* (Addison-Wesley, Reading, Mass., 1950).

where $\varphi(r)$ is the potential of the field produced by the charge e_2 located at a distance r from the charge e_1 .

The Lagrangian of the system can be written

$$L = \frac{1}{2} m_1 v_1^2 + \frac{1}{2} m_2 v_2^2 - e_1 \varphi(r), \quad (42.1)$$

where $\mathbf{v}_1 = \dot{\mathbf{r}}_1$, $\mathbf{v}_2 = \dot{\mathbf{r}}_2$, while \mathbf{r}_1 and \mathbf{r}_2 are radius-vectors drawn to the particles from an arbitrary origin.

Since the potential energy depends only on the distance between the charges, i.e. $U = U(|\mathbf{r}|)$, where

$$\mathbf{r} = \mathbf{r}_1 - \mathbf{r}_2, \quad (42.2)$$

it is convenient to pass over to the centre-of-mass system.

That is to say, we place the origin at the centre of mass, i.e. the spatial point whose radius-vector with respect to an arbitrary system of coordinates is expressed by the formula

$$\mathbf{R} = \frac{m_1 \mathbf{r}_1 + m_2 \mathbf{r}_2}{m_1 + m_2}. \quad (42.3)$$

From (42.2) and (42.3) we find

$$\begin{aligned} \mathbf{r}_1 &= \frac{m_2}{m_1 + m_2} \mathbf{r} + \mathbf{R}, \\ \mathbf{r}_2 &= -\frac{m_1}{m_1 + m_2} \mathbf{r} + \mathbf{R}, \end{aligned}$$

and, correspondingly, the velocities of the particles are

$$\begin{aligned} \mathbf{v}_1 &= \frac{m_2}{m_1 + m_2} \dot{\mathbf{r}} + \dot{\mathbf{R}} = \frac{m_2}{m_1 + m_2} \mathbf{v}_0 + \dot{\mathbf{R}}, \\ \mathbf{v}_2 &= -\frac{m_1}{m_1 + m_2} \dot{\mathbf{r}} + \dot{\mathbf{R}} = -\frac{m_1}{m_1 + m_2} \mathbf{v}_0 + \dot{\mathbf{R}}, \end{aligned} \quad (42.4)$$

where $\mathbf{v}_0 = \dot{\mathbf{r}}$ is the relative velocity of the particles, and $\dot{\mathbf{R}}$ is the velocity of the centre of mass.

Inserting these values of the velocities into the Lagrangian, we find

$$L = \frac{1}{2} M (\dot{\mathbf{R}})^2 + \frac{1}{2} \mu (\dot{\mathbf{r}})^2 - U(|\mathbf{r}|), \quad (42.5)$$

where $M = m_1 + m_2$ is the mass of the system, while the quantity

$$\mu = \frac{m_1 m_2}{m_1 + m_2} \quad (42.6)$$

is called the reduced mass.

The coordinates of the centre of mass \mathbf{R} are cyclic. Hence the corresponding generalized momentum is conserved:

$$\frac{\partial L}{\partial \mathbf{R}} = (m_1 + m_2) \mathbf{R} = \text{const}. \quad (42.7)$$

The centre of mass moves with a constant velocity (in particular, it can remain at rest).

In order to investigate the relative motion of the charges we introduce coordinates whose origin coincides with the centre of mass. Since the potential energy of the interaction depends only on the distance r , the field has spherical symmetry. Therefore the coordinate corresponding to arbitrary rotation of the system is cyclic. This means that the angular momentum conservation law holds:

$$\mathbf{L} = \mathbf{r} \times \mathbf{p} = \text{const}. \quad (42.8)$$

Taking the scalar product of this expression and the radius-vector \mathbf{r} , we have

$$\mathbf{L} \cdot \mathbf{r} = 0,$$

so that the motion takes place in the plane perpendicular to the vector \mathbf{L} .

Choosing the direction of the vector \mathbf{L} to be the z -axis, and the plane in which the motion takes place to be the plane $z = 0$, we can introduce the polar coordinates r, ψ and rewrite the Lagrangian referring to the relative motion in the form

$$L_{\text{rel}} = \frac{1}{2} \mu (\dot{r}^2 + r^2 \dot{\psi}^2) - e_1 \varphi(r). \quad (42.9)$$

The Lagrangian L_{rel} is formally the same as the Lagrangian of one particle having mass μ and moving in the external force field $e_1 \varphi$. The coordinate ψ is cyclic, and the generalized momentum

$$p_\psi = \mu r^2 \dot{\psi} = \text{const} \quad (42.10)$$

corresponds to it. Calculating L_z in polar coordinates, we have, obviously,

$$L_z = [\mathbf{r} \times \mathbf{p}]_z = \mu(xy - yx) = \mu r^2 \dot{\psi}, \quad (42.11)$$

so that the equality

$$p_\psi = L_z = \text{const} = L$$

expresses the angular momentum conservation law.

Since the Lagrangian does not depend on time, the energy conservation law holds:

$$E = \frac{1}{2} \mu (\dot{r}^2 + r^2 \dot{\psi}^2) + e_1 \varphi(r) = \text{const}. \quad (42.12)$$

Expressing $\dot{\psi}$ from (42.11) in terms of L_z , we find

$$E = \frac{1}{2} \mu \dot{r}^2 + \frac{L^2}{2\mu r^2} + e_1 \varphi = \frac{1}{2} \mu \dot{r}^2 + V(r), \quad (42.12')$$

where the quantity $V(r)$, called the effective potential energy, is equal to

$$V(r) = e_1 \varphi(r) + \frac{L^2}{2\mu r^2}. \quad (42.13)$$

The energy (42.12') is formally the same as the energy of a particle moving uniformly in a field with potential energy $V(r)$.

The character of the relative motion of the charged particles is defined by the form of the function $\varphi(r)$.

Here we shall consider the case of oppositely charged particles. Then

$$\varphi = -e_2/r, \quad (42.14)$$

where e_2 is the charge of the second particle.

The variation of the energy as a function of r in this case is shown in fig. I.22. The dashed lines show the curves $-e_1 e_2/r$ and $L^2/2\mu r^2$. The straight line $E = 0$ is given by a dotted line. The shape of the curve $V(r)$ and the position of the minimum depend on the value of the angular momentum L .

Fig. 1.22

Rewriting the formula (42.12') in the form

$$\dot{r}^2 = \frac{2}{\mu}(E - V(r)), \quad (42.15)$$

we see that the allowed region of the relative motion of the particles depends on the relation between E and $V(r)$. The regions in which $V(r) > E$ are forbidden, whereas those in which $E > V(r)$ are allowed. If the roots of the equation

$$E = V(r) \quad (42.16)$$

exist, they determine the radii r_0 at which the radial velocity reduces to zero. If $E \geq 0$, then the allowed region of motion extends from the infinitely distant region $r \rightarrow \infty$ up to the radius corresponding to the minimum distance between the particles and determined by the crossing of the straight line E with the curve $V(r)$.

If $E < 0$, then there are two radii corresponding to the smallest and largest distance between the charges. The motion is performed between these points.

In order to find the trajectory, the time should be eliminated from (42.12') and (42.11).

We then have

$$d\psi = \frac{L}{\mu r^2} dt = \frac{L}{\mu r^2} \frac{dr}{\sqrt{\frac{2}{\mu}(E - e_1\varphi(r)) - \frac{L^2}{\mu^2 r^2}}}.$$

By integration we find

$$\psi = \int \frac{dr}{r^2 \sqrt{\frac{2\mu}{L^2}(E - e_1\varphi) - \frac{1}{r^2}}} - \psi_0. \quad (42.17)$$

In particular, for the motion in the attractive Coulomb field the substitution for $\varphi(r)$ from (42.14) gives

$$\begin{aligned} \psi &= \int \frac{dr}{r^2 \sqrt{\frac{2\mu}{L^2} \left(E + \frac{e_1 e_2}{r} \right) - \frac{1}{r^2}}} = - \int \frac{du}{\sqrt{\frac{2\mu E}{L^2} + \frac{2e_1 e_2 \mu}{L^2} u - u^2}} = \\ &= - \arccos \frac{\frac{L^2 u}{e_1 e_2 \mu} - 1}{\sqrt{1 + \frac{2EL^2}{\mu(e_1 e_2)^2}}} - \psi_0, \end{aligned}$$

where

$$u = 1/r.$$

We find for the equation of the trajectory:

$$\left(\frac{L^2}{\mu e_1 e_2} \right) \frac{1}{r} = \left[1 + \sqrt{1 + \frac{2EL^2}{\mu(e_1 e_2)^2}} \cos(\psi + \psi_0) \right]. \quad (42.18)$$

Comparing this formula with the general equation of conic sections

$$p/r = 1 + \epsilon \cos(\psi + \psi_0),$$

where ϵ is the eccentricity, we see that the motion of the charges takes place over a conic section with eccentricity

$$\epsilon = \sqrt{1 + \frac{2EL^2}{\mu(e_1e_2)^2}}. \quad (42.19)$$

The parameter of the conic section is $p = L^2/\mu e_1 e_2$. Depending on the sign of E we have

$$E > 0, \quad \epsilon > 1 \quad \text{hyperbola}$$

$$E = 0, \quad \epsilon = 1 \quad \text{parabola}$$

$$E < 0, \quad \epsilon < 1 \quad \text{ellipse}$$

$$E = -\frac{\mu(e_1e_2)^2}{2L^2}, \quad \epsilon = 0 \quad \text{circle}.$$

The solution (42.18) determines the motion of each of the particles. Namely, the particles move on trajectories representing conic sections with the foci located at the centre of mass of the system.

This solution does not differ from the corresponding solution of the Kepler problem on the motion of planets. The values of the quantities characteristic of conic sections are given in the books on mechanics cited.

Let us now find the radiation from a system of two charges. Here we confine ourselves to the case of periodic motion, i.e. to the case of attraction for $E < 0$. The energy emitted during a period T is, according to (27.9) and (28.11), equal to

$$-(\Delta E)_T = \frac{2}{3c^3} \int (\ddot{\mathbf{d}})^2 dt = \frac{2}{3c^3} \left(\frac{e_1}{m_1} - \frac{e_2}{m_2} \right)^2 \int_0^T F^2 dt,$$

where

$$\mathbf{F} = \frac{e_1 e_2}{r^3} \mathbf{r}.$$

Instead of integrating over a period, we can integrate over the angle ψ by means of (42.11). Expressing r in terms of ψ according to formula (42.11), we obtain

$$\begin{aligned}
-(\Delta E)_T &= \frac{2}{3c^3} \left(\frac{e_1}{m_1} - \frac{e_2}{m_2} \right)^2 (e_1 e_2)^2 \int \frac{dt}{r^4} = \\
&= \frac{2}{3c^3} \left(\frac{e_1}{m_1} - \frac{e_2}{m_2} \right)^2 (e_1 e_2)^2 \frac{\mu}{L} \int_0^{2\pi} \frac{d\psi}{r^2} = \\
&= \frac{2}{3c^3} \left(\frac{e_1}{m_1} - \frac{e_2}{m_2} \right)^2 \frac{(e_1 e_2 \mu)^4}{\mu L^5} \int_0^{2\pi} [1 + \epsilon \cos(\psi + \psi_0)]^2 d\psi = \\
&= \frac{2}{3c^3} \left(\frac{e_1}{m_1} - \frac{e_2}{m_2} \right)^2 \frac{(e_1 e_2 \mu)^4 \pi}{\mu L^5} (2 + \epsilon^2). \quad (42.20)
\end{aligned}$$

Thus, a charge moving in a closed orbit continuously emits energy. In particular, for motion in a circular orbit $\epsilon = 0$, $L^2 = -\mu(e_1 e_2)^2/2E$, and formula (42.20) reduces to the simpler form:

$$-(\Delta E)_T = \frac{16\pi\sqrt{2\mu}}{3c^3 e_1 e_2} \left(\frac{e_1}{m_1} - \frac{e_2}{m_2} \right)^2 |E|^{5/2} \quad (42.21)$$

The energy loss due to radiation leads to the transformation of the circular orbit into a spiral.

Numerical calculation shows that a system consisting of an electron rotating about a proton emits its energy during a time $T \approx 10$ sec for linear dimensions of the orbit $\sim 10^{-8}$ cm.

We see that a planetary atomic model contradicts the laws of classical electrodynamics. Later, in expounding quantum mechanics, the cause of this contradiction will be explained. It turns out that the instability of the planetary atomic model is an illustration of the general statement on the inapplicability of the laws of classical electrodynamics to the consideration of intra-atomic phenomena.

§43. The scattering of particles and associated bremsstrahlung

We shall now consider processes in which the particles are in relative motion with either a repulsive or attractive interaction, but having an energy $E > 0$. From general considerations associated with the shape of the curve $V(r)$ (see fig. 1.22) it is clear that in both cases the motion will take place in an open orbit.

For simplicity we assume that one of the charged particles is at rest with respect to the laboratory system of coordinates. We call it the target. The other, incident particle, which is scattered, moves relative to the first one. At a sufficiently large distance, when the interaction between the particles can be disregarded, the motion of the incident particle is rectilinear. We assume that the velocity v_0 of this motion is given. When the particles approach each other the incident particle is deflected from its rectilinear motion, and the target particle, which was initially at rest, acquires momentum and is set in motion.

The particles are said to have undergone collision with each other, as a result of which they are scattered.

For reasons which will be clear from what follows, the investigation of the process of scattering leads to most important information about the nature of the interaction between the particles.

The study of scattering processes appears at present to be the basic experimental method of nuclear physics. The investigation of the interaction of particles, for example, fast electrons or protons with nuclei, is usually carried out in the following way. A beam of particles having well defined properties and a known velocity is incident upon a sample of matter containing particles of another kind. From observations on the beam of scattered particles one can draw conclusions about the nature of the interaction which led to the scattering.

In such an experimental set-up, scattering has the character of a bulk process. The behaviour of a beam, usually containing an enormous number of particles, is observed. However, the process is based on the individual interaction between the particle to be scattered and the target particle. Hence the process of scattering must be characterized by a quantity which depends neither on the properties of the incident beam nor on the properties of the target material, for example, its density, but which is determined solely by the interaction between a particle which is to be scattered and a target particle.

We characterize the incident particle beam by its intensity or the density of the flux of particles $I_0 = nv_0$, where n is the number of particles per unit volume of the beam, and v_0 is their velocity. I_0 is obviously equal to the number of particles traversing 1 cm^2 of the cross section of the beam per sec.

We choose the position of the target particle to be the origin. Let dN scattered particles per unit time enter the solid angle $d\Omega$ about the scattering centre. We define the basic quantity characterizing the process of scattering — the differential cross section for the scattering, $d\sigma$ — as the ratio

$$d\sigma = dN/I_0. \quad (43.1)$$

The cross section obviously has the dimensions of area. The number of particles scattered from the beam by the target volume V into the solid angle $d\Omega$ during the time dt is equal to

$$dN_{\text{tot}} = d\sigma I_0 \rho V dt, \quad (43.2)$$

where ρ is the number density of the target particles (ρV is the total number of target particles).

If the scattering occurs without a change in the energy of the scattered particles, then, multiplying the numerator and the denominator of (43.1) by the energy ϵ of the particle, we can write the differential cross section in the form

$$d\sigma = dI/I_{0\epsilon}, \quad (43.3)$$

where dI is the flux of energy carried by the particles per unit time in the solid angle $d\Omega$, and $I_{0\epsilon}$ is the intensity of the energy flux in the incident beam. Formula (43.3) is the same as the definition of cross section given in §36.

In addition to the differential cross section, scattering is also characterized by the total cross section

$$\sigma = \int d\sigma, \quad (43.4)$$

where the integration is carried out over all possible values of solid angle.

The quantity $d\sigma$, expressed in terms of directly measurable quantities, can be connected with parameters characterizing the individual collision process.

Consider an individual act of collision between two particles. We confine ourselves to the case where the internal energy of the particles remains unchanged. Such collisions are called elastic. It should not be thought that in elastic collisions the energy of the scattered particle does not change. The target particle receives from the scattered one a certain momentum and energy, whose value depends on the mass ratio of the particles.

In inelastic collisions, for example collision of an electron with an ion, there occurs an additional transfer of energy to the ion, whose internal state changes. Such processes are more complicated and will be considered in Part V.

Fig. 1.23

At first we shall refer the process of scattering of two particles to the centre-of-mass system. According to the results of the preceding paragraph, the problem of the relative motion of particles in the centre-of-mass system reduces to the problem of the motion of one particle with reduced mass μ relative to the motionless force centre located at the centre of mass.

At a large distance from the centre of mass let the incident particle move rectilinearly with a velocity v_0 . Its energy and angular momentum are respectively equal to

$$E = \frac{\mu v_0^2}{2}, \quad L = \mu v_0 \rho = \rho \sqrt{2\mu E}, \quad (43.5)$$

where ρ is the distance between the force centre and the straight line along which the particle would pass by if there were no interaction. The quantity ρ is called the impact parameter.

For given values of E and ρ the trajectory is completely determined. We characterize the process of scattering by the scattering (deflection) angle θ , representing the angle between the directions of motion of the particle at a large distance from the centre before and after the scattering (see fig. 1.23). It is obvious that the angle θ is the complement of the angle ψ_0 between the asymptotes of the trajectory (fig. 1.24). Because of the symmetry of the force field and the distribution of the trajectories relative to the axis of the beam, the number of scattered particles and the cross section for scattering depend only on the angle θ and not on the azimuthal angle.

The solid angle $d\Omega$ can therefore be written in the form

$$d\Omega = 2\pi \sin \theta \, d\theta.$$

Fig. 1.24

The number of particles scattered into the solid angle $d\Omega$ is correspondingly equal to

$$dN = 2\pi I_0 \sigma(\theta) \sin \theta \, d\theta = I_0 \, d\sigma, \quad (43.6)$$

where

$$d\sigma = 2\pi \sigma(\theta) \sin \theta \, d\theta.$$

Since the trajectory of the scattered particle is uniquely determined by the energy and the impact parameter (E and ρ), there corresponds to each scattering angle a trajectory with a definite value of the impact parameter. Hence it follows that the number of particles scattered at a given angle θ is equal to the number of particles having given value of the impact parameter at an infinitely large distance from the centre.

In other words, all particles having a value of the impact parameter lying in the interval $\rho, \rho + d\rho$ are scattered into the solid angle $d\Omega$. Hence the number of scattered particles can also be written in the form

$$-dN = I_0 2\pi \rho \, d\rho, \quad (43.7)$$

where $2\pi \rho \, d\rho$ is the area of the ring shown in fig. 1.23 on the left.

Comparing (43.6) and (43.7) we find

$$\sigma(\theta) = -\frac{\rho}{\sin \theta} \frac{d\rho}{d\theta} = \frac{\rho}{\sin \theta} \left| \frac{d\rho}{d\theta} \right| \quad (43.8)$$

Since to large values of ρ there correspond small deflections θ , and since the cross section, by definition, must have a positive value, we have written the absolute value of the derivative. Integrating formula (43.8) on the left with respect to scattering angles in the interval from θ to π , and on the right with respect to the corresponding values of ρ , i.e. in the interval from $\rho(\theta)$ to zero, we obtain the important relation

$$\frac{1}{2}\rho^2(\theta) = \int_{\theta}^{\pi} \sigma(\theta) \sin \theta \, d\theta. \quad (43.9)$$

In order to calculate the differential cross section it is necessary to establish a relation between the impact parameter ρ and the scattering angle θ . For this it is sufficient to calculate the trajectory and find the dependence of the angle ψ_0 between the asymptotes on the parameter ρ .

General formula (42.17) gives

$$\begin{aligned} \psi_0 &= \int \frac{L}{r^2} \frac{dr}{\sqrt{2\mu(E - U(r)) - \frac{L^2}{r^2}}} = \int \frac{dr}{r^2 \sqrt{\frac{2\mu(E - U(r))}{L^2} - \frac{1}{r^2}}} = \\ &= \int \frac{dr}{r^2 \sqrt{\frac{1}{\rho^2} \left(1 - \frac{U(r)}{E}\right) - \frac{1}{r^2}}} \end{aligned} \quad (43.10)$$

The limits of the integral are determined from the following considerations. The angle ψ_0 represents the change in the angle ψ when the particle describes all its trajectory. The trajectory has two branches: the motion of the particle from infinity to the point of closest approach r_0 , and its motion away from the point r_0 to infinity (see fig. I.24). The trajectory of the particle is always symmetric relative to the point of closest approach r_0 . This follows from the reversibility of the process of scattering: the particle moving in the opposite direction must move on the same asymptote on which the particle moves forward (see fig. I.24). Hence the integral over the trajectory can be written in the form of the sum of two equal integrals taken in the range from r_0 to infinity:

$$\psi_0 = 2 \int_{r_0}^{\infty} \frac{dr}{r^2 \sqrt{\frac{1}{\rho^2} \left(1 - \frac{U(r)}{E}\right) - \frac{1}{r^2}}}, \quad (43.11)$$

where r_0 is the root of the equation

$$E = V(r_0) = U(r_0) + \frac{\rho^2 E}{r_0^2}. \quad (43.12)$$

Since the scattering angle is $\theta = \pi - \psi_0$, formulae (43.11) and (43.12) connect the value of θ sought with the parameters of the collision — i.e. the quantities E and ρ — for an arbitrary form of the potential U depending only on the distance r .

Let us consider, in particular, the case of Coulomb repulsion:

$$U = |e_1 e_2| / r.$$

Expressions (43.12) and (43.11) then take the forms

$$E = \frac{|e_1 e_2|}{r_0} + \frac{\rho^2 E}{r_0^2}, \quad (43.13)$$

or

$$\frac{1}{r_0} = -\frac{|e_1 e_2|}{2E\rho^2} + \sqrt{\left(\frac{|e_1 e_2|}{2E\rho^2}\right)^2 + \frac{1}{\rho^2}} \quad (43.14)$$

and

$$\psi_0 = 2 \int_{r_0}^{\infty} \frac{dr}{r^2 \sqrt{\frac{1}{\rho^2} \left(1 - \frac{|e_1 e_2|}{Er}\right) - \frac{1}{r^2}}} \quad (43.15)$$

Introducing the new variable $z = 1/r$, we obtain

$$\begin{aligned} \psi_0 &= 2 \int_0^{z_0} \frac{dz}{\sqrt{\frac{1}{\rho^2} - \frac{|e_1 e_2|}{\rho^2 E} z - z^2}} = -2 \arccos \frac{\frac{|e_1 e_2|}{2\rho^2 E} + z}{\sqrt{\left(\frac{|e_1 e_2|}{2\rho^2 E}\right)^2 + \frac{1}{\rho^2}}} \bigg|_0^{z_0} = \\ &= 2 \arccos \frac{\frac{|e_1 e_2|}{2\rho^2 E}}{\sqrt{\left(\frac{|e_1 e_2|}{2\rho^2 E}\right)^2 + \frac{1}{\rho^2}}}. \end{aligned} \quad (43.16)$$

In the calculation we substituted the value $z_0 = 1/r_0$ from expression (43.14). Further we find

$$\cos \frac{1}{2}\psi_0 = \frac{\frac{|e_1 e_2|}{2\rho^2 E}}{\sqrt{\left(\frac{|e_1 e_2|}{2\rho^2 E}\right)^2 + \frac{1}{\rho^2}}},$$

or

$$\rho = \frac{|e_1 e_2|}{2E} \tan \frac{1}{2}\psi_0 = \frac{|e_1 e_2|}{2E} \tan \frac{1}{2}(\pi - \theta) = \frac{|e_1 e_2|}{2E} \cot \frac{1}{2}\theta. \quad (43.17)$$

Formula (43.17) gives the relation sought between ρ and θ . Substituting the value of ρ into (43.8), we have

$$\sigma(\theta) = \frac{\rho}{\sin \theta} \left| \frac{d\rho}{d\theta} \right| = \frac{1}{16} \frac{(e_1 e_2)^2}{E^2} \frac{1}{\sin^4 \frac{1}{2}\theta}. \quad (43.18)$$

Formula (43.18) gives the differential cross section for the scattering of particles which repel each other according to Coulomb's law. Since $\sigma \sim (e_1 e_2)^2$, it is clear that an identical result is obtained in the case of attraction (for $E > 0$). The expression found for the cross section is called the Rutherford formula. It was obtained in connection with experiments on the scattering of α -particles by atoms which allowed Rutherford to establish the nuclear structure of atoms.

Formula (43.11) can be inverted and the form of the function $U(r)$ can be found from the results of experiment. For this it is necessary to consider (43.11) as an integral equation with respect to the unknown function $U(r)$. Under certain (very general) assumptions about the form of the function $U(r)$ eq. (43.11) can be solved*.

We write θ in the form

$$\theta = \pi - \psi_0 = \pi - \int_{r_0}^{\infty} \frac{2\rho dr}{r \sqrt{\left(1 - \frac{U(r)}{E}\right) r^2 - \rho^2}}. \quad (43.19)$$

As for $U(r)$ we shall assume that it decreases with increasing r for $r \rightarrow \infty$. We introduce a new function

* We follow the work of O.B. Firsov, Zhur. Exp. i Teoret. Fiz. 24 (1953) 279.

$$F(r) = \left(1 - \frac{U(r)}{E}\right) r^2, \quad (43.20)$$

and go over from integration with respect to r to integration with respect to F . Since

$$2 \frac{dr}{r} = 2 d \ln r = \frac{d \ln r^2}{dF} dF,$$

and, using (43.12),

$$F(r_0) = \left(1 - \frac{U(r_0)}{E}\right) r_0^2 = \rho^2, \quad F(\infty) = \infty \quad (43.21)$$

we have

$$\theta = \pi - \int_{F(r_0)}^{F(\infty)} \rho \frac{d \ln r^2}{dF} \frac{dF}{\sqrt{F - \rho^2}}. \quad (43.22)$$

Writing

$$\frac{d \ln r^2}{dF} \equiv \frac{d}{dF} \ln \left(\frac{r^2}{F} \right) + \frac{d \ln F}{dF},$$

we find, substituting for the bounds $F(r_0)$ and $F(\infty)$ the values (43.21),

$$\theta = \pi + \int_{\rho^2}^{\infty} \rho \frac{d}{dF} \ln \left(\frac{F}{r^2} \right) \frac{dF}{\sqrt{F - \rho^2}} - \int_{\rho^2}^{\infty} \rho \frac{d \ln F}{dF} \frac{dF}{\sqrt{F - \rho^2}}.$$

The last integral is easy to calculate, because

$$\int_{\rho^2}^{\infty} \frac{dF}{F \sqrt{F - \rho^2}} = \frac{2}{\rho} \arctan \frac{\sqrt{F - \rho^2}}{\rho} \bigg|_{\rho^2}^{\infty} = \frac{\pi}{\rho}.$$

Hence

$$\theta = \int_{\rho^2}^{\infty} \rho \frac{d \ln \left(\frac{F'}{r'^2} \right)}{dF'} \frac{dF'}{\sqrt{F' - \rho^2}}. \quad (43.23)$$

We multiply both sides of (43.23) by the factor $1/\sqrt{\rho^2 - F}$ and integrate with respect to the parameter ρ in the range from $\rho = \sqrt{F}$ to $\rho \rightarrow \infty$. Then we have

$$\int_{\sqrt{F}}^{\infty} \frac{\theta(\rho) d\rho}{\sqrt{\rho^2 - F}} = \int_{\sqrt{F}}^{\infty} \rho d\rho \int_{\rho^2}^{\infty} \frac{d \ln \left(\frac{F'}{r'^2} \right)}{dF'} \frac{dF'}{\sqrt{(\rho^2 - F)(F' - \rho^2)}}.$$

We change the order of integration with respect to ρ and F' , writing

$$\begin{aligned} \int_{\sqrt{F}}^{\infty} \rho d\rho \int_{\rho^2}^{\infty} \frac{d \ln \left(\frac{F'}{r'^2} \right)}{dF'} dF' &= \\ &= \int_F^{\infty} \frac{d \ln \left(\frac{F'}{r'^2} \right)}{dF'} dF' \int_{\sqrt{F'}}^{\sqrt{F}} \frac{\rho d\rho}{\sqrt{-\rho^4 + \rho^2(F + F') - FF'}}. \end{aligned}$$

Further,

$$\begin{aligned} \frac{1}{2} \int_{\rho=\sqrt{F'}}^{\rho=\sqrt{F}} \frac{d\rho^2}{\sqrt{-\rho^4 + \rho^2(F + F') - FF'}} &= \\ &= -\frac{1}{2} \arcsin \frac{(F + F') - \rho^2}{\sqrt{(F + F')^2 - 4FF'}} \Big|_{\rho=\sqrt{F'}}^{\rho=\sqrt{F}} = \frac{1}{2} \pi. \end{aligned}$$

The fact that, as a result of integration with respect to ρ , a factor independent of F' is obtained allows us to reduce the integration with respect to F' to an elementary transformation. In order to obtain a more explicit result we return, before making the substitution of the limits, to the variable r , writing

$$\begin{aligned} \int_{F(r)}^{F(\infty)} \frac{d}{dF'} \ln \left(\frac{F'}{r'^2} \right) dF' &= \int_r^{\infty} \frac{d}{dr'} \ln \left(\frac{F'}{(r')^2} \right) dr' = \\ &= \ln \left(1 - \frac{U(r')}{E} \right) \Big|_r^{\infty} = -\ln \left(1 - \frac{U(r)}{E} \right) = -\ln \frac{F}{r^2}. \end{aligned}$$

According to the above assumption we put $U \rightarrow 0$ as $r \rightarrow \infty$.

As a result we arrive at the equality

$$\pi \ln \frac{\sqrt{F}}{r} = - \int_{\sqrt{F}}^{\infty} \frac{\theta(\rho) d\rho}{\sqrt{F} \sqrt{\rho^2 - F}}, \quad (43.24)$$

or

$$\frac{\sqrt{F}}{r} = \exp \left\{ - \frac{1}{\pi} \int_{\sqrt{F}}^{\infty} \frac{\theta(\rho) d\rho}{\sqrt{\rho^2 - F}} \right\}. \quad (43.25)$$

The last expression contains integration only with respect to ρ . If the dependence $\sigma(\theta)$ is known, then by virtue of (43.19) the functional dependence $\theta(\rho)$ is also given. Hence formula (43.25) gives the function $F(r)$ in implicit form.

A particularly simple result is obtained for the scattering of particles with a large energy, for which $U(r) \ll E$ for all values of r . Then formula (43.23) can be rewritten, making use of the equalities

$$\ln \frac{\sqrt{F}}{r} = \ln \frac{\sqrt{\left(1 - \frac{U(r)}{E}\right) r^2}}{r} \approx - \frac{U(r)}{2E},$$

$$\int_{\sqrt{F}}^{\infty} \frac{\theta(\rho) d\rho}{\sqrt{F} \sqrt{\rho^2 - F}} = \int_{\sqrt{\left(1 - \frac{U(r)}{E}\right) r^2}}^{\infty} \frac{\theta(\rho) d\rho}{\sqrt{\rho^2 - \left(1 - \frac{U(r)}{E}\right) r^2}} \approx \int_r^{\infty} \frac{\theta(\rho) d\rho}{\sqrt{\rho^2 - r^2}}.$$

and we find the potential energy sought:

$$U(r) \approx \frac{2E}{\pi} \int_r^{\infty} \frac{\theta(\rho) d\rho}{\sqrt{\rho^2 - r^2}}. \quad (43.26)$$

The above calculations of the scattering cross section have been carried out in the centre-of-mass system. For their practical use it is necessary to make a transition to the laboratory system.

The importance of this transition is seen from the general picture of the process of scattering from the point of view of the two coordinate systems. In

Fig. I.25

Fig. I.26

the centre-of-mass system each of the particles, the incident and the target one, move on a trajectory determined by formula (43.10). From the fact that the total momentum of the system of two particles, referred to the centre-of-mass system, is equal to zero it follows that the two particles move in opposite directions with equal momenta (fig. I.25). On the contrary, from the standpoint of the laboratory system the incident and target particles are not equivalent. Before collision the target particle was at rest. After collision it is set in motion (fig. I.26).

Our problem is to establish a relation between the angles $\theta_{c.m.}$ in the centre-of-mass system and θ_1 in the laboratory system. For this we put in the same diagram the velocities of the scattered particle after collision in the centre-of-mass ($\mathbf{v}'_{c.m.}$) and laboratory (\mathbf{v}'_1) systems. It is obvious that equalities (42.4) and (42.7) hold. The vector \mathbf{R} coincides with the direction of motion of the incident particle. Hence the angles sought for are respectively equal to (fig. I.27):

$$\begin{aligned}\theta_{c.m.} &= \angle(\mathbf{v}'_{c.m.}, \dot{\mathbf{R}}), \\ \theta_1 &= \angle(\mathbf{v}'_1, \dot{\mathbf{R}}),\end{aligned}\tag{43.27}$$

Fig. I.27

where the prime denotes that the values of the velocity are taken after collision. For brevity we omitted the index 1 occurring in (42.4).

From fig. 1.27 it is clear that

$$\tan \theta_1 = \frac{v'_{c.m} \sin \theta_{c.m}}{v'_{c.m} \cos \theta_{c.m} + |\dot{\mathbf{R}}|}. \quad (43.28)$$

According to (42.4) and (42.7) we can write

$$\dot{\mathbf{R}} = \frac{m_1}{m_1 + m_2} \mathbf{v}_0, \quad \text{since } \mathbf{v}_1 = \mathbf{v}_0, \mathbf{v}_2 = 0,$$

$$\mathbf{v}'_{c.m} = \frac{\mu}{m_1} \mathbf{v}_0, \quad \text{since } \mathbf{v}'_{c.m} = \dot{\mathbf{v}}_0 - \dot{\mathbf{R}}.$$

Substituting into (43.28), we have

$$\tan \theta_1 = \frac{\sin \theta_{c.m}}{\cos \theta_{c.m} + \frac{m_1}{m_2}} \quad (43.29)$$

Formula (43.29) establishes* the relation between the angles $\theta_{c.m}$ and θ_1 .

It should be noted that, if the mass of the target particle is $m_2 \gg m_1$, then $\theta_1 \approx \theta_{c.m}$. The meaning of this result is obvious: a very heavy particle obtains no momentum from the incident particle and remains at rest — the centre-of-mass system coincides with the laboratory system.

Knowing the relation between the scattering angles in the laboratory and centre-of-mass systems, we can express the corresponding cross sections in terms of each other. Namely, writing the number of particles scattered into the solid angle $d\Omega_1$ and $d\Omega_{c.m}$ in the two coordinate systems

$$dN = 2\pi I_0 \sigma_1(\theta_1) \sin \theta_1 d\theta_1,$$

$$dN = 2\pi I_0 \sigma_{c.m}(\theta_{c.m}) \sin \theta_{c.m} d\theta_{c.m},$$

we find the relation sought for between the cross sections in the laboratory (σ_1) and centre-of-mass ($\sigma_{c.m}$) systems:

* It should be stressed that this refers only to elastic collisions, because in such collisions the relative velocity before and after the collision has the value v_0 .

$$\sigma_1(\theta_1) = \sigma_{c.m.}(\theta_{c.m.}) \frac{\sin \theta_{c.m.} d\theta_{c.m.}}{\sin \theta_1 d\theta_1}. \quad (43.30)$$

In contrast to the differential cross section, the total cross section is the same in all coordinate systems:

$$\sigma = 2\pi \int \sigma_1(\theta_1) \sin \theta_1 d\theta_1 = 2\pi \int \sigma_{c.m.}(\theta_{c.m.}) \sin \theta_{c.m.} d\theta_{c.m.}. \quad (43.31)$$

We shall also dwell on the calculation of the energy lost by the scattered particle. From fig. 1.27 we can write, on the basis of the cosine theorem, that

$$(v'_{c.m.})^2 = (v_1')^2 + \dot{R}^2 - 2\dot{R}(v_1') \cos \theta_1. \quad (43.32)$$

Substituting the values of \dot{R} and $v'_{c.m.}$ and denoting by E_1 and E'_1 the energy of the scattered particle respectively before and after collision in the laboratory system, we find

$$\frac{E'_1}{E_1} - \frac{2\mu}{m_2} \frac{\sqrt{E'_1}}{\sqrt{E_1}} \cos \theta_1 - \frac{m_2 - m_1}{m_2 + m_1} = 0. \quad (43.33)$$

Eq. (43.33) determines the dependence of E'_1 on the scattering angle θ_1 and the mass of the particles. The largest energy loss takes place when $m_1 = m_2$ and $\theta_1 = \frac{1}{2}\pi$ (in this case $\theta_{c.m.} = \pi$). In this case $E'_1 = 0$ and the energy is completely transferred to the target particle.

We shall not dwell on other details of the theory of scattering which are covered in the books cited.

Now we turn to the calculation of the radiation arising when a beam of charged particles passes by charges at rest. This phenomenon, called bremsstrahlung, gives rise to X-rays (with a continuous spectrum) and plays an important role in the deceleration of high-energy particles moving in matter.

Since it is just high-energy particles that are of basic interest, we shall restrict ourselves to this case.

When the incident particle has a sufficiently large energy its scattering angle is small, if the improbable processes of central collision are excluded. Considering the trajectory to be almost rectilinear, one can simplify the corresponding formulae.

Let us first of all consider the radiation emitted by one particle. Locating the origin at the scattering centre, one can write the following expression for the components of forces acting on the incident particle:

$$F_x = \frac{e_1 e_2}{r^3} x, \quad F_y = \frac{e_1 e_2}{r^3} y. \quad (43.34)$$

Since the motion takes place in the (xy) plane, the component F_z of the force is absent.

Assuming that the velocity of motion of the particle is constant and is not changed by the scattering, and that the deflection from the rectilinear trajectory is small *, one can put in the formulae for the force components

$$x \approx vt, \quad y \approx \rho, \quad dt \approx dx/v. \quad (43.35)$$

The energy emitted by the particle into the solid angle $d\Omega$ in passing by the scattering centre is found by integrating the formula (28.11) (in which it should be assumed that $m_2 \rightarrow \infty$) with respect to the transit time. Taking into account (43.35), we have

$$\begin{aligned} -\Delta E d\Omega &= \int dI dt = \frac{1}{4\pi c^3} d\Omega \int [\ddot{\mathbf{d}} \times \mathbf{n}]^2 dt = \\ &= \frac{1}{4\pi c^3} \frac{e_1^2}{vm_1^2} d\Omega \int_{-\infty}^{+\infty} [\mathbf{F} \times \mathbf{n}]^2 dx. \end{aligned}$$

Developing the expression $[\mathbf{F} \times \mathbf{n}]^2$, we have

$$\begin{aligned} [\mathbf{F} \times \mathbf{n}]^2 &= F^2 - (\mathbf{F} \cdot \mathbf{n})^2 = F_x^2 + F_y^2 - (F_x n_x + F_y n_y)^2 = \\ &= (1 - n_x^2) F_x^2 + (1 - n_y^2) F_y^2 - 2F_x F_y n_x n_y, \end{aligned}$$

where n_x and n_y are the components of the unit vector \mathbf{n} in the direction of the solid angle $d\Omega$.

We now have to integrate three integrals. The first of them is

$$\int_{-\infty}^{+\infty} F_x^2 dx = e_1^2 e_2^2 \int_{-\infty}^{+\infty} \frac{x^2}{r^6} dx = 2e_1^2 e_2^2 \int_0^{+\infty} \frac{x^2 dx}{(x^2 + \rho^2)^3}.$$

* L.D.Landau and E.M.Lifshitz, *Mechanics* (Pergamon Press, Oxford, 1960).

Putting $x/\rho = \tan \varphi$, we find

$$\begin{aligned}
 \int_{-\infty}^{+\infty} F_x^2 dx &= 2e_1^2 e_2^2 \int_0^{+\infty} \frac{x^2 dx}{(x^2 + \rho^2)^3} = \\
 &= 2 \frac{e_1^2 e_2^2}{\rho^3} \int_0^{\pi/2} \frac{\tan^2 \varphi}{(\tan^2 \varphi + 1)^3} \frac{d\varphi}{\cos^2 \varphi} = \\
 &= \frac{2e_1^2 e_2^2}{\rho^3} \int_0^{\pi/2} \sin^2 \varphi \cos^2 \varphi d\varphi = \\
 &= \frac{e_1^2 e_2^2}{2\rho^3} \int_0^{\pi/2} \sin^2 2\varphi d\varphi = \frac{\pi e_1^2 e_2^2}{8\rho^3}.
 \end{aligned}$$

The second and third integrals are calculated in an analogous way:

$$\int_{-\infty}^{\infty} F_y^2 dx = 2e_1^2 e_2^2 \rho^2 \int_0^{\infty} \frac{dx}{r^6} = \frac{3\pi e_1^2 e_2^2}{8\rho^3},$$

$$\int_{-\infty}^{\infty} F_x F_y dx = 0,$$

since $F_x F_y$ is an odd function of x . Finally,

$$\begin{aligned}
 -\Delta E d\Omega &= \frac{e_1^4 e_2^2}{32c^3 v m_1^2} \frac{1}{\rho^3} \{ (1 - n_x^2) + 3(1 - n_y^2) \} d\Omega = \\
 &= \frac{e_1^4 e_2^2}{32c^3 v m_1^2} \frac{1}{\rho^3} \{ 4 - \sin^2 \theta \cos^2 \psi - \\
 &\quad - 3 \sin^2 \theta \sin^2 \psi \} \sin \theta d\theta d\psi.
 \end{aligned} \tag{43.36}$$

The energy emitted is inversely proportional to the velocity and third power of the impact parameter ρ , and depends in a rather complicated way

on the angles. A simple calculation gives for the total irradiated energy

$$-\Delta E_{\text{tot}} = -\int \Delta E \, d\Omega = \frac{\pi}{3} \frac{e_1^4 e_2^2}{c^3 m_1^2 v} \frac{1}{\rho^3}. \quad (43.37)$$

In practice the calculation of the energy loss of a fast charged particle per unit path length in matter is of basic interest. The target centres deflecting the particle are nuclei with a charge $e_2 = Ze$, where Z is the atomic number of the element and e is the charge of an electron (scattering by electrons can be disregarded). In scattering on each nucleus the particle emits energy determined by formula (43.37). Multiplying (43.37) by the number of nuclei per unit length in a cylindrical shell of radius ρ , $\rho + d\rho$ and integrating over all impact parameters, we find for the energy loss

$$\begin{aligned} -\frac{dE}{dx} &= -\int \Delta E_{\text{tot}} N 2\pi\rho \, d\rho = \frac{2\pi^2 e_1^4 Z^2 e^2 N}{3c^3 m_1^2 v} \int_{\rho_{\min}}^{\infty} \frac{d\rho}{\rho^2} = \\ &= \frac{2\pi^2 Z^2 e^2 e_1^4 N}{3c^3 m_1^2 v} \frac{1}{\rho_{\min}}, \end{aligned} \quad (43.38)$$

where N is the number of nuclei per cm^3 and ρ_{\min} is a certain minimum value of the impact parameter.

If there were no minimum limiting distance, formula (43.38) would lead to a senseless result: the energy loss of the particle due to radiation along its path in matter would be infinitely large. However, in reality it turns out that the laws of classical physics become inapplicable at small distances from the nucleus. The calculation of the minimum value of the impact parameter can be carried out only on the basis of quantum mechanics (see also §17 of Part II).

PART II

THEORY OF RELATIVITY

General Principles of the Theory of Relativity

§ 1. The creation and significance of the theory of relativity

The development by the end of the 19th and the beginning of the 20th century of the theory of the electromagnetic field, and the improvement of experimental methods of investigating electromagnetic processes allowed investigators to carry out a persistent search for direct proofs of the existence of the hypothetical ether. Within the scope of this book we cannot describe the history of this search, which did not lead to the discovery of the ether but to the development of a new view of the physical world and to the complete rejection of the concepts of space and time which had been established in physics by the end of the last century.

These classical concepts were closely associated with the successes of classical mechanics. The principles of the classical view of physics can be expressed briefly in the following words:

1. A physical phenomenon can be considered to be thoroughly understood only when a mechanical model of it has been constructed.

2. The only possible form of physical law is a dynamical law of classical mechanics. As is known, in classical mechanics it is assumed that the specification of the forces which are acting and the initial conditions completely determines the motion of any mechanical system. Thus, the initial state determines completely the behaviour of the system at any subsequent instant. It is this statement which is contained in the idea of a dynamical law.

3. All physical processes take place in space and time. The properties of space and time are established in classical mechanics. Any physical theory must be constructed according to mechanics.

It was assumed that the properties of space reduce to:

- 1) the equivalence of all directions (isotropy);
- 2) the equivalence of all points of space (homogeneity);
- 3) the Euclidean nature of space.

It was assumed that, although the motion of physical bodies always takes place in space, the bodies in no way affect the properties of space.

In classical mechanics it was also considered possible to introduce a unique universal time flowing uniformly and equally, independent of the state of motion of physical bodies.

The creation of the theory of relativity by Einstein in 1905 led to a radical revision of ideas on the properties of space and time and the character of the electromagnetic field, and to the denial of the necessity and possibility of constructing mechanical models for all physical phenomena. The theory of relativity played a paramount role in the further development of contemporary physics, in particular, atomic and nuclear physics. This role consisted not only in making use of the important relations of the theory of relativity. The theory was the first to show that classical concepts, obtained from every-day experience, which seem to be obvious, turn out to be inadequate in going to new fields of investigation. Hence it can be correctly stated that the appearance of the theory of relativity signified the beginning of the development of a new, non-classical physics.

§2. Galilean transformations

In order to characterize the motion of bodies in space it is necessary to make use of a system of physical bodies between which an interaction, for example an electromagnetic interaction, exists. In addition it is necessary to make use of a method for the measurement of time. A method of measuring time, called a clock, is provided by any periodic process. Then, knowing the velocity of light and the time required for the light to travel from one body to another, one can determine the distances between the bodies. A set of bodies provided with clocks and located at distances determined in such a way is called a reference frame. Only when one makes use of a reference frame one can speak about a definite law of motion of a body in space. If the position of a body is referred to a reference frame at every instant of time,

then the set of all positions of the body in space forms a trajectory, and the sequence of the points of the trajectory represents a law of motion.

Any set of bodies, moving according to arbitrary laws, can be chosen as a reference frame. However, in the following we shall be interested in so-called inertial frames. By inertial reference frames we shall understand those frames in which Newton's law of inertia holds. In other words, in inertial reference frames the motion of bodies which are not acted upon by external forces is uniform and rectilinear. The special role of inertial reference frames is associated with the fact that in them the motion has its simplest form. In non-inertial reference frames, for example in a rotating reference frame, even the simplest rectilinear and uniform motion is described by very complicated relations.

Our problem is the comparison of the laws of motion of a body in different reference frames. If a certain physical law does not change in the transition from one reference frame to another, then we say that it is invariant under this transformation.

Long ago it had been established that mechanical phenomena are equivalent in all inertial reference frames. In other words, the laws of classical mechanics are invariant under transition from one inertial reference frame to others.

Let us consider two reference frames K and K' moving relative to each other. We shall call K' the moving frame, and K the frame at rest. The relative character of such a terminology will be particularly clear from what follows.

It is easy to obtain relations between the velocity and position of a moving body with respect to the two inertial reference frames. We direct the x -axis and x' -axis along the velocity vector \mathbf{v} of the relative motion. Then the relative motion will take place only along the positive direction of the x -axis. Moreover, we match the origins of the two frames at the initial instant $t = 0$ (fig. II.1).

Fig. II.1

It should be noted, according to the above, that in order to find the laws of transformation from reference frame K to K' , the law of inertial motion of a given body must have the same form in the two reference frames. That is to say, in both frames the acceleration of such a body is the same and equal to zero, i.e.

$$\ddot{x} = \ddot{x}' = 0, \quad \ddot{y} = \ddot{y}' = 0, \quad \ddot{z} = \ddot{z}' = 0.$$

On integrating we find

$$\dot{x} = \dot{x}' + v, \quad \dot{y} = \dot{y}', \quad \dot{z} = \dot{z}'. \quad (2.1)$$

The second integration gives

$$x = x' + vt, \quad y = y', \quad z = z'. \quad (2.2)$$

Here we have tacitly assumed that time has an absolute character and is the same in all reference frames. For completeness we should then write

$$t' = t. \quad (2.3)$$

Formulae (2.2) and (2.3) are the Galilean law of transformation, while formula (2.1) is called the law of addition of velocities of classical mechanics. Of course, formulae (2.1) and (2.2) can easily be written also in vector form, without specifying the choice of orientation of the coordinate axes, as follows:

$$\dot{\mathbf{r}} = \dot{\mathbf{r}}' + \mathbf{v}, \quad \mathbf{r} = \mathbf{r}' + \mathbf{v}t. \quad (2.4)$$

The invariance of the laws of classical mechanics in the transition from one inertial reference frame to another is expressed mathematically by the fact that they are invariant under a Galilean transformation. This means that if in Newton's equations

$$m\ddot{x} = -\frac{\partial U}{\partial x}, \quad m\ddot{y} = -\frac{\partial U}{\partial y}, \quad m\ddot{z} = -\frac{\partial U}{\partial z},$$

one makes the substitution $x \rightarrow x', y \rightarrow y', z \rightarrow z'$, i.e. passes from the frame K to the frame K' , they will remain the same, if the law of transformation of coordinates and time is the Galilean law (2.2)–(2.3). Indeed, since the equa-

tions of motion involve only accelerations, under Galilean transformations we have

$$m\ddot{x}' = -\frac{\partial U}{\partial x'}, \quad m\ddot{y}' = -\frac{\partial U}{\partial y'}, \quad m\ddot{z}' = -\frac{\partial U}{\partial z'},$$

which is the same as the equations of motion in the reference frame K.

It should be emphasized that the reference frames K and K' are completely equivalent. We could consider the transition from the reference frame K' to K with equal success.

Thus, a uniform and rectilinear motion of the reference frame has no effect on mechanical processes taking place among a system of material points. This statement is called the Galilean principle of relativity. It should be noted that the term "the Galilean principle of relativity" was introduced in association with the creation of the theory of relativity. The term "relativity" emphasizes the complete equivalence of inertial reference frames. The terms "at rest" and "a uniform and rectilinear motion" are of relative character. In classical mechanics only a relative motion has meaning. On the other hand, the ideas of absolute rest and absolute motion have no real significance. The principle of relativity in mechanics is usually formulated by the words "the uniform and rectilinear motion of a system of material points has no effect upon the inner motion of the system". The principle of relativity in classical mechanics (the Galilean principle) is restricted to inertial reference frames.

The Galilean principle of relativity is based on the concepts of classical physics about space and time. This principle, as well as formula (2.4) for the addition of velocities which results from it, is confirmed by such a vast amount of experimental evidence, in particular that associated with the phenomena of the world around us, that it is adopted as being self-evident.

§3. Attempts to determine an absolute velocity

Shortly after the formulation of the Maxwell-Lorentz theory of the electromagnetic field the problem arose of its generalization to the case of moving bodies.

There is, however, a profound difference between the equations of classical mechanics and those of electrodynamics.

Maxwell's equations involve a characteristic velocity — the velocity of propagation of electromagnetic waves in a vacuum (the velocity of light). Hence

they are not invariant under Galilean transformations. One can easily verify this by the direct substitution of the velocity c by the sum $(c+v)$.

The question naturally arose as to the reference frame with respect to which the velocity of light is to be measured. The Lorentz classical electrodynamics appeared to give an unambiguous answer to this question: it is measured with respect to a hypothetical medium called the universal ether.

The ether was endowed with the properties of an all-pervading, homogeneous and isotropic medium, motionless and filling all space. In the Lorentz theory the existence of an absolute isolated reference frame was assumed. To move meant to move with respect to the ether, and the velocity of motion with respect to the ether was the absolute velocity.

Thus in the Lorentz theory, as distinct from classical mechanics, a decisive attempt to renounce the principle of relativity was made. The fact that the Maxwell-Lorentz equations, in contrast to the Newtonian ones, turned out not to be invariant under Galilean transformations, appeared to be a direct consequence of the renunciation of the principle of relativity.

It is clear that the basic problem confronting electrodynamics at the end of the 19th century was the problem of the experimental determination of an absolute velocity and of obtaining direct proof of the existence of the ether *.

We cannot here go into the history of the search for the ether, which can serve as an example of the inventiveness and persistence of many investigators.

We shall consider only the basic ideas of two possible experiments. Let a source and detector of electromagnetic waves be mounted on a body moving with a velocity v relative to the motionless ether. If the source-detector direction coincides with the direction of motion of the body with respect to the ether v , then light will traverse the source-detector distance l in a time $T_1 = l/(c-v)$. By measuring the time T_1 one can find the velocity v with respect to the ether. However, since c is very large, and the velocities attainable at the end of the last century were small, such a measurement was beyond the feasible accuracy of experiment. It was possible, however, to compare the time T_1 with the time T_2 during which light traverses the same

* See, for example, R. Becker, *Electromagnetic fields and interactions* (Blackie, London, 1964); W. Panofsky and M. Phillips, *Classical electricity and magnetism* (Addison-Wesley, 1964); and, in particular, L. I. Mandelshtam, *Sobr. soch. (Collected papers)*, Part V (Izdatelstvo Akademii Nauk SSSR, 1950). In these books the reader can acquaint himself with the history of the problem, as well as with the detailed methods of carrying out the experiments.

distance l in a direction perpendicular to the velocity v . During the time T_2 the detector traverses a path vT_2 with respect to the ether, so that the total path traversed by the light from the source to the detector is equal to $\sqrt{l^2 + v^2 T_2^2}$. Correspondingly, for the time T_2 we have

$$T_2 = \frac{\sqrt{l^2 + v^2 T_2^2}}{c},$$

or

$$T_2 = \frac{l/c}{\sqrt{1 - \frac{v^2}{c^2}}}.$$

By making the rays travelling from the source to the detector along the direction of the velocity v interfere with those in the perpendicular direction, it was possible to determine the difference between T_1 and T_2 and thus the velocity v with a high degree of accuracy.

In 1881 such an experiment was carried out by Michelson, who made use of the velocity of the orbital motion of the Earth as the velocity of the source.

He made the rays which traversed the path from the source to the detector in the direction of motion of Earth interfere with those in the direction perpendicular to it. It should be noted that nowadays the accuracy of measurements by electronic techniques allows one to measure the difference $(T_1 - T_2)$ directly, without having recourse to interference.

To the surprise of Michelson's contemporaries, no difference between the times T_1 and T_2 could be detected. It turned out that T_1 and T_2 were equal to each other to a very high degree of accuracy.

The following direct experiment may serve as another basic experiment. Let a source of light be moving, and a detector be at rest with respect to the ether. Then the dependence of the velocity of light on the velocity of the source can be found directly. In 1912 De Sitter proposed choosing the radiation of the so-called binary stars as radiation coming to the Earth from the moving source. Binary stars represent two stars close to each other, rotating about a common centre of mass. By observing the velocity of light emitted as the star was moving towards the Earth and when it was moving in the opposite direction (after half of the period of revolution) one could determine the velocity of the star with respect to the ether. However, here also no effect of the motion of the source on the value of the velocity of light was discovered.

A number of attempts were made to explain the negative result of this and many other similar experiments (for example, a change in the law of interaction between charges with a change in the value of their absolute velocity; see §20). However, all these attempts turned out to be unsuccessful. The solution of the problem was given only in the Einstein theory of relativity.

§4. Postulates of the Einstein theory of relativity

The negative result of Michelson's experiment led Einstein to revise the basic concepts of classical physics and, above all, the notions on the properties of space and time.

As a result he created the theory of relativity, which is also called the special theory of relativity.

The theory is based on two principles or postulates:

- 1) Einstein's principle of relativity,
- 2) the principle of the existence of a limiting velocity of propagation of interactions.

According to Einstein's principle of relativity, a uniform and rectilinear motion of bodies has no effect on processes taking place in them. In other words, all laws of nature are the same in inertial reference frames. If in a certain inertial reference frame an arbitrary law of nature is expressed in the form of an equation in which a physical quantity is a function of coordinates and time, then, performing the transformation of the coordinates and time to another inertial reference frame, we must obtain the same functional dependence of the physical quantity on the new coordinates and time. This statement is briefly formulated by the words: "the laws of nature are invariant under a transformation from one inertial reference frame to another". It is clear that Einstein's principle of relativity is a generalization of the Galilean principle of relativity. The latter established the relativity of inertial motion and the impossibility of introducing the notions of absolute motion and absolute rest within the framework of classical mechanics. The negative result of Michelson's experiment, as was first realized by Einstein, pointed out that the ideas of absolute motion and rest have no meaning in the theory of the electromagnetic field.

However, there is a profound difference between the Galilean and Einstein's principle of relativity. In the latter the transformation from one inertial reference frame to another is not associated with formulae for the transformation of coordinates and the law of addition of velocities of classical mechanics. Indeed, as an example, Maxwell's equations do not satisfy these

transformations. Hence, in Einstein's theory, a new law of transformation of coordinates and time had to be found for going from one inertial reference frame to another. The second postulate of the theory of relativity stating that any interactions between bodies propagate in vacuum with a universal finite velocity equal to the velocity of light in vacuum, $c = 3 \times 10^{10}$ cm/sec, and independent of the motion and state of the bodies serves this purpose. It is obvious that this postulate expresses directly the result of Michelson's experiment.

The second postulate of the theory of relativity was closely associated with the development of electrodynamics. It demonstrated clearly the inadequacy of the theory of action at a distance of classical mechanics. In electrodynamics it was established that there exists a finite velocity of propagation of electromagnetic interactions, numerically equal to the velocity of light in vacuum. Theoretical studies carried out later on by Einstein in association with the development of the so-called general theory of relativity showed also that the gravitational interaction has the nature of waves propagating in vacuum with the velocity of light. It is beyond doubt that the specific interaction between nuclear particles has the character of a short-range action.

It cannot be excluded that further development of physics may lead to the discovery of new forms of interaction. However, the principle of the limiting velocity of propagation of interactions expresses the hypothesis that the velocity of propagation of interactions in vacuum has a universal character and is associated directly with the properties of space and time and not with the physical nature of the interactions.

The existence of the limiting velocity of propagation of interactions indicates that there is a certain connection between intervals of space and time. This connection will be demonstrated more clearly in analysing the conclusions of the theory of relativity: At the same time, the existence of the limiting velocity automatically assumes the restriction of the velocity of motion of material bodies to the value c . If any particles could move with a velocity higher than that of light, then these particles could bring about an interaction between bodies with a velocity higher than the limiting velocity. Thus, Einstein's second postulate restricts the value of all velocities of motion possible in nature and the velocity of propagation of interactions to the value c .

The principle of the existence of a limiting velocity of propagation of interactions is closely associated with Einstein's principle of relativity. Indeed, it is easily seen that, if the velocity of propagation of interactions depended on the velocity of particles or on the nature of the interaction (i.e. if it were different for the electromagnetic and gravitational interaction), then the

principle of relativity would be violated. For example, if the velocity of light depended on the velocity of a rectilinear and uniform motion of the source of light, then the latter could be determined experimentally.

The propagation of interactions is, in the theory of relativity, often called the propagation of signals. By a signal one understands any interaction between bodies at a finite distance from each other and in a state of rest or relative motion. The principle of the existence of a finite velocity of propagation of interaction is called the principle of existence of a finite velocity of propagation of signals. The overall content of the theory of relativity follows from its two postulates. In particular, formulae for the transformation of coordinates and time, in place of the Galilean transformation formulae, result directly from the basic postulates of Einstein. At present both postulates of the theory of relativity are confirmed by a whole set of experimental data obtained in investigating atomic and nuclear processes, motions of fast particles in accelerators, and other devices.

In what follows we shall present a number of examples illustrating the last statement.

§5. The Lorentz transformation

Proceeding from the postulates of Einstein's theory of relativity formulated above one can find the law of transformation relating space coordinates and time in two reference frames in uniform rectilinear motion relative to each other.

- Let x, y, z, t and x', y', z', t' be the coordinates and time in inertial reference frames K and K' , and v the velocity of their relative motion.

There are no grounds for assuming that the time in the frame K' coincides with the time in the frame K , as was implicitly assumed in classical physics.

To simplify the calculations we shall choose the direction of velocity to be the direction of the x -axis and x' -axis, as is shown in fig. II.1.

We assume that at a certain instant t' at the point with coordinates (x', y', z') there occurs a physical process, which we shall call for brevity an event. Our problem is to find the "coordinates" of this event in the reference frame K , i.e. to find the values (x, y, z, t) characterizing the same physical process in the reference frame K .

To establish the analytical relationship between the values (x, y, z, t) and (x', y', z', t') we consider the propagation of a spherical electromagnetic wave in the two reference frames.

We choose as the time origin, $t = 0$, the instant at which the origin of the

reference frame K' coincides with the origin of the reference frame K . Let the spherical electromagnetic wave begin to propagate at the instant $t = 0$ from the origin. In the frame K the equation of the wave front has the form

$$x^2 + y^2 + z^2 - c^2 t^2 = 0. \quad (5.1)$$

Since, according to Einstein's principle of relativity, the law and velocity of propagation of a wave must be the same in all inertial reference frames, in addition to (5.1) we can with equal justification write the equation of the spherical wave in the reference frame K' :

$$(x')^2 + (y')^2 + (z')^2 - c^2 (t')^2 = x^2 + y^2 + z^2 - c^2 t^2 = 0. \quad (5.2)$$

The formulae for the transformation of coordinates and time must: 1) not violate the relations (5.1) and (5.2), and 2) be linear. The requirement of linearity is associated with the homogeneity of space, which means that there are no points which stand out in particular for their properties.

First of all we note that, since the motion of the reference frame K' is along the x -axis, the transformation of the coordinates (y, z) must have the form

$$y' = y, \quad z' = z. \quad (5.3)$$

The law of transformation of x' in terms of x can be written from the following considerations: if at the instant $t = 0$ the origins of the reference frames K and K' coincided, then the coordinate of the point $x' = 0$ in the reference frame K is written as follows: $x = vt$. Consequently, in the most general case one can write that

$$x' = \alpha(v)(x - vt), \quad (5.4)$$

where the coefficient $\alpha(v)$ depends only on the velocity of the relative motion.

Making no arbitrary assumptions about the coincidence of time in the two reference frames, we can write t' in the form of a linear homogeneous function of x and t :

$$t' = \beta t + \gamma x. \quad (5.5)$$

The coefficients β and γ can, generally speaking, depend on the velocity v . If

it turned out that $\gamma = 0$ and $\beta = 1$, then we would come back to the Galilean transformation.

In order to determine the coefficients α , β and γ , corresponding to the requirements of Einstein's principle of relativity, we have to substitute (5.4) and (5.5) into (5.2). This gives

$$\alpha^2(x - vt)^2 + y^2 + z^2 - c^2(\beta t + \gamma x)^2 \equiv x^2 + y^2 + z^2 - c^2 t^2.$$

In order for this identity to be satisfied it is necessary to equate the coefficients of x^2 , t^2 and xt :

$$\alpha^2 - c^2 \gamma^2 = 1,$$

$$\alpha^2 v^2 - c^2 \beta^2 = -c^2,$$

$$\alpha^2 v + c^2 \beta \gamma = 0.$$

From these three equations we find the unknown values of α , β and γ :

$$\alpha = \beta = \frac{1}{\sqrt{1 - v^2/c^2}},$$

$$\gamma = -\frac{\alpha v}{c^2} = -\frac{v}{c^2 \sqrt{1 - v^2/c^2}}.$$

We have chosen the positive sign of the square root.

Substituting the values of α , β and γ into the formulae for the transformation of coordinates (5.4) and (5.5) and taking into account (5.3), we find

$$x' = \frac{x - vt}{\sqrt{1 - v^2/c^2}}, \quad (5.6a)$$

$$y' = y, \quad (5.6b)$$

$$z' = z, \quad (5.6c)$$

$$t' = \frac{t - vx/c^2}{\sqrt{1 - v^2/c^2}}. \quad (5.6d)$$

Formulae (5.6a)–(5.6d) are called the Lorentz transformation formulae.

According to Einstein's principle of relativity these transformations replace the Galilean transformations.

Before going on to a discussion of the consequences of the Lorentz transformation we shall write formulae for the inverse transformation from the frame K' to K . On the basis of Einstein's principle of relativity the reference frames K and K' are completely equivalent. We could repeat all the previous reasoning, taking the initial frame to be K' and not K . However, in this case the velocity of the relative motion is equal to $(-v)$ and not to v . Hence we obtain:

$$x = \frac{x' + vt'}{\sqrt{1 - v^2/c^2}}, \quad (5.7a)$$

$$y = y', \quad (5.7b)$$

$$z = z', \quad (5.7c)$$

$$t = \frac{t' + vx'/c^2}{\sqrt{1 - v^2/c^2}}. \quad (5.7d)$$

The same result is found if the eqs. (5.6a)–(5.6d) are solved with respect to non-primed quantities.

The importance of the consequences following from the Lorentz transformation leads us to stress once more that their derivation is based only on Einstein's principle of relativity, the principle of the constancy of the limiting velocity of propagation of interactions, and the assumption of the uniformity of all points of space and time. These propositions are at present confirmed by a vast amount of experimental material and their validity is beyond any doubt.

A remarkable feature of the Lorentz transformation is the fact that, at relative velocities of motion small in comparison with the velocity of light, it goes over into the Galilean transformation. Indeed, at $v \ll c$ one can disregard values of the second order of smallness containing $(v/c)^2$ and write

$$x \approx x' + vt', \quad t' \approx t,$$

which are the same as formulae (2.2) and (2.3).

Thus, in the limiting case $v \ll c$ the transformation laws of the theory of relativity and classical mechanics are the same. This means that the theory of relativity does not reject the Galilean transformation as incorrect but includes

it in a valid law — the Lorentz transformation — as a particular case holding at velocities of motion which are small in comparison with the velocity of light.

In what follows we shall see that this reflects the general relation between the theory of relativity and classical physics. The laws and relations of the theory of relativity go over into the laws of classical physics in the limiting case of velocities small in comparison with the velocity of light c .

§6. Consequences of the Lorentz transformation.

Space and time intervals

The Lorentz transformation leads to conclusions radically contradicting the usual notions of the properties of space and time which arose from everyday experience and which we formulated in §2. Indeed, from the Lorentz transformation it follows directly that concepts of space and time intervals are relative. In other words, the ideas “the size of a body” or “the time lapse between two physical events” have no absolute character and are different in different reference frames.

Consider first of all the concept of spatial extension (length). Let there be a body at rest in a certain reference frame K' . We shall henceforth call this body the scale. The scale is not acted upon by any forces which could deform it and change its size. We denote by L_0 the length of the scale in the direction of motion (x' -axis). This length, measured in that reference frame in which the scale is at rest (frame K'), will be called the proper length of the scale. By means of a Lorentz transformation we shall find the length of the scale in the reference frame K , i.e. the length of the scale moving with a velocity v relative to the frame K . In the reference frame K' let the coordinates of the beginning and end of the scale be respectively x'_1 and x'_2 . We shall find these coordinates in the reference frame K .

Since the scale moves relative to the reference frame K , it is necessary, in order to measure its size, to fix the coordinates of its beginning and end at the same instant, measured in the reference frame K . For the realization of this measurement it would be possible to fix at an instant t the position of the beginning and end of the scale by means of a light signal coming from the reference frame K' .

At a certain instant t let the beginning and end of the scale have the coordinates x_1 and x_2 in the reference frame K . By means of formula (5.6a) we find

$$x'_2 = \frac{x_2 - vt}{\sqrt{1 - \frac{v^2}{c^2}}}, \quad x'_1 = \frac{x_1 - vt}{\sqrt{1 - \frac{v^2}{c^2}}}.$$

On subtracting we have

$$x'_2 - x'_1 = \frac{x_2 - x_1}{\sqrt{1 - \frac{v^2}{c^2}}},$$

or, denoting the difference between the coordinates of the beginning and end of the scale (the length of the scale in the reference frame K) by L , we obtain

$$L = L_0 \sqrt{1 - \frac{v^2}{c^2}}. \quad (6.1)$$

We see that the length of a scale moving with a velocity v relative to the reference frame K turns out to be $\sqrt{1 - v^2/c^2}$ times smaller than its proper length. This contraction of the size of a body is often called the Lorentz contraction. Since the dimensions of the scale in the direction perpendicular to the velocity remain unchanged, the volume of the scale turns out to be connected with its proper volume by the formula

$$V = V_0 \sqrt{1 - \frac{v^2}{c^2}}. \quad (6.2)$$

Thus, the length and volume of a scale which does not undergo the action of external forces turn out to be relative quantities. In other words, the statement that the distance between two points of space is equal to L has no meaning without specifying to which reference frame this quantity is referred. The distance between two points depends on the motion of the reference frame.

In classical physics the absolute character of the notion of the length of a scale was considered as something self-evident. Here lies the fundamental difference between views on the properties of space in the theory of relativity and classical physics.

It should be borne in mind that the two reference frames K and K' are completely equivalent. Hence, if the scale is at rest in the reference frame K, then its length in the reference frame K' will be smaller than in the frame K in the same ratio. There is a complete reciprocity between the two reference

frames. One can verify this by a direct calculation using the Lorentz transformation formulae (5.7a)–(5.7d).

It is easy to show that the negative result of Michelson's experiment follows automatically from the existence of the Lorentz contraction. Indeed, when light passes along the direction of motion of the Earth and in the opposite direction, from the point of view of an observer at rest (to which all the reasoning of §3 refers) the length l must be reduced $\sqrt{1-v^2/c^2}$ times. From the point of view of the observer at rest the time T_1 needed for a ray of light to traverse the total path is equal to

$$T_1 = \frac{l\sqrt{1-\frac{v^2}{c^2}}}{c+v} + \frac{l\sqrt{1-\frac{v^2}{c^2}}}{c-v} = \frac{2l}{c} \frac{1}{\sqrt{1-\frac{v^2}{c^2}}}.$$

Correspondingly, the time difference is

$$T_2 - T_1 = 0$$

It should be stressed that the contraction of length — the compression of a body in the direction of motion — is of a purely kinematical character. No internal tensions causing a deformation arise in the body. In this sense one can speak about a "rigid" or, more precisely, non-deformable body in the theory of relativity. On the other hand, the notion of an absolutely rigid body is incompatible with the inferences of the theory of relativity. Indeed, if one assumes the existence of an absolutely rigid body, i.e. a body with invariable distances between all the particles constituting it, then such a body could be used for the transmission of an interaction with a velocity as large as one likes. A blow delivered to one of its ends would be transmitted to the other end with infinitely large velocity. Hence, from the point of view of the theory of relativity, the existence of absolutely rigid bodies cannot be assumed, even as an idealization.

The concept of time also undergoes a very fundamental modification in the theory of relativity.

At a point x' in the reference frame K' , let a certain physical process take place during a time interval $\Delta t_0 = t'_2 - t'_1$, where t'_1 and t'_2 are the time of the beginning and end of the process. Then in the reference frame K for the instants t_1 and t_2 we can write

$$t_2 = \frac{t'_2 + \frac{vx'}{c^2}}{\sqrt{1 - \frac{v^2}{c^2}}}, \quad t_1 = \frac{t'_1 + \frac{vx'}{c^2}}{\sqrt{1 - \frac{v^2}{c^2}}}.$$

Subtracting we find the time interval from the beginning to the end of the process in the reference frame K:

$$\Delta t = t_2 - t_1 = \frac{\Delta t_0}{\sqrt{1 - \frac{v^2}{c^2}}} \quad (6.3)$$

The time Δt_0 , measured in the reference frame moving together with the body in which the process takes place, is called the proper time.

Formula (6.3) shows that the proper time Δt_0 between two physical events is $\sqrt{1 - v^2/c^2}$ times smaller than the time lapse between these events in the reference frame K.

In the theory of relativity it is customary to speak about the comparison of the clock run in different inertial reference frames. The clock is understood to be an arbitrary periodical process. Then it can be said that the time shown by the clock depends on the velocity of its motion. A clock moving relative to a certain reference frame runs more slowly from the point of view of this frame than a clock at rest in it (the latter clock being identical with the moving one)

Thus, as distinct from Newtonian physics, the course of time turns out to be dependent on the state of motion. There is no universal time, and the notion of the time interval between two physical events turns out to be relative. Here it should again be stressed that there is a complete reciprocity between the reference frames K and K'. The above reasoning could be reversed. If a physical process takes place at the point x in the reference frame K and lasts Δt , then in the frame K' it will last

$$\Delta t' = \frac{t_2 - \frac{vx}{c^2}}{\sqrt{1 - \frac{v^2}{c^2}}} - \frac{t_1 - \frac{vx}{c^2}}{\sqrt{1 - \frac{v^2}{c^2}}} = \frac{\Delta t}{\sqrt{1 - \frac{v^2}{c^2}}},$$

as is seen from the Lorentz transformations (5.6a)–(5.6d).

Formula (6.3) for the change in rate of the moving clock has been experimentally confirmed in several ways. The most obvious of them is the follow-

ing. In cosmic rays the decay of the positive and negative muon (μ^+ - and μ^- -meson, with a mass of 207 electron masses) into a positron (electron) and two neutrinos is observed. The decay has been observed for μ -mesons decelerated almost to rest as well as when they are moving with a velocity close to that of light. The lifetimes of a moving meson and a meson at rest are connected by the relativistic relation

$$\tau_{\text{mov}} = \frac{\tau_{\text{rest}}}{\sqrt{1 - \frac{v^2}{c^2}}}.$$

Since v is close to the velocity of light, τ_{mov} must be considerably larger than τ_{rest} .

A number of experimental methods permit the determination of the value of τ_{rest} , which turns out to be 2×10^{-6} sec. If the lifetime of mesons were not dependent on the velocity, they would traverse a path equal to $v\tau_{\text{rest}} \approx 600$ m (for $v \approx c$). In reality, as shown by measurements, the mesons decay after traversing a path of about 20 km. To such a range there corresponds the lifetime

$$\tau_{\text{mov}} = \frac{20 \text{ km}}{c} \approx 7 \times 10^{-5} \text{ sec} \approx 50 \tau_{\text{rest}}$$

The relativistic change of the lifetime in this case turns out to be a very large effect.

Two questions naturally arise. First, why before the creation of the theory of relativity were all available experimental data in agreement with the Newtonian ideas of the absolute character of the length of the body and a unique universal time. Second, is the contraction of the length of moving bodies and the slowing down of the running of a moving clock real or apparent.

The answer to the first question is very simple. Before experiments designed to observe the motion of the Earth relative to the ether physicists did not encounter processes taking place with objects which moved with a velocity comparable to the velocity of light c . In other words, the velocities of all bodies observed in physics before the discovery of the electron were small in comparison with the velocity of light.

For velocities which are small compared with the velocity of light one can, with a sufficient degree of accuracy, make use of the earlier notions of space and time. Moreover, at the time of Einstein's creation of the theory of relativity Michelson's experiment was the sole undeniable indication of the inade-

quacy of classical physics. As will be seen from what follows, in the course of the past 50 years the situation has changed radically. The theory of relativity has become one of the bases of contemporary theoretical physics and a number of branches of experimental physics. Numerous experimental confirmations of the theory of relativity will, in part, be considered below. In particular, atomic and especially nuclear physics, as a rule, investigate the processes and behaviour of moving particles whose velocities are very close to the velocity of light. All the basic relations of the theory of relativity are widely used in nuclear physics for purely practical calculations. Some of these will be given below.

In considering the second question it should be emphasized that the rather widely used terms "an apparent contraction of the scale" and "an apparent change of the running of a clock" are inconvenient. Usually the authors wish to stress by the term "apparent" the purely kinematical character of the contraction. At the same time, the contraction of the scale and the slowing down of the running of the clock are a real and objective fact which is by no means connected with any illusions of the observer. It goes without saying that all values of the length of a given scale or time interval obtained in different reference frames are equivalent. They are all "correct". The difficulty in understanding these statements is associated solely with our habit of considering the notions of length and time interval as absolute notions, whereas in reality they are relative ones. Hence it is also senseless to ask which length of the scale is the true one and which is the apparent one, as it is senseless to say "in reality a given body is moving (or is at rest)". The concepts of length and time interval are as relative as are the concepts of motion and rest.

The true character of the contraction of a moving scale can be illustrated by the following example. Let there be two charged bodies A and B at rest in two separate reference frames. They are each spherical in the reference frame in which they are at rest. If one of the bodies, for example A, moves together with the reference frame K, then from the point of view of the reference frame K' its longitudinal (with respect to the direction of motion) dimension undergoes a contraction, whereas its transverse dimensions remain unchanged. The interaction between the bodies A and B then corresponds to the interaction between a charged sphere B and a charged ellipsoid A. In this case, from the point of view of the reference frame K', the body B is a sphere and the body A is an ellipsoid, whereas from the point of view of the reference frame K the body A remains a sphere and the body B transforms into an ellipsoid. However, the magnitude of the A-B interaction will be the same in the two reference frames.

An example of the calculation of the interaction between rapidly moving electric charges will be considered in §20.

§7. Einstein's law of addition of velocities and angular transformations

An important consequence of the Lorentz transformation is the relativistic law of addition of velocities, which in the theory of relativity replaces the Galilean law of addition of velocities.

It is found most simply by writing the Lorentz transformation formulae for the differentials of the space coordinates and time:

$$dx = \frac{dx' + v dt'}{\sqrt{1 - \frac{v^2}{c^2}}},$$

$$dy = dy',$$

$$dz = dz',$$

$$dt = \frac{dt' + \frac{v dx'}{c^2}}{\sqrt{1 - \frac{v^2}{c^2}}}.$$

Let x', y', z' be the coordinates of a material point moving in the reference frame K' . The components of the velocity of the point in the reference frame K' will be

$$u'_x = \frac{dx'}{dt'}, \quad u'_y = \frac{dy'}{dt'}, \quad u'_z = \frac{dz'}{dt'},$$

and in the reference frame K

$$u_x = \frac{dx}{dt}, \quad u_y = \frac{dy}{dt}, \quad u_z = \frac{dz}{dt}.$$

Dividing the differentials of the coordinates by the differential of time, we find

$$u_x = \frac{dx}{dt} = \frac{u'_x + v}{1 + \frac{u'_x v}{c^2}}, \quad (7.1)$$

$$u_y = \frac{dy}{dt} = \frac{u'_y \sqrt{1 - \frac{v^2}{c^2}}}{1 + \frac{u'_x v}{c^2}}, \quad (7.2)$$

$$u_z = \frac{dz}{dt} = \frac{u'_z \sqrt{1 - \frac{v^2}{c^2}}}{1 + \frac{u'_x v}{c^2}}. \quad (7.3)$$

Formulae (7.1)–(7.3) are called Einstein's law of addition of velocities. They replace the formulae of addition of velocities (2.1) of classical mechanics.

At $v \ll c$ Einstein's law of addition of velocities goes over directly into (2.1), since in this case

$$1 + \frac{u'_x v}{c^2} \approx 1, \quad \sqrt{1 - \frac{v^2}{c^2}} \approx 1.$$

As was to be expected, it follows from formulae (7.1) and (7.2) that the velocity of light c is the limiting velocity. If, for example, a particle in the reference frame K' moves along the x -axis with a velocity $u = u'_x = c$, then in motionless reference frame K its velocity is

$$u = \frac{c + v}{1 + \frac{cv}{c^2}} = c.$$

If a particle moves in the reference frame K' with a velocity smaller than the velocity of light, for example

$$u' = u'_x = c - \alpha \quad (\alpha > 0),$$

while the reference frame K' moves relative to K with a velocity $v = c - \beta$ ($\beta > 0$), then the velocity of the particle relative to the motionless frame K is equal to

$$u = \frac{(2c - \alpha - \beta)c}{2c - \alpha - \beta + \frac{\alpha\beta}{c}} < c.$$

Thus, the sum of two velocities, each of which is smaller than the velocity of light c , will always be smaller than the velocity of light. The sum of two velocities, one of which is equal to c and the other smaller than c , is equal to the velocity of light.

From the law of addition of velocities it follows directly that the value of an angle is relative and changes in transition from one inertial reference frame to the other. Since

$$\tan \theta = u_y / u_x,$$

where θ is the angle formed by the velocity vector of the particle and the x -axis, we find from (7.2) and (7.1) that

$$\tan \theta = \frac{u' \sqrt{1 - \frac{v^2}{c^2}} \sin \theta'}{v + u' \cos \theta'}, \quad (7.4)$$

where $u'_x = u' \cos \theta'$, $u'_y = u' \sin \theta'$.

The last formula expresses the law of angular transformations in the theory of relativity. It connects the angles θ' and θ , formed by the velocity vector with the x' -axis and x -axis respectively.

In conclusion it is emphasized that the velocity v should be a velocity with which a real body can move or a real process of interaction (signal) can propagate. One can imagine, without coming into conflict with the theory of relativity, processes having a velocity higher than the velocity c but which have a kinematical character and cannot transport bodies or realize interactions.

Consider, for example, the velocity of motion of an imaginary point P, at which a line A intersects a line B as the line B rotates. If the angle α at which A intersects B is arbitrarily small, and the length of the moving line is arbitrarily large, the velocity of motion of the point P can also be arbitrarily large. However, the motion of the imaginary point of intersection of the lines is not accompanied by a transfer of energy and cannot serve as a means for the transmission of signals and interactions.

§ 8. Simultaneity, short-range action and action at a distance

Let two physical events take place simultaneously at a time t' , at points x'_1 and x'_2 in an inertial reference frame K' . From the point of view of classical physics two events which are simultaneous in one reference frame take place simultaneously in all other inertial reference frames.

In the theory of relativity the situation is different.

Consider the inertial reference frame K relative to which the frame K' moves with a velocity v in the positive direction of the x -axis. In the reference frame K the first event takes place at an instant

$$t_1 = \frac{t' + \frac{x'_1 v}{c^2}}{\sqrt{1 - \frac{v^2}{c^2}}}.$$

The second event takes place at an instant

$$t_2 = \frac{t' + \frac{x'_2 v}{c^2}}{\sqrt{1 - \frac{v^2}{c^2}}}.$$

Consequently, in the reference frame K the events do not take place simultaneously for there is a time lapse

$$\Delta t = t_2 - t_1 = \frac{v(x'_2 - x'_1)}{c^2 \sqrt{1 - \frac{v^2}{c^2}}}. \quad (8.1)$$

Moreover, depending on the sign of $(x'_2 - x'_1)$ the time interval Δt can be positive or negative, i.e. in the reference frame K "the first" event can take place earlier or later than "the second" one.

Thus, the concept of simultaneity turns out to be relative.

The sole, but very important exception is the case when two events occur at the same place, i.e. at an instant t' at a point x' . Then, according to (8.1), in all inertial reference frames (for any v) $\Delta t = 0$, i.e. the two events take place absolutely simultaneously.

The above illustrates particularly clearly that the theory of relativity is incompatible with the notion of action at a distance. Two events can be in a

mutual relationship as cause and effect only where they occur at the same place simultaneously as is required by the concept of short-range action. If, on the contrary, the cause and effect could be spatially separated (and the interaction propagated with an infinitely large velocity), then there would always exist an infinitely large number of inertial reference frames in which the effect would precede the cause.

It should be stressed that the concepts of relativity and simultaneity were assumed from the very beginning as the basis of the theory of relativity (in the form of the principle of a finite limiting velocity of propagation of interactions) and they can be considered only as an obvious example of the internal consistency of the theory.

§9. Absolute values in the theory of relativity. Intervals and proper time

The theory of relativity revolutionized the teaching of classical physics about the absolute character of space and time.

The relative character of space and time intervals seemed to be so paradoxical that the authors of a number of popular expositions of the theory of relativity, which appeared in particular around 1920, presented the ideological content of the theory by the scathing, but absolutely untrue aphorism: "The theory of relativity showed that all in the universe is relative".

In reality the situation is just the opposite. The task which the theory of relativity sets itself is to find absolute laws of nature which do not depend on the choice of the inertial reference frame *.

Thus, the theory of relativity by no means denies the existence of absolute quantities and concepts. It states only that a number of concepts, considered as absolute in classical physics, for example the magnitudes of space and time intervals, are in reality relative.

In this connection the opinion was often expressed that the term "theory of relativity" is unsuitable, since it does not reflect the content of this branch of physics. It was pointed out that the theory of relativity could with more justice be called "the theory of physical invariance". However, it should be borne in mind that at the time the theory of relativity was first introduced its critical aspect — the establishment of the relativity of space and time intervals — appeared to be more fundamental and new.

* In the general theory of relativity, which we cannot go into within the framework of this book, the problem of finding absolute laws of nature is extended to arbitrary reference frames.

The problem of finding absolute expressions for the laws of nature is closely connected with the finding of invariant, absolute quantities. The first of such quantities is the universal velocity of propagation of interactions — the velocity of light c . The second, also very important invariant quantity, is the so-called interval.

The notion of interval in the theory of relativity is a generalization of the usual notions of the interval (i.e. distance) between two points and the interval (i.e. lapse of time) between two events. Let there take place at a point in space with coordinates (x, y, z) at a time t , a physical phenomenon which we shall call an event. At another point x_1, y_1, z_1 at an instant t_1 another event takes place. Then the quantity

$$s = \sqrt{c^2(t_1 - t)^2 - (x_1 - x)^2 - (y_1 - y)^2 - (z_1 - z)^2} \quad (9.1)$$

is called the interval between the two events.

The invariance of the interval with respect to the Lorentz transformation can be checked by a direct calculation. In the moving reference frame K' we have

$$s' = \sqrt{c^2(t'_1 - t')^2 - (x'_1 - x')^2 - (y'_1 - y')^2 - (z'_1 - z')^2}$$

Obviously,

$$\begin{aligned} (x'_1 - x')^2 &= \frac{(x_1 - x)^2 + v^2(t_1 - t)^2 - 2v(x_1 - x)(t_1 - t)}{1 - v^2/c^2}, \\ c^2(t'_1 - t')^2 &= \frac{c^2(t_1 - t)^2 - 2v(x_1 - x)(t_1 - t) + \frac{v^2}{c^2}(x_1 - x)^2}{1 - v^2/c^2}, \\ (y'_1 - y')^2 &= (y_1 - y)^2, \\ (z'_1 - z')^2 &= (z_1 - z)^2. \end{aligned}$$

The substitution of these expressions into s' with some elementary calculations gives

$$s' = s.$$

Thus, the statement: "two physical events are separated by an interval s " is of absolute character. It is valid in all inertial reference frames.

The interval between two events taking place at infinitesimally close points with an infinitesimally small time separation is often considered. In this case the interval between two events is

$$ds = \sqrt{c^2 dt^2 - dx^2 - dy^2 - dz^2} . \quad (9.2)$$

The value of the interval s can be real or imaginary, depending on the sign of the expression under the radical.

Consider at first the case of a real interval:

$$c^2(\Delta t)^2 > (\Delta x)^2 + (\Delta y)^2 + (\Delta z)^2 .$$

In this case it is always possible to find some reference frame in which the two events take place at the same point. For this it is necessary that the condition

$$\sqrt{c^2(\Delta t)^2 - (\Delta x)^2 - (\Delta y)^2 - (\Delta z)^2} = c \Delta t'$$

be fulfilled. In principle it can always be fulfilled for a positive value of the expression under the radical. Hence real intervals are called "time-like intervals". In particular, it is obvious that if two events take place involving the same physical system, the interval between these events is time-like. Indeed, during the time Δt between two successive events the system can traverse a path

$$\sqrt{(\Delta x)^2 + (\Delta y)^2 + (\Delta z)^2} < c \Delta t ,$$

since its velocity is always smaller than the velocity of light. As an example of a time-like interval one can cite the interval between two events representing successive indications of the same clock.

An imaginary interval is called a "space-like interval". If two events are separated by a space-like interval, then one can always find a reference frame in which they take place at the same instant. For this it is necessary that the equality

$$\sqrt{c^2(\Delta t)^2 - (\Delta x)^2 - (\Delta y)^2 - (\Delta z)^2} = i \sqrt{(\Delta x')^2 + (\Delta y')^2 + (\Delta z')^2}$$

be fulfilled. This equality always holds for negative values of the expression under the radical at the left.

We shall now return to the determination of the proper time and show that the proper time as well as the interval is an invariant, absolute quantity.

Let the inertial frame K' be given. At a certain point x', y', z' let there take place two successive events separated by a time interval dt_0 . It should be stressed that the time t_0 is measured by a clock which is at rest in the reference frame K' (or, as is said, by the proper clock of the reference frame K'), and that the time dt_0 is the proper time which has elapsed between the two events. The interval between the two events is by definition equal to

$$ds = \sqrt{c^2(dt_0)^2 - (dx')^2 - (dy')^2 - (dz')^2} = c dt_0.$$

Thus, the proper time is connected with the interval by the relation

$$dt_0 = c^{-1} ds \quad (9.3)$$

and is invariant.

The proper time can be expressed in terms of the time dt in an arbitrary reference frame, i.e. in terms of the time measured by a clock moving with respect to K' with a velocity $(-v)$, by substituting the expression for ds into (9.3):

$$\begin{aligned} dt_0 &= \frac{1}{c} \sqrt{c^2 dt^2 - dx^2 - dy^2 - dz^2} = \\ &= dt \sqrt{1 - \frac{1}{c^2} \left\{ \left(\frac{dx}{dt} \right)^2 + \left(\frac{dy}{dt} \right)^2 + \left(\frac{dz}{dt} \right)^2 \right\}} = \\ &= dt \sqrt{1 - \frac{v^2}{c^2}}. \end{aligned} \quad (9.4)$$

The finite interval of the proper time, t_0 , is equal to

$$t_0 = \int_0^{t_0} \sqrt{1 - \frac{v^2}{c^2}} dt. \quad (9.5)$$

It should be emphasized that formula (9.5) is derived for the case of the motion of the clock together with an inertial reference frame, i.e. a motion with a constant velocity.

Formula (9.5) is often applied to accelerated motion, considering v as a function of time. However, it should be borne in mind that an accelerated motion of a reference frame cannot be considered in the special theory of

relativity. Hence, in the case of accelerated motion, the quantity t_0 determined by formula (9.5) does not have the meaning of proper time but is a convenient quantity, invariant under Lorentz transformations.

§10. The invariance of physical laws under Lorentz transformations.

Four-dimensional formulation of the theory of relativity

According to the principle of relativity all physical laws — the laws of mechanics, electrodynamics, statistical physics and so on — must be the same in all inertial reference frames. This means that all physical laws must be formulated in such a way that they may remain invariant under Lorentz transformations. In the following the relations which are invariant under Lorentz transformations will be called relativistically invariant or Lorentz-invariant relations.

The equations of mechanics which are invariant under Galilean transformations obviously do not satisfy the requirement of invariance under Lorentz transformations and, consequently, their form must be altered. On the contrary, the laws of electrodynamics (i.e. Maxwell's equations, as will be shown later) were formulated from the very beginning in such a way that they turned out to be relativistically invariant. From the point of view of the theory of relativity, Maxwell's equations are a model of "a correctly formulated" physical law.

The realization of the general aims of the theory of relativity — i.e. finding relativistically invariant forms of physical laws — had a great effect on the overall further development of physics. Thus, for example, the progress made in the course of the last several decades in quantum mechanics and, in particular, in the quantum theory of fields, has been closely associated with the fulfilment of the requirements of the theory of relativity.

It should be noted that the requirement of the invariance of physical laws under certain transformations of reference frames is not a specific feature of the theory of relativity. It is well known that the requirement of invariance of physical laws under a rotation of the reference frame is associated with the isotropy of space.

Indeed, every physical law is formulated in such a way that the quantities involved in it refer to a certain system of coordinate axes. It is clear that the content of a physical law cannot depend on the orientation of the coordinate axes in space. For example, the Newtonian equations

$$m\ddot{x} = F_x \quad m\ddot{y} = F_y, \quad m\ddot{z} = F_z \quad (10.1)$$

do not depend on the orientation in space of the system of coordinate axes (x, y, z) to which the components of forces and accelerations refer. The equations of motion remain unchanged under any rotation of the axes of this reference frame: under rotation, every one of the components of the acceleration and force transforms according to one and the same law, so that the equalities (10.1) are not violated. This property of the invariance of physical laws under rotations of the reference frame can be formulated more precisely in the following way. In classical physics all physical laws are formulated in the form of equalities of the type

$$\alpha = \beta \quad (10.2)$$

or

$$\alpha = \beta, \quad (10.3)$$

$$\alpha_{ik} = \beta_{ik}. \quad (10.4)$$

The first of these contains the relation between scalar quantities, which remain unchanged under rotation of the coordinate axes. The second one relates vector quantities, which change under rotation of the coordinate axes. That is to say if for simplicity of notation one restricts oneself to the rotation about the z -axis through an angle φ , then the x -component and y -component of vectors change according to the well-known formulae of analytical geometry:

$$\begin{aligned} x &= x' \cos \varphi - y' \sin \varphi, \\ y &= x' \sin \varphi + y' \cos \varphi. \end{aligned} \quad (10.5)$$

Since, however, the components of any vectors, in particular those of the acceleration and force vectors, change according to this law, the equality (10.3) (or the equality (10.1) which is a particular case of it) is not violated.

The equality (10.4) shows in a general form that the tensor order of the quantities on the two sides of it are the same.

Thus, every physical law must be formulated in such a way that it will contain only quantities of the same tensor order. In classical mechanics the laws of transformation of coordinates which must leave physical laws unchanged reduce to the following:

1. Invariance under Galilean transformations.
2. Invariance under spatial translations and rotations of the coordinate frame.

3. Invariance under the replacement of t by $(t + t')$, expressing the uniformity of the flow of time.

4. Invariance under the change of the sign of time $t \rightarrow -t$, indicating the reversibility of the laws of mechanics, which are symmetric with respect to the future and past.

The theory of relativity puts forward, instead of condition 1, the more general requirement of the invariance of physical laws under Lorentz transformations. We shall often call this invariance relativistic invariance.

The conditions 2–4 are also preserved in the theory of relativity.

At first sight it might seem that the diversity of physical laws and the physical quantities occurring in them rule out a general method of approach to the establishment of their relativistically invariant formulations. In practice, however, this is not so.

In order to find a general method of working out relativistically invariant expressions we again turn to the expression for the interval ds .

We introduce a completely formal quantity

$$\tau = ict, \quad (10.6)$$

which will be called the fourth coordinate or the imaginary time. It goes without saying that τ , as an imaginary quantity, has no direct physical meaning.

By means of the imaginary time the interval can be written in the form

$$-ds^2 = dx^2 + dy^2 + dz^2 + d\tau^2 \quad (10.7)$$

In this notation Lorentz transformations take on a new interpretation.

We assume, without going into the physical content of our treatment for the present, that the quantities x, y, z, τ are orthogonal coordinates in a certain imaginary four-dimensional space.

The Lorentz transformation represents a linear transformation of the four coordinates (x, y, z, τ) which leaves the quantity ds^2 unchanged. It is easy to see that, from the geometrical point of view, the quantity ds^2 represents the square of the distance between two points in a four-dimensional space. Consequently, the Lorentz transformation is a linear transformation which leaves the distance between two arbitrary points in this space unchanged. From geometry it is known that there are only two such linear transformations: parallel displacement and rotation. Parallel displacement represents a trivial transformation which amounts to the change of the origin of the system of the coordinates x, y, z, t . Hence the only linear transformation leaving the

value of the interval unchanged is a rotation in the four-dimensional space (x, y, z, t) .

In what follows we shall confirm this conclusion by a direct calculation.

Such a geometrical interpretation of the Lorentz transformation, which is due to Minkowski, allows one to draw conclusions directly about the relativistically invariant form of physical laws.

Namely, in order that an expression may be relativistically invariant it must have the form

$$a = b, \quad (10.8)$$

where a and b are scalars, or

$$a_\alpha = b_\alpha, \quad (10.9)$$

where a_α and b_α are four-dimensional vectors having four components $(\alpha = x, y, z, \tau)$ and, in general,

$$a_{\alpha\beta\gamma\dots} = b_{\alpha\beta\gamma\dots}, \quad (10.10)$$

where $a_{\alpha\beta\gamma\dots}$ and $b_{\alpha\beta\gamma\dots}$ are four-dimensional tensors of an arbitrary rank. Under rotations of coordinate axes in the space (x, y, z, τ) all quantities involved in the relativistically invariant expression transform according to one and the same law, so that equalities of the type (10.8)–(10.10) are not violated. These conditions of invariance in the case of the Minkowski four-dimensional space represent a direct analogue of the conditions of invariance under a rotation of the reference frame in the real three-dimensional space.

It should be stressed that the introduction of the idea of a four-dimensional space with coordinates x, y, z, τ has a formal character. It is in no way equivalent to the statement of the existence of a real space with four dimensions.

The time coordinate τ is a purely imaginary quantity, which underlines its special character and basic difference from the space coordinates x, y, z . Nevertheless, the introduction of the time coordinate τ has a profound physical meaning. It points to the indissoluble connection between space and time, about which we have already spoken.

Later we shall have to reduce a number of important physical laws and relations to a relativistically invariant form. For this it is necessary to find their four-dimensional generalization. How this is to be done will be seen by concrete examples.

In the meantime we shall verify the fact that the rotation transformation in the four-dimensional space (x, y, z, τ) is identical with the Lorentz transformation. For simplicity of notation we assume, as before, that the motion of inertial reference frames is performed in the direction of matched axes x and x' . In a four-dimensional interpretation this corresponds to a rotation in the plane (x, τ) , the orientation of the axes y, z remaining unchanged.

If the rotation angle is denoted by φ , then by analogy with (10.5) one can write the relation between the initial coordinates (x, τ) and the transformed coordinates (x', τ') :

$$x = x' \cos \varphi - \tau' \sin \varphi, \quad (10.11)$$

$$\tau = \tau' \cos \varphi + x' \sin \varphi. \quad (10.12)$$

The rotation angle φ must, obviously, be different for different values of the velocity v . We write the transformations (10.11) and (10.12) for the τ -axis of the reference frame K' , i.e. for points which have $x' = 0$. Then, obviously,

$$x = -\tau' \sin \varphi,$$

$$\tau = \tau' \cos \varphi.$$

Dividing the upper expression by the lower one, we obtain

$$\tan \varphi = -x/\tau,$$

or

$$\tan \varphi = ix/ct = iv/c, \quad (10.13)$$

where v is the velocity of uniform motion of the origin of the coordinate frame K' (the point $x' = 0$) with respect to the reference frame K . From the equality (10.13) one can easily find the values of the quantities $\sin \varphi$ and $\cos \varphi$ involved in formulae (10.11) and (10.12):

$$\cos \varphi = \frac{1}{\sqrt{1 + \tan^2 \varphi}} = \frac{1}{\sqrt{1 - \frac{v^2}{c^2}}},$$

$$\sin \varphi = \tan \varphi \cos \varphi = \frac{iv/c}{\sqrt{1 - \frac{v^2}{c^2}}}.$$

Hence

$$x = \frac{x' - i \frac{v}{c} \tau'}{\sqrt{1 - \frac{v^2}{c^2}}}, \quad (10.14)$$

$$\tau = \frac{\tau' + i \frac{v}{c} x'}{\sqrt{1 - \frac{v^2}{c^2}}}. \quad (10.15)$$

Passing over from τ to a time t , we see that formulae (10.14) and (10.15) are the same as the Lorentz transformation.

It is not out of place to stress the conditional character of the graphical representation of Lorentz transformations. The rotation angle in fig. II.2 is an imaginary angle. Of course, we cannot picture a rotation through an imaginary angle. The merits and shortcomings of the graphical representation of Lorentz transformations are clearly seen from the following. Let a clock be at rest at a certain point x' in the reference frame K' . This physical event at a moment τ'_1 is represented by the first point, and at a moment τ'_2 by the

Fig. II.2

Fig. II.3

second point on the axis τ' . The time interval $\Delta\tau'$ is equal to the length of the section from point 1 to point 2. In passing over to the reference frame K (rotation through an angle φ) the segment $\Delta\tau'$ turns into a segment $\Delta\tau$ on the axis τ . We see clearly that it makes no sense to speak about which one of the reference frames is more correct and which one of the time intervals $\Delta\tau$ and $\Delta\tau'$ is the true time interval between the two physical events. A shortcoming of the geometrical consideration is the fact that the interrelation between $\Delta\tau$ and $\Delta\tau'$ in the drawing is the reverse of the true one: in the drawing $\Delta\tau$ is smaller than $\Delta\tau'$, whereas in reality it is larger in the ratio $1/\sqrt{1-v^2/c^2}$. The misrepresentation is due to the fact that we cannot show in the drawing the imaginary value of the angle φ and replace it by a real angle.

The length transformation (fig. II.3) and the Einstein theorem of addition of velocities allow an analogous geometrical interpretation. To the addition of velocities v_1 and v_2 there correspond two successive rotations in the plane (x, τ) : to the rotation through an angle φ_1 there corresponds the transition from the reference frame K to the reference frame K' moving with the velocity v_1 with respect to K; to the rotation through an angle φ_2 there corresponds the transition from the reference frame K' to a reference frame K'' moving with the velocity v_2 with respect to K'. Consequently, to the transition from K to K'', i.e. to the addition of velocities v_1 and v_2 there corresponds the rotation in the space (x, τ) through an angle

$$\varphi = \varphi_1 + \varphi_2.$$

Velocities v_1 and v_2 are connected with rotation angles φ_1 and φ_2 by the relation (10.13) which involves the tangent of the rotation angle. To an angle φ there corresponds a $\tan \varphi$ given by

$$\tan \varphi = \tan (\varphi_1 + \varphi_2) = \frac{\tan \varphi_1 + \tan \varphi_2}{1 - \tan \varphi_1 \tan \varphi_2}.$$

Substituting the values of $\tan \varphi$, $\tan \varphi_1$ and $\tan \varphi_2$ from (10.13) into the above relation, it is easy to arrive at the Einstein theorem of addition of velocities.

§ 11. Four-dimensional vectors and tensors.

Four-dimensional velocity and acceleration

We now pass on to four-dimensional vectors which, according to the results of the preceding paragraph, must figure in relativistically invariant expressions.

First of all we introduce the four-dimensional radius vector r_α ($\alpha = 1, 2, 3, 4$) whose projections onto mutually orthogonal coordinate axes are equal to x, y, z, τ .

In the Lorentz transformation – a rotation in the four-dimensional space – the components of the vector r_α transform according to the law

$$r_\alpha = \gamma_{\alpha\beta} r'_\beta,$$

such that the square of the vector r_α^2 remains invariant:

$$r_\alpha^2 = r_\alpha r_\alpha = x^2 + y^2 + z^2 + \tau^2 = \text{const}$$

For this the coefficients of the Lorentz transformation must obviously satisfy the requirement

$$\gamma_{\alpha\beta} \gamma_{\alpha\lambda} = \delta_{\beta\lambda},$$

often called the condition of orthogonality. Indeed, we have

$$r_\alpha^2 = (\gamma_{\alpha\beta} r'_\beta)(\gamma_{\alpha\lambda} r'_\lambda) = \gamma_{\alpha\beta} \gamma_{\alpha\lambda} r'_\beta r'_\lambda = \delta_{\beta\lambda} r'_\beta r'_\lambda = r'^2_\beta$$

This requirement imposes a necessary restriction upon the coefficients of the transformation $\gamma_{\alpha\beta}$. In the particular case where the Lorentz transformation corresponds to a rotation in the plane (x, τ) with unchanged values of y and z , making use of (10.14) and (10.15) one can easily write for $\gamma_{\alpha\beta}$

$$\gamma_{\alpha\beta} = \begin{vmatrix} \frac{1}{\sqrt{1-\frac{v^2}{c^2}}} & 0 & 0 & -i\frac{v}{c} \\ \sqrt{1-\frac{v^2}{c^2}} & 0 & 0 & \frac{1}{\sqrt{1-\frac{v^2}{c^2}}} \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ -i\frac{v}{c} & 0 & 0 & \frac{1}{\sqrt{1-\frac{v^2}{c^2}}} \\ \sqrt{1-\frac{v^2}{c^2}} & 0 & 0 & \sqrt{1-\frac{v^2}{c^2}} \end{vmatrix} \quad (11.1)$$

We generalize the definition of the vector r_α to the case of an arbitrary 4-vector. By definition, a set of quantities (components) a_x, a_y, a_z, a_τ , which under a Lorentz transformation (i.e. a rotation of the axes in the four-dimensional space) transform according to the same law as the components of the radius vector r_α , i.e. according to the law

$$a_\alpha = \gamma_{\alpha\beta} a'_\beta,$$

is called a 4-vector a_α . If one restricts oneself to rotations in the (x, τ) -plane, then, making use of the definition of $\gamma_{\alpha\beta}$ (or the analogy with (10.14) and (10.15)) one can write the transformation law in the form

$$a_x = \frac{a'_x - i \frac{v}{c} a'_\tau}{\sqrt{1 - \frac{v^2}{c^2}}}, \quad (11.2)$$

$$a_y = a'_y, \quad a_z = a'_z, \quad (11.3)$$

$$a_\tau = \frac{a'_\tau + i \frac{v}{c} a'_x}{\sqrt{1 - \frac{v^2}{c^2}}}. \quad (11.4)$$

For four-dimensional vectors, as for three-dimensional ones, one can introduce the idea of the scalar product

$$c = a_\alpha b_\alpha = \mathbf{a} \cdot \mathbf{b} + a_\tau b_\tau,$$

where c is a scalar quantity. The vectors a_α and b_α are called orthogonal if their scalar product is equal to zero. We do not consider other vectorial algebraic operations, since we shall not need them in what follows.

An important characteristic of a 4-vector is the scalar corresponding to the square of the vector $*$, i.e. to the scalar product

* Here and in what follows we make use of an abbreviated notation for summation. Repeated indices imply summation, for example

$$a_\alpha b_\alpha = \sum_\alpha a_\alpha b_\alpha, \quad a_\alpha^2 = a_\alpha a_\alpha = \sum_\alpha a_\alpha^2.$$

$$a_\alpha^2 = a_\alpha a_\alpha = a_x^2 + a_y^2 + a_z^2 + a_\tau^2 = \text{invar.} \quad (11.5)$$

The invariance of a_α^2 is seen directly from geometrical considerations: Lorentz transformations are a rotation in the four-dimensional space. The square of a 4-vector, like the square of the radius 4-vector r_α^2 , is not necessarily positive. If the square of the vector $a_\alpha^2 > 0$, then a_α is called a space-like vector. The vector for which $a_\alpha^2 < 0$ is called a time-like vector.

We shall consider the determination of two important 4-vectors: the 4-vector of velocity and the 4-vector of acceleration.

We have to find a 4-vector of velocity in the form of the derivative of the radius 4-vector with respect to a certain invariant — i.e. a scalar. The choice of this scalar is determined by the fact that, at small velocities $v \ll c$, the spatial components of the 4-vector of velocity must go over into the components of the ordinary velocity.

Because of this, it is natural to define the 4-vector of velocity by the relation

$$u_\alpha = \frac{dr_\alpha}{dt_0} \quad (11.6)$$

For the components of the 4-velocity we have, by eq. (9.4),

$$u_x = \frac{dx}{dt \sqrt{1 - \frac{v^2}{c^2}}} = \frac{v_x}{\sqrt{1 - \frac{v^2}{c^2}}}, \quad (11.7)$$

$$u_y = \frac{v_y}{\sqrt{1 - \frac{v^2}{c^2}}}, \quad (11.8)$$

$$u_z = \frac{v_z}{\sqrt{1 - \frac{v^2}{c^2}}}, \quad (11.9)$$

$$u_\tau = \frac{d\tau}{dt_0} = \frac{ic \, dt}{dt \sqrt{1 - \frac{v^2}{c^2}}} = \frac{ic}{\sqrt{1 - \frac{v^2}{c^2}}}. \quad (11.10)$$

For $v \ll c$ the three spatial components of the velocity are the same as the components of the usual three-dimensional velocity. The fourth component u_τ of the velocity is purely imaginary. Except for the factor (ic) it represents the coefficient of transition from the proper time dt_0 to the time dt .

An important feature of the 4-vector of velocity is the fact that its components are not independent of each other. Indeed, squaring the vector u_α , we find

$$u_\alpha^2 = u_x^2 + u_y^2 + u_z^2 + u_\tau^2 = -c^2. \quad (11.11)$$

Thus, the 4-vector of velocity is a time-like vector, and its absolute value is a constant. This property of the 4-vector is associated, of course, with the fact that the velocity of motion of material bodies cannot exceed the velocity of light.

Now we define the four-dimensional acceleration w_α as

$$w_\alpha = \frac{du_\alpha}{dt_0}. \quad (11.12)$$

Expressing w_α in terms of the velocity \mathbf{v} and the acceleration $\dot{\mathbf{v}}$, we find its components:

$$\begin{aligned} w_x &= \frac{du_x}{dt} \frac{dt}{dt_0} = \frac{1}{\sqrt{1 - \frac{v^2}{c^2}}} \frac{d}{dt} \frac{v_x}{\sqrt{1 - \frac{v^2}{c^2}}} = \\ &= \frac{\dot{v}_x}{\left(1 - \frac{v^2}{c^2}\right)} + \frac{v_x(\mathbf{v} \cdot \dot{\mathbf{v}})}{c^2 \left(1 - \frac{v^2}{c^2}\right)^2}, \end{aligned} \quad (11.13)$$

$$w_y = \frac{\dot{v}_y}{\left(1 - \frac{v^2}{c^2}\right)} + \frac{v_y(\mathbf{v} \cdot \dot{\mathbf{v}})}{c^2 \left(1 - \frac{v^2}{c^2}\right)^2}, \quad (11.14)$$

$$w_z = \frac{\dot{v}_z}{\left(1 - \frac{v^2}{c^2}\right)} + \frac{v_z(\mathbf{v} \cdot \dot{\mathbf{v}})}{c^2 \left(1 - \frac{v^2}{c^2}\right)^2}, \quad (11.15)$$

$$w_\tau = \frac{dt}{dt_0} \frac{d}{dt} \left[\frac{ic}{\sqrt{1 - \frac{v^2}{c^2}}} \right] = \frac{i}{c} \frac{\mathbf{v} \cdot \dot{\mathbf{v}}}{\left(1 - \frac{v^2}{c^2}\right)^2}. \quad (11.16)$$

A simple calculation shows that the square of the four-dimensional acceleration is equal to

$$w_{\alpha}^2 = \frac{\dot{v}^2 - \frac{1}{c^2} [\dot{v}^2 v^2 - (\mathbf{v} \cdot \dot{\mathbf{v}})^2]}{\left(1 - \frac{v^2}{c^2}\right)^3} = \frac{\dot{v}^2 - \left[\frac{\mathbf{v}}{c} \times \dot{\mathbf{v}}\right]^2}{\left(1 - \frac{v^2}{c^2}\right)^3} > 0. \quad (11.17)$$

Thus the 4-acceleration is a space-like vector.

Differentiating the equality (11.11) with respect to t_0 , we find

$$u_{\alpha} \frac{du_{\alpha}}{dt_0} = u_{\alpha} w_{\alpha} = 0. \quad (11.18)$$

This last equality means that the vectors u_{α} and w_{α} are orthogonal to each other in the four-dimensional space.

In addition to the definition of 4-vectors one can introduce 4-tensors. The set of quantities $A_{\alpha\beta}$ which transform as the product of two vectors $a_{\alpha}b_{\beta}$, i.e.

$$A_{\alpha\beta} = \gamma_{\alpha\lambda} \gamma_{\beta\mu} A'_{\lambda\mu}, \quad (11.19)$$

is called a second-rank 4-tensor. The tensor $A_{\alpha\beta}$ represents a set of sixteen quantities (a second-rank tensor in the three-dimensional space represents a set of nine quantities). As in the case of a 4-vector, the τ -components of a 4-tensor, i.e. the quantities $A_{\alpha\tau}$, are purely imaginary, whereas all remaining components are real. Any tensor $A_{\alpha\beta}$ can be resolved into a symmetric part and an antisymmetric part (with respect to the permutation of subscripts). Writing

$$A_{\alpha\beta} = \frac{1}{2} (A_{\alpha\beta} + A_{\beta\alpha}) + \frac{1}{2} (A_{\alpha\beta} - A_{\beta\alpha}) = A_{\alpha\beta}^s + A_{\alpha\beta}^{as},$$

it is easily seen that

$$A_{\alpha\beta}^s = A_{\beta\alpha}^s,$$

$$A_{\alpha\beta}^{as} = -A_{\beta\alpha}^{as}.$$

Lorentz transformations leave this decomposition unchanged.

Purely antisymmetric tensors will play an important role in what follows. From the condition of antisymmetry it follows that such tensors have six independent components and can be written in the form of a table:

$$A_{\alpha\beta}^{\text{as}} = \begin{vmatrix} 0 & A_{xy} & A_{xz} & A_{x\tau} \\ -A_{xy} & 0 & A_{yz} & A_{y\tau} \\ -A_{xz} & -A_{yz} & 0 & A_{z\tau} \\ -A_{x\tau} & -A_{y\tau} & -A_{z\tau} & 0 \end{vmatrix} \quad (11.20)$$

Making use of the properties of the quantities $\gamma_{\alpha\beta}$ (11.1) one can find the law of transformation of the components of a 4-tensor. We restrict ourselves to the case of an antisymmetric tensor and write one of the components in detail:

$$\begin{aligned} A_{xy} &= \gamma_{x\lambda} \gamma_{y\mu} A'_{\lambda\mu} = \gamma_{xx} \gamma_{yy} A'_{xy} + \gamma_{x\tau} \gamma_{y\tau} A'_{\tau y} = \\ &= \frac{A'_{xy} - i \frac{v}{c} A'_{y\tau}}{\sqrt{1 - \frac{v^2}{c^2}}} \end{aligned}$$

The other terms reduce to zero by virtue of the definition of $\gamma_{\alpha\beta}$ and $A_{\alpha\beta}^{\text{as}}$. The law of transformation of the remaining components is easily found in the same way. As a result, for the transformation of the components of the antisymmetric tensor we obtain

$$\begin{aligned} A_{xy} &= \frac{A'_{xy} - i \frac{v}{c} A'_{y\tau}}{\sqrt{1 - \frac{v^2}{c^2}}}, & A_{x\tau} &= A'_{x\tau}, \\ A_{xz} &= \frac{A'_{xz} - i \frac{v}{c} A'_{z\tau}}{\sqrt{1 - \frac{v^2}{c^2}}}, & A_{y\tau} &= \frac{A'_{y\tau} + i \frac{v}{c} A'_{xy}}{\sqrt{1 - \frac{v^2}{c^2}}}, \\ A_{yz} &= A'_{yz}, & A_{z\tau} &= \frac{A'_{z\tau} + i \frac{v}{c} A'_{xz}}{\sqrt{1 - \frac{v^2}{c^2}}}. \end{aligned} \quad (11.21)$$

The invariants of 4-tensors, i.e. combinations remaining invariant under Lorentz transformations, are an important characteristic of 4-tensors. For anti-symmetric tensors of the second rank, which we shall need in what follows, the invariants are scalar quantities:

- 1) the product $A_{\alpha\beta}A_{\alpha\beta}$ (quadratic invariant),
- 2) the product $A_{\alpha\lambda}A_{\lambda\mu}A_{\mu\alpha}$ (cubic invariant) ,
- 3) the product $A_{\alpha\lambda}A_{\lambda\mu}A_{\mu\nu}A_{\nu\alpha}$ (biquadratic invariant).

One can verify the invariance of these quantities by the direct substitution of the transformation law (11.19) and the values of the quantities $\gamma_{\alpha\beta}$. Other scalar relations can either be expressed in terms of these three invariants or are equal to zero. Thus, for example, the scalar $A_{\alpha\alpha}$, representing the sum of diagonal elements, is equal to zero for antisymmetric tensors.

Relativistic Mechanics

§12. The dynamical equations of a material point

We now turn to the consideration of the dynamics of a material point in the theory of relativity.

As in classical mechanics, a material point is understood to be a body whose dimensions can be neglected. Having physical applications in mind, we shall often speak not about the motion of a material point but about the motion of a particle.

First of all we note that the Newtonian law of inertia is invariant under Lorentz transformations. Indeed, if a particle moves without acceleration in an inertial reference frame K , then under a linear transformation of the coordinates to another reference frame K' the motion will remain without acceleration. However, the equations of dynamics, which are invariant under Galilean transformations, possess no invariance properties under Lorentz transformations.

In order to find the relativistically-invariant form of the equations of dynamics it is necessary to represent them in the form of a four-dimensional relation of the type of (10.9).

The inertial properties of a body or a particle may be characterized by a certain scalar — the invariant mass or the rest mass m . The value of the rest mass is a constant characteristic of every kind of elementary particle. The

4-momentum p_α of a particle is defined as follows:

$$p_\alpha = mu_\alpha. \quad (12.1)$$

For the components we have:

$$\begin{aligned} p_x &= \frac{mv_x}{\sqrt{1 - \frac{v^2}{c^2}}}, & p_y &= \frac{mv_y}{\sqrt{1 - \frac{v^2}{c^2}}}, \\ p_z &= \frac{mv_z}{\sqrt{1 - \frac{v^2}{c^2}}}, & p_\tau &= \frac{icm}{\sqrt{1 - \frac{v^2}{c^2}}} \end{aligned} \quad (12.2)$$

In the limiting case $v \ll c$ the three spatial components of the momentum go over into the ordinary components of the particle momentum:

$$p_x = mv_x, \quad p_y = mv_y, \quad p_z = mv_z.$$

A natural relativistic generalization of the equations of Newtonian dynamics are the equations

$$\frac{dp_\alpha}{dt_0} = \frac{d}{dt_0} mu_\alpha = F_\alpha, \quad (12.3)$$

where F_α is a four-dimensional vector called the four-dimensional force or Minkowski force, and α runs through the values x, y, z, τ . The relativistically-invariant character of the eqs. (12.3) follows directly from what was said in §11: the right-hand and left-hand side of (12.3) involve four-dimensional vectors, which change in the same way under a four-dimensional rotation (Lorentz transformation), and the scalar m which does not change at all.

In the following we shall call the relations (12.3) the equations of relativistic dynamics.

We write the components of these equations. We have:

$$\frac{dp_x}{dt_0} = \frac{1}{\sqrt{1 - \frac{v^2}{c^2}}} \frac{d}{dt} \frac{mv_x}{\sqrt{1 - \frac{v^2}{c^2}}} = F_x,$$

or

$$\frac{d}{dt} \frac{mv_x}{\sqrt{1 - \frac{v^2}{c^2}}} = F_x \sqrt{1 - \frac{v^2}{c^2}}. \quad (12.4)$$

For $v \ll c$ eq. (12.4) must go over into the ordinary Newtonian equation.

The left-hand side of formula (12.4) is the derivative of the momentum with respect to ordinary time. We require that the right-hand side of eq. (12.4) should be the component \mathcal{F}_x of the ordinary force. Consequently, the component F_x of the 4-force is connected with that of the ordinary force \mathcal{F}_x of classical mechanics by the relation

$$F_x \sqrt{1 - \frac{v^2}{c^2}} = \mathcal{F}_x. \quad (12.5)$$

Then formula (12.4) is written in the form

$$\frac{d}{dt} \frac{mv_x}{\sqrt{1 - \frac{v^2}{c^2}}} = \mathcal{F}_x. \quad (12.6)$$

For $v \ll c$ formula (12.6) reduces to the Newtonian equation.

Analogous relations can be written for the two remaining spatial components:

$$\frac{d}{dt} \frac{mv_y}{\sqrt{1 - \frac{v^2}{c^2}}} = \mathcal{F}_y, \quad (12.7)$$

$$\frac{d}{dt} \frac{mv_z}{\sqrt{1 - \frac{v^2}{c^2}}} = \mathcal{F}_z. \quad (12.8)$$

Now we write the fourth component of the relation (12.3). Making use of (11.10), we find

$$\frac{d}{dt} \frac{icm}{\sqrt{1 - \frac{v^2}{c^2}}} = F_\tau \sqrt{1 - \frac{v^2}{c^2}}. \quad (12.9)$$

To find the physical meaning of the component F_τ of the 4-force we multiply (12.3) by u_α and sum over all components α ($\alpha = x, y, z, \tau$).

Obviously, by virtue of (11.18) we have

$$u_\alpha \frac{dm u_\alpha}{dt_0} = F_\alpha u_\alpha = 0,$$

or

$$F_x u_x + F_y u_y + F_z u_z + F_\tau u_\tau = 0.$$

Substituting the values of $F_x, F_y, F_z, u_x, u_y, u_z$ and u_τ , we have

$$\begin{aligned} \mathcal{F}_x \frac{v_x}{\left(\sqrt{1 - \frac{v^2}{c^2}}\right)^2} + \mathcal{F}_y \frac{v_y}{\left(\sqrt{1 - \frac{v^2}{c^2}}\right)^2} + \\ + \mathcal{F}_z \frac{v_z}{\left(\sqrt{1 - \frac{v^2}{c^2}}\right)^2} + F_\tau \frac{ic}{\sqrt{1 - \frac{v^2}{c^2}}} = 0. \end{aligned}$$

From which it follows that

$$F_\tau \sqrt{1 - \frac{v^2}{c^2}} = \frac{i}{c} \mathcal{F} \cdot \mathbf{v}.$$

The right-hand side of this equation contains the work done by the force \mathcal{F} on the particle per unit time. Thus, the component F_τ of the 4-force turns out to be connected with the work done by the three-dimensional force \mathcal{F} :

$$F_\tau = \frac{i}{c} \frac{\mathcal{F} \cdot \mathbf{v}}{\sqrt{1 - \frac{v^2}{c^2}}}. \quad (12.10)$$

Making use of (12.10) we write (12.9) in the form

$$\frac{d}{dt} \frac{mc^2}{\sqrt{1 - \frac{v^2}{c^2}}} = \mathcal{F} \cdot \mathbf{v}. \quad (12.11)$$

On the right-hand side of (12.11) the product $\mathcal{F} \cdot \mathbf{v}$ gives the work done by the force on the particle in unit time. Consequently, on the left-hand side of the equation we must have the change of the energy in unit time.

Thus, we define the total energy of a particle as follows:

$$E = \frac{mc^2}{\sqrt{1 - \frac{v^2}{c^2}}} \quad (12.12)$$

Finally, we find the expression for the acceleration. The equations of motion can be written in the form

$$\frac{d}{dt} \frac{m\mathbf{v}}{\sqrt{1 - \frac{v^2}{c^2}}} = \frac{m}{\sqrt{1 - \frac{v^2}{c^2}}} \frac{d\mathbf{v}}{dt} + \frac{\mathbf{v}}{c^2} \frac{d}{dt} \frac{mc^2}{\sqrt{1 - \frac{v^2}{c^2}}} = \mathcal{F},$$

or

$$\frac{m}{\sqrt{1 - \frac{v^2}{c^2}}} \frac{d\mathbf{v}}{dt} + \frac{\mathbf{v}}{c^2} \frac{dE}{dt} = \mathcal{F}. \quad (12.13)$$

By means of (12.11) one can rewrite (12.13) in the form

$$\mathbf{w} = \frac{d\mathbf{v}}{dt} = \frac{\sqrt{1 - \frac{v^2}{c^2}}}{\gamma} \left(\mathcal{F} - \frac{\mathbf{v}}{c^2} (\mathcal{F} \cdot \mathbf{v}) \right) \quad (12.14)$$

§ 13. Momentum, energy and mass in relativistic mechanics

We shall now discuss the properties of the mechanical quantities introduced in the preceding paragraph, i.e. the rest mass, momentum and energy.

According to (12.2) the connection between the rest mass m and the three-dimensional momentum \mathbf{p} is determined by the relation

$$\mathbf{p} = \frac{m\mathbf{v}}{\sqrt{1 - \frac{v^2}{c^2}}}, \quad (13.1)$$

which for $v \ll c$ is the same as the usual expression of classical mechanics. Hence one would think that it could be taken that the scalar m is the same as the mass of a body moving with a small velocity.

However, as will be seen from what follows, the properties of the invariant mass m (the rest mass) differ essentially from those which are attributed to mass in classical mechanics. Namely, the rest mass does not satisfy the conservation law. There are physical processes in which the rest mass of the particles before the beginning of the process is not equal to that of the particles remaining after the end of the process.

Examples of phenomena of this kind will be given below. The singularity (from the point of view of the concept of mass in classical mechanics) of the rest mass m and the possibility of its non-conservation are particularly clear from the fact that the presence of rest mass is not a necessary property of particles.

For example, the existence in nature of elementary particles whose rest mass is equal to zero is beyond any doubt. Light quanta (photons) are such particles. According to all available experimental (see § 16) and theoretical data, the neutrino is also a particle with zero rest mass. The neutrino is a neutral particle playing an important role in nuclear processes (it arises in particular in β -decay).

It is clear that, if in the processes of mutual transformation, which play a most important role in the world of elementary particles, there are transitions of particles with non-zero rest mass into particles with zero rest mass, then the rest mass is not conserved. Such processes indeed occur in nature, and some of them are well investigated. Examples will be presented in § 16.

In spite of its unusual properties, the rest mass is a very important characteristic of bodies.

Every elementary particle has a well defined value of rest mass (including also the value zero), which does not change from sample to sample. Hence the rest mass is a fundamental characteristic of an elementary particle.

One can speak of the rest mass of a body consisting of many elementary particles in the same way as of the rest mass of an elementary particle. If the dimensions of the body are neglected, it can be considered as a material point with a rest mass m . The question as to how the rest mass of the body is connected with the rest masses of the constituent particles will be discussed below.

In addition to the rest mass, a mass $m(v)$, called the relativistic mass or simply mass and defined as the factor of proportionality between the vectors \mathbf{p} and \mathbf{v} , is often introduced:

$$\mathbf{p} = m(v) \mathbf{v}, \quad (13.2)$$

where

$$m(v) = \frac{m}{\sqrt{1 - \frac{v^2}{c^2}}} . \quad (13.3)$$

The relativistic mass depends on the velocity and is hence a function not only of the properties of the particle but also of the state of its motion.

However, it should be stressed that the relativistic mass $m(v)$ is not a relativistically-invariant quantity. Indeed, the quantity $\sqrt{1 - v^2/c^2}$ is not invariant (the law of transformation of $\sqrt{1 - v^2/c^2}$ is found most simply from (9.4), taking into account that dt_0 is an invariant and that the law of transformation of the time dt is known).

If a particle moves with different velocities relative to two reference frames, then its mass, measured by devices located in these reference frames, will be different.

The energy of a particle was determined by the relation (12.12). Before going on to a discussion of this relation, we note that the following important relation, connecting the time component of the momentum 4-vector and the energy, results from (12.12) and (12.2):

$$p_\tau = i E/c . \quad (13.4)$$

Thus, p_τ is the same as the energy of the particle apart from the constant factor. The importance of (13.4) lies in the fact that by means of it the momentum and energy may be combined into one 4-vector, called the energy-momentum 4-vector,

$$p_\alpha = (p_x, p_y, p_z, i E/c) . \quad (13.5)$$

The components of the energy-momentum 4-vector are not relativistically-invariant quantities. The three-dimensional momentum as well as the energy turn out to be relative quantities. In transition from one inertial reference frame to another the components of the energy-momentum 4-vector transform according to formulae (11.1)–(11.4), i.e.

$$p_x = \frac{p'_x + \frac{E'}{c^2} v}{\sqrt{1 - \frac{v^2}{c^2}}} , \quad (13.6)$$

$$p_y = p'_y, \quad (13.7)$$

$$p_z = p'_z, \quad (13.8)$$

$$E = \frac{p_x c}{i} = \frac{E' + v p'_x}{\sqrt{1 - \frac{v^2}{c^2}}}. \quad (13.9)$$

These relations show that under Lorentz transformations the energy and the components of the momentum are expressed in terms of each other. The energy and momentum are not separately invariant quantities, but the square of the 4-vectors, i.e. the quantity

$$p_\alpha^2 = p_x^2 + p_y^2 + p_z^2 + p_\tau^2 = p_x^2 + p_y^2 + p_z^2 - E^2/c^2 = \text{invar}. \quad (13.10)$$

Substituting the values of the energy (12.12) and the components of the momentum (12.2) into (13.10), one can easily calculate the value of this invariant, which turns out to be

$$I = p_x^2 + p_y^2 + p_z^2 - E^2/c^2 = -m^2 c^2. \quad (13.11)$$

Thus, the energy-momentum 4-vector is a time-like vector.

We now return to the determination of the energy (12.12) of a particle. For $v \ll c$ formula (12.12) goes over into

$$E = mc^2 \left(1 + \frac{v^2}{2c^2} + \dots \right) \approx mc^2 + \frac{1}{2}mv^2. \quad (13.12)$$

The second term is the same as the kinetic energy of a particle in classical mechanics. However, for $v = 0$ the energy of the particle outside a force field

$$E_0 = mc^2 \quad (13.13)$$

turns out to be different from zero.

At first sight it may seem that such a determination of the energy is arbitrary. Since the energy is found from the differential relation (12.11), it can be chosen to be

$$E = \frac{mc^2}{\sqrt{1 - \frac{v^2}{c^2}}} + \text{const}. \quad (13.14)$$

If the arbitrary constant is chosen to be equal to $(-mc^2)$, then the energy determined in such a way at $v \ll c$ will be the same as the energy of the particle in classical mechanics.

In fact, however, it is easy to show that the constant must be set equal to zero, as was done in (12.12). We cannot require in advance that, without exception, all quantities of relativistic mechanics should assume the classical form for $v \ll c$. However, in any case it is beyond any doubt that for $v \ll c$ the Lorentz transformations must be the same as the Galilean transformations and, consequently, the ordinary law of addition of velocities must hold. In order that the transformation (13.6) of the momentum for $v \ll c$ may go over into the theorem of addition of velocities of classical mechanics, the condition $E' \rightarrow mc^2$ must be fulfilled. Then from (13.6) it follows that

$$p_x = p'_x + mv,$$

or

$$v_x = v'_x + v.$$

If the energy were determined by formula (13.14) and not by (12.12) and if for $v \ll c$ it tended to the limit $E' \rightarrow 0$, then the Lorentz transformation for the velocity would not reduce to the formula of addition of velocities of classical mechanics.

Thus, the theory of relativity leads to a new, very important conclusion: the energy of a particle at rest is equal to mc^2 . It is natural to call the quantity mc^2 the rest energy. Every particle possessing a rest mass m has also a rest energy mc^2 .

The energy of a moving particle can be connected with the relativistic mass by the relation

$$E = m(v)c^2, \quad (13.15)$$

analogous to (13.13).

Formulae (13.13) and (13.15), often called Einstein's formulae, show that every particle possessing a mass m has, at the same time, an energy E . The energy and mass are indissolubly connected with each other and are proportional to each other. This statement is often called the principle of equivalence of mass and energy.

Of course, the notions of equivalence and identity should not be confused. The energy and mass are different physical characteristics of particles, and the principle of equivalence established only their proportionality to each

other. The relation between the mass and energy is similar to the relation between the gravitational and inertial mass in classical mechanics: the two masses are indissolubly connected with each other and proportional to each other, but are at the same time different characteristics. *

At present Einstein's formula (13.15) as well as formulae (13.2) and (13.3) are confirmed by a vast amount of experimental material and their validity is beyond doubt.

If the particle is not acted upon by any external forces, then the energy conservation law

$$\frac{dE}{dt} = 0 \quad \text{or} \quad E = \text{const}, \quad (13.16)$$

and the momentum conservation law

$$\frac{dp}{dt} = 0 \quad (13.17)$$

hold. From Einstein's formula it follows that with the energy conservation law the law of conservation of the relativistic mass

$$m(v) = \text{const} \quad (13.18)$$

automatically holds.

As distinct from classical physics, where there are two independent conservation laws (i.e. the energy conservation law and the mass conservation law) there is in the theory of relativity only one conservation law, the law of conservation of energy or relativistic mass.

We shall come back to the physical interpretation of the energy conservation law in the theory of relativity in §15–17.

In conclusion we note that E is usually called the total energy. This should not lead to misunderstanding: E does not include the potential energy of the particle in an external field, if such a field acts on the particle. Sometimes one introduces the kinetic energy E_{kin} defining it as the energy of motion of the particle, i.e.

$$E_{\text{kin}} = E - mc^2 = mc^2 \left[\frac{1}{\sqrt{1 - \frac{v^2}{c^2}}} - 1 \right] = [m(v) - m]c^2. \quad (13.19)$$

* For more detail see: V.A.Fock, *The theory of space, time and gravitation* (Pergamon, London, 1964).

We introduce one more useful formula, connecting the energy and the three-dimensional momentum. From (12.12) and (13.1) it follows directly that

$$p = Ev/c^2. \quad (13.20)$$

By means of formula (13.13) one can find the expression for the classical radius of electron r_0 , introduced in Part I.

We have already discussed in §18 of Part I the fundamental difficulty of classical field theory associated with the problem of the self energy of the electron. For the energy of the electron in its own field one obtains the expression

$$U = e/r_0,$$

which diverges as $r_0 \rightarrow 0$.

If it is assumed that the overall mass of the electron is associated with the energy of the field produced by it, i.e. if

$$U \sim mc^2$$

for the electron at rest, then for r_0 one obtains the value

$$r_0 \sim e^2/mc^2,$$

which is the same as the inequality (29.6) of Part I. However, it should be borne in mind that the problem of the self energy is not solved at all by introducing the radius of the electron.

We have stressed that in the theory of relativity no body whatever, including the electron, can be considered as a perfectly rigid ball of given radius. Hence the quantity r_0 cannot be interpreted as the true "radius" of the electron. It is the minimum dimension of the space region in which use can still be made of the relations of classical field theory, the limit of applicability of its concepts. We note that, as has already been said in §29 of Part I, the true limit of applicability of classical field theory sets in at considerably larger distances.

§ 14. Lagrange's equations; the Lagrangian and Hamiltonian

As in classical mechanics, equations of motion can be written in generalized coordinates in the form of Lagrange's equations. For this we must first of all find the Lagrangian.

By definition the Lagrangian is a quantity whose derivatives with respect to the components of velocity represent the components of the momentum, while its derivatives with respect to coordinates represent the components of the force.

Hence we have

$$\frac{\partial L}{\partial v_i} = p_i = \frac{mv_i}{\sqrt{1 - \frac{v^2}{c^2}}}, \quad (14.1)$$

$$\frac{\partial L}{\partial x_i} = \mathcal{F}_i = - \frac{\partial U_{\text{field}}}{\partial x_i}, \quad (14.2)$$

where U_{field} is the potential energy of the external field, depending only on the coordinates of the particle. Eqs. (14.1) and (14.2) are satisfied by the Lagrangian:

$$L = -mc^2 \sqrt{1 - \frac{v^2}{c^2}} - U_{\text{field}} \quad (14.3)$$

We see that in relativistic mechanics the Lagrangian no longer represents the difference between the kinetic and potential energy.

By means of the Lagrangian one can write Lagrange's equations in generalized coordinates q_i :

$$\frac{d}{dt} \frac{\partial L}{\partial \dot{q}_i} - \frac{\partial L}{\partial q_i} = 0, \quad (14.4)$$

or

$$\frac{d}{dt} p_i - \frac{\partial L}{\partial q_i} = 0,$$

where

$$p_i = \frac{\partial L}{\partial \dot{q}_i}$$

are generalized momenta.

Knowing the Lagrangian one can then find the Hamiltonian H . If the Lagrangian does not depend explicitly on time, then, by definition,

$$\begin{aligned}
 H = \sum q_i p_i - L &= \frac{mv^2}{\sqrt{1 - \frac{v^2}{c^2}}} + mc^2 \sqrt{1 - \frac{v^2}{c^2}} + U_{\text{field}} = \\
 &= \frac{mc^2}{\sqrt{1 - \frac{v^2}{c^2}}} + U_{\text{field}} .
 \end{aligned} \tag{14.5}$$

The velocity can be expressed in terms of the momentum by means of the relations (12.2), from which it follows that

$$p_x^2 + p_y^2 + p_z^2 = p^2 = \frac{m^2 v^2}{1 - \frac{v^2}{c^2}}$$

A simple calculation gives

$$H = \sqrt{p^2 c^2 + m^2 c^4} + U_{\text{field}} . \tag{14.6}$$

Formula (14.6) shows that in relativistic mechanics the Hamiltonian is just the total energy expressed in terms of the momentum of the particle.

For large values of the momentum, when $p \gg mc$, the expression for the Hamiltonian of a free particle attains a simple form:

$$H \approx pc . \tag{14.7}$$

A motion with such a large momentum, for which the approximate formula (14.7) is valid, is called an ultrarelativistic motion. It is clear that for particles with zero rest mass formula (14.7) is valid. We shall often make use of it in considering processes in which light quanta (photons) take part.

§15. The mechanics of a system of particles in the theory of relativity

Up to now we have restricted ourselves to the consideration of one particle. The formulation of the mechanics of a system of particles in the theory of relativity is a much more complex problem. Nevertheless, in this case also a number of important general laws can be established.

A system of particles as a whole can be characterized by its energy E , momentum \mathbf{P} and rest mass M . If we are interested in the motion of the system as a whole, then, disregarding internal processes in the system and its spatial extension, the system can be considered as one material point. For the system as a whole one can write the equality

$$E = Mc^2, \quad (15.1)$$

where M is the rest mass of the entire system. Since it is always true that $M > 0$, the energy of a system of particles, like the energy of a single free particle, is an essentially positive quantity.

However, in general it is impossible to find expressions for the energy and momentum of the system in terms of the corresponding quantities for its individual particles, or to find general relations between the energy and momentum. The interaction existing between the particles can lead, for example, to the dependence of E on time (it should be recalled that E denotes the sum of the rest energy and kinetic energy, but does not include the energy of interaction). Hence the actual construction of the mechanics of a system of particles is restricted to a relatively few simple cases. These are:

- 1) a system of non-interacting particles,
- 2) a system of particles which are at large distances from one another and are moving with very large velocities,
- 3) systems of particles with a weak electromagnetic interaction.

The last case will be considered later, in § 25.

In a system of non-interacting particles the energy and momentum possess additive properties, so that

$$E = \sum_{i=1}^N E_i = \sum_{i=1}^N \frac{m_i c^2}{\sqrt{1 - \frac{v_i^2}{c^2}}}, \quad (15.2)$$

$$\mathbf{P} = \sum_{i=1}^N \mathbf{p}_i = \sum_{i=1}^N \frac{m_i \mathbf{v}_i}{\sqrt{1 - \frac{v_i^2}{c^2}}}, \quad (15.3)$$

where N is the number of particles in the system, and the index i refers to every one of the particles. The velocities of all particles are constant and, consequently, the total energy and total momentum of the system are also constant in time.

It is easily seen that the quantities E and \mathbf{P} form a 4-vector of energy and

momentum. Indeed, one can write

$$E = \sum_{i=1}^N \frac{m_i c^2}{\sqrt{1 - \frac{v_i^2}{c^2}}} = \text{const} , \quad (15.4)$$

$$\mathbf{P} = \sum_{i=1}^N \frac{m_i \mathbf{v}_i}{\sqrt{1 - \frac{v_i^2}{c^2}}} = \text{const} . \quad (15.5)$$

Hence the 4-vector

$$P_\alpha = \sum_{i=1}^N p_\alpha^{(i)} \quad (15.6)$$

can be introduced. Every term of the sum $p_\alpha^{(i)}$ is the 4-vector of the energy and momentum of an individual particle.

Before passing on to the discussion of the consequences of these propositions, we shall show that in the very important second case cited above the properties of a system of interacting particles can be reduced to those of non-interacting particles.

Consider a system of particles moving at large distances from one another. By the assumption that the velocities of the particles are very large, of the order of magnitude of the velocity of light, the energy

$$E_i = \frac{m_i c^2}{\sqrt{1 - \frac{v_i^2}{c^2}}}$$

is in general large in comparison with the interaction energy at large distances. Hence it can be assumed that, as for free particles, the total energy and momentum of the system are expressed by formulae (15.4) and (15.5).

When particles approach each other (this situation is often called a collision) the interaction between the particles can become appreciable and formulae (15.4) and (15.5) lose their applicability. However, when particles again diverge to large distances after collision the formulae (15.4) and (15.5) are again applicable. It is obvious, moreover, that the total energy and momentum of the particles which have diverged cannot differ from the energy and momentum before the interaction. Hence the conservation laws can be written in the form

$$\sum_{i=1}^N \frac{m_i c^2}{\sqrt{1 - \frac{v_i^2}{c^2}}} = \sum_{k=1}^{N^*} \frac{m_k c^2}{\sqrt{1 - \frac{v_k^2}{c^2}}}, \quad (15.7)$$

$$\sum_{i=1}^N \frac{m_i \mathbf{v}_i}{\sqrt{1 - \frac{v_i^2}{c^2}}} = \sum_{k=1}^{N^*} \frac{m_k \mathbf{v}_k}{\sqrt{1 - \frac{v_k^2}{c^2}}}. \quad (15.8)$$

Here the indices i and k refer to particles before and after the interaction. The asterisk in the sums on the right underlines the fact that the number of particles in the system before and after the interaction can be different (see § 17).

The quantities E and \mathbf{P} , referring to particles before and after the interaction, form a 4-vector of energy and momentum. According to (13.11), one can write the invariant for this 4-vector:

$$I = P_\alpha^2 = \sum_\alpha \left(\sum_i p_\alpha^{(i)} \right)^2 = \text{invar} = -M^2 c^2. \quad (15.9)$$

The constancy of the invariant I expresses the general energy-momentum conservation law.

We transform this invariant to a form convenient for practical use. We have

$$\begin{aligned} \sum_\alpha \left(\sum_i p_\alpha^{(i)} \right)^2 &= \sum_{i, \alpha} (p_\alpha^{(i)})^2 + 2 \sum_{k < i, \alpha} p_\alpha^{(i)} p_\alpha^{(k)} = \\ &= \sum_i (\mathbf{p}_i)^2 - \sum_i \frac{E_i^2}{c^2} + 2 \sum_{k < i} \mathbf{p}_i \mathbf{p}_k - 2 \sum_{k < i} \frac{E_i E_k}{c^2}. \end{aligned}$$

Here we have carried out the summation over the index α of the 4-vector and made use of formula (13.4) for $p_\tau^{(i)}$. Regrouping the terms in the sum, we find

$$\begin{aligned} I &= \left[\sum_i (\mathbf{p}_i)^2 + 2 \sum_{k < i} \mathbf{p}_i \mathbf{p}_k \right] - \frac{1}{c^2} \left[\sum_i E_i^2 + 2 \sum_{k < i} E_i E_k \right] = \\ &= \left(\sum_i \mathbf{p}_i \right)^2 - \frac{1}{c^2} \left(\sum_i E_i \right)^2 = \mathbf{P}^2 - \frac{E^2}{c^2} = -M^2 c^2. \quad (15.10) \end{aligned}$$

Thus, we can write

$$P^2 - \frac{E^2}{c^2} = (P^*)^2 - \frac{(E^*)^2}{c^2}, \quad (15.11)$$

where the values of the quantities after the interaction are denoted by an asterisk. The components of the 4-vector P_α transform, in the transition from one inertial reference frame to another, according to the general formulae (13.6)–(13.9).

It often turns out to be convenient to make use of a reference frame in which the total momentum is equal to zero. Such a reference frame, as in classical mechanics, is called the centre of mass system $K^{(c.m.)}$.

Let a reference frame K be given in which a system of particles has a momentum P and an energy E . Let us find the velocity of motion $V^{(c.m.)}$ of the centre of mass of the system with respect to the reference frame K . The velocity $V^{(c.m.)}$ characterizes the motion of the system as a whole. For simplicity we assume that the velocity of the centre of mass of the system is directed along the x -axis. Then according to the inverse of (13.6)–(13.9) we have

$$P_x^{(c.m.)} = 0 = \frac{P_x - V^{(c.m.)} \frac{E}{c^2}}{\sqrt{1 - \frac{(V^{(c.m.)})^2}{c^2}}}, \quad (15.12)$$

$$P_y^{(c.m.)} = 0 = P_y, \quad P_z^{(c.m.)} = 0 = P_z, \quad (15.13)$$

$$E^{(c.m.)} = \frac{E - V^{(c.m.)} P_x}{\sqrt{1 - \frac{(V^{(c.m.)})^2}{c^2}}}. \quad (15.14)$$

Quantities referred to the centre of mass system are denoted by the superscript $c.m.$.

From (15.12) we obtain

$$V^{(c.m.)} = \frac{P_x c^2}{E}. \quad (15.15)$$

In the general case of an arbitrary orientation of the velocity vector of the centre of mass system, instead of (15.15) one obtains

$$\mathbf{V}^{(c.m)} = \frac{\mathbf{P}c^2}{E}. \quad (15.16)$$

In contrast to classical mechanics, the velocity of the centre of mass in relativistic mechanics cannot be represented as the derivative of the coordinate of the centre of mass with respect to time:

$$\mathbf{V}^{(c.m)} \neq \frac{d}{dt} \mathbf{R}^{(c.m)}.$$

The quantity $\mathbf{P}c^2/E$ cannot, in general, be expressed in the form of the derivative of any quantity with respect to time. Hence it is impossible in relativistic mechanics to introduce the notion of the coordinate of the centre of mass for an arbitrary system of interacting particles. In §25 it will be shown that in the case of a system of weakly interacting particles use can be made, in a certain approximation, of the concept of the centre of mass.

We shall also discuss some properties of the rest mass of a system of particles.

Consider a centre of mass system K' . We write the invariant of the 4-vector of energy and momentum (15.10) for this system in the form

$$(\mathbf{P}^{(c.m)})^2 c^2 - (E^{(c.m)})^2 = -M^2 c^4. \quad (15.17)$$

Since $\mathbf{P}^{(c.m)} = 0$, formula (15.17) in the system K' assumes the form

$$E^{(c.m)} = Mc^2, \quad (15.18)$$

where M is the rest mass.

On the other hand, according to the general formula (15.2),

$$E^{(c.m)} = \sum_{i=1}^N \frac{m_i c^2}{\sqrt{1 - \frac{v_i^2}{c^2}}},$$

where v_i is the velocity of the i th particle referred to the centre of mass system. Then for the rest mass we obtain

$$M = \sum_{i=1}^N \frac{m_i}{\sqrt{1 - \frac{v_i^2}{c^2}}} \quad (15.19)$$

We see that the rest mass of a system of particles is not equal to the sum of the rest masses of individual particles $\sum m_i$, but depends on the velocities of their motion with respect to the centre of mass system.

Consider, for example, the case where a system of particles represents an ideal gas. The ideal gas obviously satisfies the requirements regarding the character of the interaction between the particles about which we have spoken earlier. Then, according to (15.17), the rest mass M of the gas depends on the internal motion of the gas particles or, what is the same, on the temperature of the gas.

The difference between the rest mass M of the system and the sum $\sum m_i$ of the rest masses of the particles forming the system is of great significance for processes occurring in nature. We shall discuss this in the next paragraph.

In the general case of a system of particles with an arbitrary interaction formula (15.2) is not an expression for the total energy of the system; it gives only the sum of the rest masses and kinetic energies of the particles.

It is necessary to include the energy of interaction between the particles in the total energy. It turns out, however, that in relativistic mechanics the idea of a potential energy of interaction of a system of particles does not exist. The potential energy of interaction of particles must depend only on their position. If the position of any particle is changed, then the potential energy of the system of particles and the forces acting on individual particles must change instantly. In other words, the concept of a potential energy of interaction of a particle is associated with the concept of action at a distance and cannot be admitted in the theory of relativity. In general, it appears to be impossible to write an expression for the energy of a system of interacting particles. The same holds also for the momentum of the system, which in the theory of relativity is not a time-independent quantity.

Besides systems interacting via collisions, an approximate expression can be found for the interaction of charged particles in the special theory of relativity. This will be done in §25. The gravitational interaction of bodies is considered in the general theory of relativity the subject of which is beyond the scope of our book.

§16. The energy-momentum conservation law in nuclear physics

The energy-momentum conservation law and the mass-energy relation have not only found experimental confirmation, but have become basic propositions in contemporary nuclear physics. As far back as the first work of Ein-

stein it was pointed out that the mass-energy relation could be checked experimentally in investigating the phenomena of radioactivity. Indeed, a characteristic feature of radioactive decay as, after all, of all other nuclear processes, is a large change in the energy of the system and the high energies of the nuclear particles produced. Of the whole variety of nuclear processes in which relativistic effects play an essential role, we have to confine ourselves within the framework of this book to only the most essential or typical ones.

The purpose of the examples presented below is to show that the relations of relativistic mechanics are a necessary basis for a study of processes taking place with atomic nuclei and elementary particles.

1. *Reactions involving the decay of particles.* A number of basic processes occurring with atomic nuclei and elementary particles arise in fusion reactions and the decay of particles. The energy-momentum conservation law imposes a fundamental restriction on the possible reactions. Consider the decay of one particle or body into two others. We shall assume that the decay takes place spontaneously, i.e. as a result of internal changes in the system, without the action of external forces on the system.

Let the disintegrating particle have a mass M . In the centre of mass system the momentum before the decay is zero. The invariant of the 4-vector of energy and momentum is equal to

$$I = \mathbf{p}^2 c^2 - E^2 = -M^2 c^4$$

After the decay two particles arise with masses m_1, m_2 , momenta $\mathbf{p}_1, \mathbf{p}_2$ and energies E_1, E_2 .

In the centre of mass system the total momentum after the decay is zero:

$$\mathbf{p}_1 + \mathbf{p}_2 = 0.$$

The invariant I can be written in the form

$$I = (\mathbf{p}_1 + \mathbf{p}_2)^2 c^2 - (E_1 + E_2)^2 = -M^2 c^4,$$

or

$$Mc^2 = E_1 + E_2.$$

Writing the energies E_1 and E_2 in the form

$$E_1 = m_1 c^2 + E_{\text{kin}}^{(1)},$$

$$E_2 = m_2 c^2 + E_{\text{kin}}^{(2)},$$

we have

$$Mc^2 = (m_1 + m_2)c^2 + E_{\text{kin}}^{(1)} + E_{\text{kin}}^{(2)}. \quad (16.1)$$

Since the kinetic energies of the particles produced after the decay are each greater than zero, it follows from (16.1) that the spontaneous decay of a body is possible only if the inequality

$$M > m_1 + m_2 \quad (16.2)$$

is fulfilled, i.e. only if the mass of the body is larger than the sum of the rest masses of the decay products. Conversely, in the cases when the mass of the body is smaller than the sum of the masses of the decay products, a spontaneous decay of the body is impossible. For the decay to occur in this case it is necessary to supply energy from outside.

Making use of the equalities $E_1 = \sqrt{p_1^2 c^2 + m_1^2 c^4}$ and $E_2 = \sqrt{p_2^2 c^2 + m_2^2 c^4}$ and taking into account that $p_1^2 = p_2^2$, one can easily find the energy of the particles produced in the decay.

Namely, we have

$$E_2^2 = p_2^2 c^2 + m_2^2 c^4 = E_1^2 + m_2^2 c^4 - m_1^2 c^4$$

On the other hand,

$$E_1^2 = (Mc^2 - E_2)^2,$$

hence

$$E_1 = \frac{(M^2 - m_2^2 + m_1^2)c^2}{2M}, \quad E_2 = \frac{(M^2 - m_1^2 + m_2^2)c^2}{2M}$$

2. Stability of atomic nuclei. The general results obtained above allow one to clarify the very important problem of stability of atomic nuclei.

Consider an atomic nucleus consisting of Z protons and $A - Z$ neutrons (where Z is the atomic number, and A is the mass number) and having a mass M . The protons and neutrons in the nucleus possess considerable kinetic energies. However, strong attractive forces — nuclear forces — acting between them ensure the stability of the system as a whole. The rest energy of the nucleus Mc^2 is made up of the rest energy of all particles constituting it, $\sum m_i c^2$, and the energy of internal motion and interaction of the particles.

In order for a nucleus to be stable and that the motion of nuclear particles should not lead to its spontaneous decay, it is obviously necessary that the inequality

$$Mc^2 < \sum m_i c^2 \quad (16.3)$$

be fulfilled. The quantity

$$\Delta mc^2 = \sum m_i c^2 - Mc^2, \quad (16.4)$$

called the nuclear binding energy, is a measure of the stability of the nucleus. If, in particular, Δmc^2 is negative, the nucleus is unstable and decays spontaneously.

In addition to the binding energy, the quantity

$$\Delta m = \sum m_i - M, \quad (16.5)$$

called the mass defect, serves as a measure of the stability of the nucleus. In order for a nucleus to be stable it is necessary that the mass defect be positive. If the mass defect of a nucleus is positive, then according to (16.1) the nucleus is stable with respect to decay into its constituent particles — protons and neutrons. However, this does not mean that the nucleus is absolutely stable and that it can exist for an indefinitely long time.

Assume that as a result of a decay of a nucleus, for example according to the scheme

$$M \rightarrow M_1 + M_2,$$

nuclei with masses M_1 and M_2 are produced. Such a decay is in principle possible if the atomic numbers Z_1 and Z_2 and mass numbers A_1 and A_2 of the product nuclei satisfy the equalities

$$Z_1 + Z_2 = Z, \quad A_1 + A_2 = A.$$

Let Δm_1 and Δm_2 be the mass defects of the product nuclei. If the mass defect Δm of the initial nucleus is smaller than the sum of the mass defects of the product nuclei, i.e.

$$\Delta m < (\Delta m_1 + \Delta m_2),$$

then the system arising after the decay possesses a higher stability than the

initial system. Hence when $\Delta m < (\Delta m_1 + \Delta m_2)$ the nucleus, which is stable with respect to the decay into individual elementary particles, is not stable with respect to the decay into two parts. As a result of transformations of the nuclear particles, a decay configuration will arise in the nucleus after the lapse of a certain time interval. The initial nucleus then decays into two nuclei with masses M_1 and M_2 .

As an example the nucleus ${}^8_4\text{Be}$ can be considered. This nucleus has a mass $M = 8.005\,31$ amu, which is smaller than the sum of the masses of four protons and four neutrons: $\sum m_i = 4 \times 1.007\,825$ amu + $4 \times 1.008\,665$ amu = $8.065\,960$ amu. Hence the nucleus ${}^8_4\text{Be}$ is stable with respect to decay into individual protons and neutrons. However, the mass of ${}^8_4\text{Be}$ is larger than the mass of two nuclei of ${}^4_2\text{He}$: $2M_{\text{He}} = 2 \times 4.002\,603$ amu = $8.005\,206$ amu. Hence the nucleus ${}^8_4\text{Be}$ is unstable and must decay spontaneously into two α -particles, which indeed occurs.

On the contrary, the mass defect of the nucleus ${}^9_4\text{Be}$ is not only positive but also exceeds the sum of the mass defects of all nuclei into which it could decay. Hence the nucleus ${}^9_4\text{Be}$ is absolutely stable.

Knowing the masses of all isotopes one can easily determine their stability from the values of the mass defects.

For details we refer the readers to more specialized texts.

3. Energy yield of nuclear reactions. The application of the energy conservation law to a nuclear reaction of the type

where A and B are the initial nuclei, and C and D are the reaction products, allows one to find the energy yield of the reaction

$$Q = [(M_A + M_B) - (M_C + M_D)]c^2, \quad (16.6)$$

if the masses of all the nuclei are known.

As an important example from which the relations of the theory of relativity can be checked in a particularly obvious way, we consider the reaction

The masses of all the nuclei figuring in the reaction have been measured with a high degree of accuracy.

$$M({}^7_3\text{Li}) = 7.016\,004 \text{ amu},$$

$$M({}^1_1\text{H}) = 1.007\,825 \text{ amu}.$$

The total initial mass is 8.023 829 amu. The total final mass is $2M({}_2^4\text{He}) = 2 \times 4.002\,603 = 8.005\,206$ amu. As a result of the reaction the rest mass of the particles is reduced by

$$\Delta m = 0.018\,623 \text{ amu.}$$

The corresponding energy, representing the kinetic energy of the two α -particles, must be equal to (1 amu = 931.48 MeV)

$$E = \Delta mc^2 = 17.3 \text{ MeV,}$$

which agrees to a high degree of accuracy with the measured values of the energy.

In this example it is seen that the rest mass of the particles is not conserved.

In the course of the reaction a rest mass equal to Δm vanishes. However the energy conservation law

$$E_{\text{Li}} + E_{\text{H}} = 2E_{\text{He}}$$

must hold and also the relativistic mass conservation law

$$m_{\text{Li}}(v) + m_{\text{H}}(v) = 2m_{\text{He}}(v).$$

The above reaction is only one example of nuclear reactions in which the rest mass conservation law is not fulfilled.

4. *Decay of elementary particles.* A number of elementary particles turn out to be unstable with respect to decay. It is impossible to discuss here all the known cases of decay, and we can dwell only on some of them, illustrating in an obvious way the importance of the application of conservation laws to the analysis of decay.

As an example we shall consider the decay of charged and neutral mesons. As is well known, the existence of three kinds of π -mesons (pions) has been established: π^+ with a positive charge, π^- with a negative charge and π^0 , the neutral meson. The charged mesons have masses of $273m_e$, and the neutral meson has a mass of $264m_e$. The charge of the charged mesons is equal in its absolute value to that of an electron. In addition to π -mesons, two kinds of μ -mesons (muons) have been discovered: the positive μ^+ and the negative μ^- with the same absolute value of the charge and a mass equal to $207m_e$.

It turns out that both π -mesons and μ -mesons are unstable. The lifetime of

charged π^\pm -mesons is 2.6×10^{-8} sec, and that of the neutral π^0 -meson is about $10^{-15} - 10^{-16}$ sec. As mentioned earlier, μ^\pm -mesons have a lifetime of 2×10^{-6} sec.

It is clear that the establishment of the decay scheme of all these particles is of fundamental importance for contemporary physics.

We begin with the decay of charged π -mesons. A charged π^\pm -meson decays into a μ^\pm -meson and a neutrino ν :

$$\pi^\pm \rightarrow \mu^\pm + \nu.$$

The neutrino is a neutral particle with a very small rest mass, which, in contrast to photons, does not cause any ionization of atoms in its passage through matter. The study of the above reaction allows one to estimate most accurately the rest mass of the neutrino. *

That is to say, knowing the rest masses of π -mesons and μ -mesons one can find the kinetic energy of the μ -meson E_{kin}^μ as a function of the rest mass of the neutrino.

In the centre of mass system the momentum of the π -meson before decay is equal to zero. After decay the total momentum remains equal to zero, so that the momenta of the μ -meson and neutrino are of the same magnitude $p_\mu = p_\nu = p$ and of opposite direction, $(\mathbf{p}_\mu + \mathbf{p}_\nu) = 0$. The law of conservation of the energy-momentum 4-vector reduces to the energy conservation law

$$m_\pi c^2 = E^\mu + E^\nu,$$

or

$$m_\pi c^2 = (E_{\text{kin}}^\mu + m_\mu c^2) + \sqrt{p_\nu^2 c^2 + m_\nu^2 c^4},$$

or, since in the centre of mass system $p_\nu = p_\mu$, we have

$$m_\pi c^2 = (E_{\text{kin}}^\mu + m_\mu c^2) + \sqrt{p_\mu^2 c^2 + m_\nu^2 c^4} \quad (16.7)$$

We make use of the identity

$$E_{\text{kin}} + mc^2 = \sqrt{p^2 c^2 + m^2 c^4},$$

or

$$E_{\text{kin}}^2 + 2mc^2 E_{\text{kin}} = p^2 c^2, \quad (16.8)$$

* For the properties of the neutrino see § 123 of Part V.

and rewrite (16.7) in the form

$$m_{\pi}c^2 - (E_{\text{kin}}^{\mu} + m_{\mu}c^2) = \sqrt{(E_{\text{kin}}^{\mu})^2 + 2m_{\mu}c^2E_{\text{kin}}^{\mu} + m_{\nu}^2c^4}$$

Squaring the above formula we find for the energy of the μ -meson (referred to the centre of mass system) produced in the decay of a π -meson

$$E_{\text{kin}}^{\mu} = \frac{(m_{\pi}c^2 - m_{\mu}c^2)^2 - m_{\nu}^2c^4}{2m_{\pi}c^2} \quad (16.9)$$

The kinetic energy, E_{kin}^{μ} , of the μ -meson may be measured from the ionization caused by it. It turns out always to have a unique value. From the measured value of E_{kin}^{μ} it follows that, within the limits of experimental accuracy, $m_{\nu} = 0$. Moreover, the fixed value of E_{kin}^{μ} points out the correctness of the assumed decay scheme. If two or more neutral particles appeared in the decay, then E_{kin}^{μ} would not have a well defined value but would depend on the distribution of the kinetic energy between the neutral particles.

This is just the case realized in the decays of μ -mesons, which proceed according to the scheme

$$\mu^{\pm} \rightarrow e^{\pm} + 2\nu.$$

Here e^{-} stands for an electron, and e^{+} stands for a positron.

The theory of positrons will be discussed in detail in Part V. Here we point out only that the positron has a positive charge of the same magnitude as the electron charge and a mass equal to that of the electron. The electron, π^{-} -meson and μ^{-} -meson on the one hand, and the positron, π^{+} -meson and μ^{+} -meson on the other hand form groups of antiparticles. Antiparticles are produced in pairs which can be annihilated, producing γ -quanta. *

Experiment shows that in the decay of μ -mesons the kinetic energy of the electrons or positrons produced has no well defined value but varies from one decay to another.

Thus, it is clear that the energy carried away by neutral particles escaping direct observation can be distributed between them in different ways. This

* For the properties of elementary particles see: Y.V. Novozhilov, *Elementary particles* (Gordon and Breach, New York, 1961) (a popular and very good exposition), and E.V. Shpol'skii, *Atomnaya fizika* (Atomic particles), Vol. II (Gostekhizdat, Moscow, 1951).

would be impossible for a decay according to the scheme which is valid for π -mesons, i.e. with the production of one neutrino.

The kinetic energy of the charged particle is on the average equal to $\frac{1}{3}$ of the total energy of the μ -meson. The remaining $\frac{2}{3}$ are on the average equally distributed between the two neutrinos.

Consider, finally, the decay of the π^0 -meson, which proceeds according to the scheme

$$\pi^0 \rightarrow \gamma + \gamma,$$

where γ stands for a photon. γ -quanta are detected by the ionization they produce. A certain relation is observed between the angle of divergence of the photons and their energy. This relation can be established from the conservation laws.

Before the decay the invariant of the 4-vector of energy and momentum in a reference frame moving together with the π^0 -meson reduces to

$$I = -m_\pi^2 c^4,$$

since in this reference frame the total momentum is equal to zero.

After the decay in the laboratory system I is equal to

$$I = (\mathbf{p}_1 + \mathbf{p}_2)^2 c^2 - (E_1 + E_2)^2,$$

where $\mathbf{p}_1, \mathbf{p}_2, E_1, E_2$ are the momenta and energies of the two photons. Hence

$$-m_\pi^2 c^4 = (\mathbf{p}_1 + \mathbf{p}_2)^2 c^2 - (E_1 + E_2)^2,$$

or, since the rest mass of photons is equal to zero,

$$\begin{aligned} m_\pi^2 c^4 &= (p_1 + p_2)^2 c^2 - (\mathbf{p}_1 + \mathbf{p}_2)^2 c^2 = \\ &= 2p_1 p_2 c^2 (1 - \cos \varphi) = 4p_1 p_2 c^2 \sin^2 \frac{1}{2} \varphi, \end{aligned}$$

where φ is the angle between the directions of flight of the photons.

Consequently,

$$\sin \frac{1}{2} \varphi = \frac{m_\pi c^2}{2\sqrt{E_1 E_2}}. \quad (16.10)$$

This dependence of the angle of divergence on the energy of the photons is in good agreement with that observed experimentally.

5. *Electron-positron pair production by γ -quanta and positron-electron annihilation.* The experimental discovery of the theoretically predicted phenomena of electron-positron pair production and positron-electron annihilation with the production of γ -quanta appeared to be a basic confirmation of the validity of relativistic quantum mechanics, which the reader will meet in Part V of the book. At the same time, these phenomena serve as good illustrations of the relations of the theory of relativity.

Consider first of all the question of the possibility of electron-positron pair production by a γ -quantum in vacuum. Let a γ -quantum with energy $E = pc$ produce an electron and a positron. It is easily seen that such a process is incompatible with conservation laws. Indeed, if the photon produces an electron-positron pair with the minimum possible energy — i.e. the rest energy — and a momentum equal to zero, then it has an energy $E = 2mc^2$ and a momentum $p = E/c > 0$, where m is the electron mass. If the momentum of the pair differs from zero, then it is always possible to transform to the centre of mass system where it is equal to zero, and our reasoning is still correct.

Thus, the momentum differs from zero before the pair production, and is equal to zero after the pair production. This would clearly contradict the momentum conservation law, and therefore such a process is impossible. Pair production can take place only in the presence of a third body; usually an atomic nucleus, which itself takes the excess momentum. Since the nucleus also acquires a certain part of the energy, the energy threshold of pair production by a γ -quantum lies above $2mc^2$. The threshold energy of the γ -quantum is determined by the requirement that all the particles — the electron, positron and nucleus — should have a momentum equal to zero in the centre of mass system.

To find this threshold we shall find the invariant of the energy-momentum 4-vector.

Before the reaction there was a γ -quantum with a threshold kinetic energy E_{thresh} and a momentum $p = E_{\text{thresh}}/c$ and a nucleus at rest with a mass M . After the reaction there was an electron-positron pair and the nucleus which acquired a part of the momentum and energy.

The value of the invariant of the energy-momentum 4-vector before the reaction was

$$I = \left(\frac{E_{\text{thresh}}}{c} \right)^2 c^2 - (E_{\text{thresh}} + Mc^2)^2$$

The value of the invariant after the reaction can be taken in any reference frame, including the centre of mass system. The merit of the latter is the fact that in it the total momentum of all the particles is equal to zero and the value of the invariant reduces to

$$I = -(Mc^2 + 2mc^2)^2.$$

Thus, we have

$$(Mc^2 + E_{\text{thresh}})^2 - E_{\text{thresh}}^2 = (Mc^2 + 2mc^2)^2.$$

Hence for the threshold energy of the γ -quantum we find

$$E_{\text{thresh}} = 2mc^2 \left(1 + \frac{m}{M} \right) \quad (16.11)$$

The threshold energy for other processes producing electron-positron pairs, for example the collision between two electrons, can be found in a completely analogous way.

The process which is the reverse of the process of pair production by γ -quanta is called pair annihilation. In annihilation an electron and a positron fuse to produce γ -quanta. The essence of this process from the point of view of contemporary quantum theory will be discussed briefly in Part V. The process of annihilation usually takes place at small values of kinetic energy of the positron. Hence the difference between the energy of the initial state and the energy of the final state amounts to

$$\Delta E = mc^2 - (-mc^2) = 2mc^2 = 1.02 \text{ MeV}$$

The simultaneous conservation of energy and momentum requires that this energy should be emitted in the form of (at least) two γ -quanta emerging in opposite directions and having an energy of 0.51 MeV each.

It has been established in a number of experiments that the annihilation of positrons is indeed accompanied by such radiation. The phenomenon of the annihilation of positrons serves as one of the most effective confirmations of the mass-energy relation. It should be noted that the process of annihilation is sometimes incorrectly interpreted as "the transformation of matter into energy" or as "the disappearance of particles". It is clear that the γ -quanta arising in the annihilation of a positron are as material as the electron and positron.

In § 13 we have already discussed the properties of the rest mass and conservation laws in the theory of relativity and have seen that the transformation of particles with a rest mass different from zero into particles having no rest mass can in no way be considered as the disappearance of particles or the transformation of mass into energy.

6. As the last example of the use of conservation laws in nuclear physics we shall consider the determination of the energy threshold of the reaction in which a π -meson is produced in a proton-proton collision:

where π^+ is a positive π -meson with mass m_π .

We write the value of the invariant $E^2 - p^2c^2$ before and after the collision. Before the collision,

$$(E_{\text{thresh}} + 2Mc^2)^2 - p^2c^2 = (E_{\text{thresh}} + 2Mc^2)^2 - \\ - E_{\text{thresh}}(E_{\text{thresh}} + 2Mc^2).$$

Here we have assumed that one of the protons was at rest before the collision and made use of formula (16.8). If the incident proton has the threshold energy, then the particles produced in the reaction, the deuteron and π^+ -meson, have the minimum possible energy, which corresponds to the rest energy in the centre of mass system. In the centre of mass system one can write

$$E^2 - p^2c^2 = (2Mc^2 + m_\pi c^2)^2.$$

From the conservation of the invariant $(E^2 - p^2c^2)$ we have

$$(E_{\text{thresh}} + 2Mc^2)^2 - E_{\text{thresh}}(E_{\text{thresh}} + 2Mc^2) = (2Mc^2 + m_\pi c^2)^2$$

Hence the threshold value of the kinetic energy is

$$E_{\text{thresh}} = \frac{[(2M + m_\pi)^2 - 4M^2]c^2}{2M} = \frac{(4m_\pi M + m_\pi^2)c^2}{2M} = \\ = m_\pi c^2 \left(2 + \frac{m_\pi}{2M} \right) = 292 \text{ MeV}. \quad (16.12)$$

This value of E_{thresh} is in good agreement with the measured value.

The examples quoted are of a purely illustrative character, and have been used intentionally to introduce the diverse problems of nuclear physics. They show, however, that in all nuclear processes in which rather considerable changes in the energy of the system are to be taken into account the laws of the theory of relativity and, in particular, the mass-energy relation play a fundamental role.

§17. The theory of collisions between relativistic particles. Compton effect

The theory of collisions between relativistic particles is of great importance for nuclear physics. In the absence of nuclear reactions between the colliding particles the interaction between them can, with a sufficient degree of accuracy, be considered as an elastic collision (i.e. a collision without a change in the internal state of the nuclear particles). This refers, in particular, to collisions between elementary particles, for example, mesons, protons or photons with electrons.

We shall consider first of all the elastic collisions of particles with a rest mass differing from zero. We assume that a fast particle with mass μ and momentum \mathbf{p} collides with another particle having a mass m . We consider the second particle to be at rest and free. Such an approximation is legitimate for a sufficiently large velocity of the incident particle. After collision the particle which was initially at rest will move with a momentum \mathbf{p}_1 directed at an angle φ to the momentum of the incident particle. The latter will be deflected from the initial direction of flight by an angle θ and will have a momentum \mathbf{p}_2 (fig. II.4).

Fig. II.4

We can write the energy and momentum conservation laws in the form of (15.7) and (15.8):

$$\mathbf{p} = \mathbf{p}_1 + \mathbf{p}_2, \quad (17.1)$$

$$mc^2 + E = E_1 + E_2, \quad (17.2)$$

where E and E_2 represent the energy of the incident particle before and after collision respectively, and E_1 is the energy after collision of the particle which was initially at rest. These relations are sufficient to find all of the quantities characterizing the process of collision.

Suppose, for example, that we have to find the energy acquired by the particle which was initially at rest as a function of the angle φ . It is simpler to find, not the total energy E_1 of the particle, but its kinetic energy $E_1^{(\text{kin})} = E_1 - mc^2$. From (17.2) we have, obviously,

$$\sqrt{p^2 c^2 + \mu^2 c^4} = \sqrt{p_2^2 c^2 + \mu^2 c^4} + E_1^{(\text{kin})} \quad (17.3)$$

Since on the basis of (17.1)

$$p_2^2 = p^2 + p_1^2 - 2pp_1 \cos \varphi, \quad (17.4)$$

we can eliminate p_2 from (17.3) and (17.4). Moreover, p_1^2 can be expressed in terms of E_1 by means of (16.8). Rearranging and squaring (17.3) and substituting the value for p_2^2 from (17.4), we obtain after some manipulation

$$pp_1 c^2 \cos \varphi = E_1^{(\text{kin})} \{ \sqrt{p^2 c^2 + \mu^2 c^4} + mc^2 \}.$$

Squaring the above relation and expressing p_1^2 again in terms of $E_1^{(\text{kin})}$, we finally obtain

$$E_1^{(\text{kin})} = \frac{2mp^2 c^4 \cos^2 \varphi}{\{ \sqrt{p^2 c^2 + \mu^2 c^4} + mc^2 \}^2 - p^2 c^2 \cos^2 \varphi}, \quad (17.5)$$

i.e. the dependence on p and φ of the energy transferred to the motionless particle, as well as the dependence on the masses m and μ of the particles.

Formula (17.5) shows that the energy transferred has its largest value for $\varphi = 0$, i.e. for the motion of the initially stationary particle in the direction of flight of the incident particle (i.e. head-on collision). Then,

$$(E_1)_{\max}^{(\text{kin})} = 2mc^2 \frac{p^2 c^2}{\{\sqrt{p^2 c^2 + \mu^2 c^4} + mc^2\}^2 - p^2 c^2}. \quad (17.6)$$

Consider some particular cases of formula (17.6). Let, for example, the incident particle be a proton or a meson, and let the particle at rest be an electron. Then $\mu \gg m$. In addition, we assume the incident particle to be very fast, so that $pc \gg \mu c^2$. Then from (17.6) we find

$$\begin{aligned} (E_1)_{\max}^{(\text{kin})} &= 2mc^2 \frac{p^2 c^2}{\mu^2 c^4 + 2mc^2 \sqrt{p^2 c^2 + \mu^2 c^4} + m^2 c^4} \\ &\approx 2mc^2 \frac{p^2 c^2}{2mc^2 pc + \mu^2 c^4}. \end{aligned} \quad (17.6')$$

If the momentum of the incident particle is so large that the inequality

$$pc \gg \frac{\mu^2 c^4}{mc^2} = \frac{\mu}{m} \mu c^2$$

is fulfilled, then the maximum transferred energy amounts to

$$(E_1)_{\max}^{(\text{kin})} \approx pc \approx E,$$

i.e. to the energy of the incident particle.

Now consider the case when the incident particle is a light particle, for example, an electron, and the particle at rest is a heavy particle (i.e. $\mu \ll m$). If, moreover, the first particle possesses a momentum $pc \gg \mu c^2$, then from (17.6') we obtain for the energy transferred

$$(E_1)_{\max}^{(\text{kin})} \approx 2mc^2 \frac{p^2 c^2}{2mc^2 pc + m^2 c^4}.$$

If the inequality $pc \gg mc^2$ is satisfied, then

$$(E_1)_{\max}^{(\text{kin})} \approx pc \approx E. \quad (17.7)$$

Thus, we see that for very large momenta the laws for elastic collisions in relativistic mechanics differ in a fundamental way from the analogous laws in classical mechanics. For sufficiently large momenta a total energy transfer

from a heavy particle to a light one is possible, and also from a light particle to a heavy one. It should be noted that in this case in classical mechanics the elastic collision is accompanied by only a negligible energy transfer. *

Other limiting cases can be easily obtained from the general expression (17.5). In particular, it is easy to show that for small momenta $pc \ll \mu c^2$ and $pc \ll mc^2$ the energy transferred is given by a formula which is the same as the corresponding expression for the non-relativistic theory of collisions.

An important case of elastic collision is the collision of a photon with an electron. This phenomenon, called the Compton effect, was first studied carefully in connection with the elucidation of the quantum nature of light. The Compton effect plays a role in a number of practical problems of contemporary nuclear physics. The photon has a rest mass μ equal to zero and $E = pc$, $E_2 = p_2c$. Hence formulae (17.2) and (17.1) assume the forms

$$E = E_2 + E_1^{(\text{kin})}, \quad (17.8)$$

$$p_1^2 = \left(\frac{E}{c}\right)^2 + \left(\frac{E_2}{c}\right)^2 - \frac{2EE_2}{c^2} \cos \theta, \quad (17.9)$$

where $E_1^{(\text{kin})} = \sqrt{p_1^2 c^2 + m_e^2 c^4} - m_e c^2$, m_e is the mass of the electron, and θ is the angle between the direction of flight of the photon before and after collision (scattering angle).

Expressing $p_1^2 c^2$ in eq. (17.9) in terms of the kinetic energy of the electron by means of (16.8), we write (17.9) in the form

$$(E_1^{(\text{kin})})^2 + 2m_e c^2 E_1^{(\text{kin})} = E^2 + E_2^2 - 2EE_2 \cos \theta. \quad (17.10)$$

First of all we find the energy of the photon undergoing the collision. Eliminating $E_1^{(\text{kin})}$ from (17.8) and (17.10), we easily find

$$E_2 = \frac{m_e c^2 E}{m_e c^2 + E(1 - \cos \theta)}. \quad (17.11)$$

This formula relates the energy of the scattered photon to that of the incident one and to the scattering angle θ .

Transforming from energies to wavelengths according to the well-known quantum formula $E = h\nu = hc/\lambda$, one can obtain the following value for the decrease in the wavelength $\Delta\lambda$ in Compton scattering:

* See § 43 of Part I.

$$\Delta\lambda = hc \left(\frac{1}{E_2} - \frac{1}{E} \right) = \frac{h}{m_e c} (1 - \cos \theta) = \Lambda (1 - \cos \theta). \quad (17.12)$$

The quantity $\Lambda = h/m_e c = 0.0242 \text{ \AA}$ is called the Compton wavelength.

Formula (17.12) shows that the change in the wavelength is independent of the wavelength of the incident radiation. The maximum change in the wavelength is equal to 2Λ .

Knowing the energy of the scattered photon, one can easily find the energy transferred to the electron. It turns out to be

$$E_1^{(\text{kin})} = E - E_2 = \frac{\Lambda(1 - \cos \theta)}{\lambda + \Lambda(1 - \cos \theta)} E, \quad (17.13)$$

i.e. relatively not large for $\lambda \gg \Lambda$. On the contrary, for $\lambda \approx \Lambda$ the energy transferred to the electron turns out to be considerable, of the order of magnitude of E .

The importance of this result lies particularly in the fact that it is of a general character. We have more than once pointed out in Part I that classical electrodynamics contains in itself the limits of its applicability. Namely, classical electrodynamics become inapplicable in the region of small distances, of the order of magnitude of the classical radius of the electron $r_0 = 2.5 \times 10^{-13} \text{ cm}$. We have mentioned, however (see §29 of Part I), that in fact the limit of applicability of the classical theory lies much higher, at distances of the order of $2 \times 10^{-10} \text{ cm}$, which corresponds to the order of magnitude of the Compton wavelength.

The unsuitability of classical electrodynamics for phenomena taking place in a region of space with a linear dimension of the order of Λ is obviously associated with the fact that in this region quantum effects begin to make themselves felt. The scattering of light serves as a concrete example of this.

For $\lambda \gg \Lambda$ the change in the wavelength of the scattered light and the energy transferred to the free electron are relatively small. Hence the scattering of light is sufficiently well described by the classical theory. The scattering is coherent. The change in the wavelength $\Delta\lambda \approx \Lambda$ is very small in comparison with the wavelength itself; no energy transfer to the free electron takes place, and the cross section for the scattering is given by the Thomson formula (36.13) of Part I.

As λ approaches Λ (hard X-rays and γ -rays) the classical scattering is replaced by the Compton effect. The change in the wavelength of the light becomes comparable with the wavelength. The radiation knocks out recoil electrons (moving mainly forward in the direction of the incident photon),

and the cross section for scattering, as is seen in fig. I.17, §36, decreases with the energy of the photon. The phenomenon assumes a clearly pronounced quantum character and a classical treatment of the phenomenon of scattering becomes quite impossible.

The quantum-mechanical calculation of the cross section for Compton scattering will be given in Part V.

Relativistic Electrodynamics

§ 18. Charge conservation, the four-dimensional current and the equation of continuity

We shall now turn from relativistic mechanics to relativistic electrodynamics. We shall take as the basis of relativistic electrodynamics the assumption of the invariance and conservation of electric charge. The charge is a fundamental quantity characterizing the properties of particles, and the charge constancy is strictly observed in all known physical processes.

The charge conservation law

$$\nabla \cdot (\rho \mathbf{u}) + \frac{\partial \rho}{\partial t} = 0 \quad (18.1)$$

must hold in all inertial reference frames. In order to give a relativistically invariant form to the charge conservation law, one can, following the usual method, write it in four-dimensional form.

For this it is sufficient to introduce the 4-vector j_α , called the four-dimensional current and defined by the relation

$$j_\alpha = (\rho \mathbf{u}, ic\rho). \quad (18.2)$$

Then (18.1) is easily written in four-dimensional form:

$$\frac{\partial j_\alpha}{\partial x_\alpha} = \frac{\partial j_x}{\partial x} + \frac{\partial j_y}{\partial y} + \frac{\partial j_z}{\partial z} + \frac{\partial j_\tau}{\partial \tau} = 0. \quad (18.3)$$

It is formula (18.3), written in four-dimensional form, which is the relativistically invariant expression. Hence it follows that the quantity j_α , which we determined formally, indeed represents a 4-vector.

From the definition of the 4-vector j_α it follows directly that, in passing from one reference frame to another, its components must transform according to formulae (11.1)–(11.4). If this transformation law is applied to the fourth component $j_\tau = ic\rho$, then we obtain the invariance of the electric charge, $de = \rho dV$ which is present in an arbitrary volume element dV . Indeed, let us consider the change of j_τ in the transition from the reference frame K' in which the charges are at rest to the reference frame K . The reference frame K' moves relative to K with a velocity v . In the reference frame K' the velocity $\mathbf{u} = 0$ and, for the vector j_α , only the component j_τ differs from zero.

From the formula (11.4) for the transformation of the fourth component of the 4-vector we find the expression for the change in the charge density:

$$\rho = \frac{\rho'}{\sqrt{1 - \frac{v^2}{c^2}}}. \quad (18.4)$$

Multiplying (18.4) by the volume element dV , we have

$$\rho dV = de = \frac{\rho' dV'}{\sqrt{1 - \frac{v^2}{c^2}}}.$$

The change in the volume (6.2) gives

$$dV = dV' \sqrt{1 - \frac{v^2}{c^2}},$$

so that

$$\rho dV = \rho' dV'.$$

Thus, the charge in any volume element is invariant under Lorentz transformations. This can obviously be interpreted in the following way: as the volume decreases because of the Lorentz contraction the charge density increases in the same ratio, so that the total charge is not changed.

§19. The relativistically invariant formulation of the equations of the electromagnetic field potentials

We have pointed out earlier that the theory of the electromagnetic field was formulated "correctly" from the point of view of the theory of relativity from the very beginning. This means that the Maxwell-Lorentz system of equations is relativistically invariant, satisfying the requirements of the theory of relativity.

One can verify this most simply by considering the equations for the potentials.

According to what was said in §10 of Part I the system of equations

$$\nabla^2 A - \frac{1}{c^2} \frac{\partial^2 A}{\partial t^2} = -\frac{4\pi}{c} \rho u, \quad (19.1)$$

$$\nabla^2 \varphi - \frac{1}{c^2} \frac{\partial^2 \varphi}{\partial t^2} = -4\pi \rho, \quad (19.2)$$

taking into account the gauge condition

$$\nabla \cdot A + \frac{1}{c} \frac{\partial \varphi}{\partial t} = 0, \quad (19.3)$$

is completely equivalent to the Maxwell-Lorentz equations.

The relativistic invariance of the system (19.1)–(19.3) follows directly from the fact that this system can be written without any changes in the four-dimensional form.

Indeed, we multiply (19.2) by i and note that then the right-hand sides of eqs. (19.1)–(19.2) contain the components of the 4-vector of the current density. Hence it follows that also the left-hand sides represent the components of a 4-vector which we shall call the 4-potential A_α :

$$A_\alpha = (A, i\varphi).$$

By means of the 4-vectors A_α and j_α eqs. (19.1) and (19.2) can be written in the form

$$\square A_\alpha = -\frac{4\pi}{c} j_\alpha, \quad (19.4)$$

where \square denotes D'Alembert's operator (the D'Alembertian):

$$\square = \nabla^2 - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} = \frac{\partial^2}{\partial x_\alpha^2}. \quad (19.5)$$

The gauge condition may be written at once in the four-dimensional form

$$\frac{\partial A_\alpha}{\partial x_\alpha} = 0. \quad (19.6)$$

Thus, the complete system of equations for potentials is written in the relativistically invariant form. This means that the laws of electrodynamics are the same in all inertial reference frames.

Further, we see that the electromagnetic field potentials and, consequently, the electric and magnetic field vectors, are not themselves invariant quantities. The relative character of the values of the field vectors is in no way something new and unexpected. It is sufficient to recall that a moving charge produces a magnetic field which, however, is absent in a reference frame moving together with the charge.

The law of transformation of the potentials can easily be written, since they transform according to the general formula for the transformation of the components of a 4-vector (11.1)–(11.4).

We have, obviously,

$$A_x = \frac{A'_x + \frac{v}{c} \varphi'}{\sqrt{1 - \frac{v^2}{c^2}}}, \quad (19.7)$$

$$A_y = A'_y, \quad (19.8)$$

$$A_z = A'_z, \quad (19.9)$$

$$\varphi = \frac{\varphi' + \frac{v}{c} A'_x}{\sqrt{1 - \frac{v^2}{c^2}}}. \quad (19.10)$$

In the following paragraphs we shall apply these formulae to the treatment of the electromagnetic field of moving charges.

§ 20. The field of a moving charge

Consider the simple problem of finding the electromagnetic field produced by a uniformly moving charge, when the velocity v of the charge is comparable with the velocity of light. In the reference frame K' moving with the charge the magnetic field is absent, and the electric field potential is expressed by the formula

$$\varphi' = e/r'.$$

In the inertial reference frame K with respect to which the charge moves with a velocity v the electric field potential, according to (19.10), has the form

$$\varphi = \frac{\varphi'}{\sqrt{1 - \frac{v^2}{c^2}}} = \frac{e}{r' \sqrt{1 - \frac{v^2}{c^2}}}. \quad (20.1)$$

We need the formula for the transformation of the length of the radius vector. We have

$$\begin{aligned} r' &= \sqrt{(x')^2 + (y')^2 + (z')^2} = \sqrt{\left[\frac{x - vt}{\sqrt{1 - \frac{v^2}{c^2}}} \right]^2 + y^2 + z^2} = \\ &= \sqrt{\frac{(x - vt)^2 + \left(1 - \frac{v^2}{c^2}\right)(y^2 + z^2)}{1 - \frac{v^2}{c^2}}}. \end{aligned}$$

The asymmetry of this formula is associated with the fact that the motion takes place along the x -axis.

Thus we find

$$\varphi = \frac{e}{\sqrt{(x - vt)^2 + \left(1 - \frac{v^2}{c^2}\right)(y^2 + z^2)}} \quad (20.2)$$

We note that $x = vt$, $y = 0$, $z = 0$ represent the coordinates of the point at which the charge is found at an instant t , so that the radius vector drawn

from the charge to the point of observation N (x, y, z) can be written in the form

$$\mathbf{r} = \mathbf{i}(x - vt) + \mathbf{j}y + \mathbf{k}z \quad (20.3)$$

and

$$r = \sqrt{(x - vt)^2 + y^2 + z^2} \quad (20.4)$$

It is convenient to simplify (20.2), expressing φ in terms of r and the angle ψ formed by the vector \mathbf{r} and the x -axis (fig. 11.5).

Fig. 11.5

From fig. 11.5 it is seen that

$$x - vt = r \cos \psi,$$

$$y^2 + z^2 = r^2 \sin^2 \psi,$$

and, consequently,

$$\begin{aligned} \sqrt{(x - vt)^2 + \left(1 - \frac{v^2}{c^2}\right)(y^2 + z^2)} &= r \sqrt{\cos^2 \psi + \left(1 - \frac{v^2}{c^2}\right) \sin^2 \psi} = \\ &= r \sqrt{1 - \frac{v^2}{c^2} \sin^2 \psi}. \end{aligned}$$

Hence we have

$$\varphi = \frac{e}{r \sqrt{1 - \frac{v^2}{c^2} \sin^2 \psi}}. \quad (20.5)$$

Passing on to the calculation of the vector potential \mathbf{A} we note that in the reference frame K' there is no magnetic field and $\mathbf{A}' = 0$. From formulae

(19.7) and (19.10) we find

$$\begin{aligned}
 A_x &= \frac{v}{c} \frac{\varphi'}{\sqrt{1 - \frac{v^2}{c^2}}} = \frac{v}{c} \varphi = \\
 &= \frac{ev}{c \sqrt{(x - vt)^2 + \left(1 - \frac{v^2}{c^2}\right)(y^2 + z^2)}} = \frac{ev}{cr \sqrt{1 - \frac{v^2}{c^2} \sin^2 \psi}} \\
 A_y &= 0, \quad A_z = 0.
 \end{aligned}$$

In vector form this can be written

$$\mathbf{A} = \varphi \mathbf{v} / c \quad (20.6)$$

Knowing the field potentials one can then find the fields themselves.

In calculating the electric field \mathbf{E} it should be kept in mind that in our case of a uniformly moving charge the differentiation with respect to time reduces to the differentiation with respect to the coordinate x according to the formula

$$\frac{\partial}{\partial t} = -v \frac{\partial}{\partial x}.$$

Indeed, in a uniform motion \mathbf{A} and φ depend on the coordinate and time according to $f(x - vt)$. For such a function

$$\frac{\partial f}{\partial t} = \frac{\partial f}{\partial (x - vt)} \frac{\partial (x - vt)}{\partial t} = -v \frac{\partial f}{\partial x},$$

from which we find

$$\begin{aligned}
 E_x &= -\frac{\partial \varphi}{\partial x} - \frac{1}{c} \frac{\partial A_x}{\partial t} = -\frac{\partial \varphi}{\partial x} + \frac{v^2}{c^2} \frac{\partial \varphi}{\partial x} = -\left(1 - \frac{v^2}{c^2}\right) \frac{\partial \varphi}{\partial x} = \\
 &= \left(1 - \frac{v^2}{c^2}\right) \frac{e(x - vt)}{\left\{(x - vt)^2 + \left(1 - \frac{v^2}{c^2}\right)(y^2 + z^2)\right\}^{3/2}},
 \end{aligned}$$

$$\begin{aligned}
 E_y &= -\frac{\partial \varphi}{\partial y} - \frac{1}{c} \frac{\partial A_y}{\partial t} = \\
 &= \left(1 - \frac{v^2}{c^2}\right) \frac{ey}{\left\{(x-vt)^2 + \left(1 - \frac{v^2}{c^2}\right)(y^2 + z^2)\right\}^{3/2}}, \\
 E_z &= -\frac{\partial \varphi}{\partial z} - \frac{1}{c} \frac{\partial A_z}{\partial t} = \\
 &= \left(1 - \frac{v^2}{c^2}\right) \frac{ez}{\left\{(x-vt)^2 + \left(1 - \frac{v^2}{c^2}\right)(y^2 + z^2)\right\}^{3/2}},
 \end{aligned}$$

or, in vector form,

$$\mathbf{E} = \left(1 - \frac{v^2}{c^2}\right) \frac{e\mathbf{r}}{r^3 \left(1 - \frac{v^2}{c^2} \sin^2 \psi\right)^{3/2}}. \quad (20.7)$$

When $v \ll c$ formula (20.7) goes over, of course, into the electrostatic expression for the field of a charge at rest.

We can also find the magnetic field \mathbf{H} easily:

$$\mathbf{H} = \nabla \times \mathbf{A} = \frac{1}{c} \nabla \times (\mathbf{v}\varphi) = -\frac{1}{c} \mathbf{v} \times \nabla \varphi = \frac{1}{c} \mathbf{v} \times \mathbf{E}. \quad (20.8)$$

Formulae (20.5) and (20.7) show that, in contrast to the field of a charge at rest, the electric field of a moving charge does not have spherical symmetry.

The scalar potential φ has a constant value at the surface of the ellipsoid:

$$(x-vt)^2 + \left(1 - \frac{v^2}{c^2}\right)(y^2 + z^2) = \text{const.}$$

This ellipsoid is obtained from a sphere compressed in the direction of the x -axis by a factor $\sqrt{1 - v^2/c^2}$.

The character of the field distribution is most clearly seen from the formula

$$|E| = \frac{e \left(1 - \frac{v^2}{c^2}\right)}{r^2 \left(1 - \frac{v^2}{c^2} \sin^2 \psi\right)^{3/2}}. \quad (20.9)$$

On the x -axis ($\psi = 0$) the field is less than the electrostatic field by a factor of $(1 - v^2/c^2)$, while in the plane perpendicular to the x -axis it is increased in the ratio $1/\sqrt{1 - v^2/c^2}$.

As the velocity increases the equipotential ellipsoid gets more and more oblate, while the value of the field in the direction of motion decreases and in the perpendicular direction increases. When $v \sim c$ the field is concentrated in a small angular interval near the plane perpendicular to the direction of motion. The width of this interval is $\Delta\psi \sim \sqrt{1 - v^2/c^2}$.

The magnetic field \mathbf{H} is always perpendicular to the direction of motion and to the electric field vector \mathbf{E} . For $v \sim c$, $|\mathbf{H}| \sim |\mathbf{E}|$. At small velocities ($v \ll c$), it can be assumed that

$$\mathbf{H} = \frac{1}{c} \mathbf{v} \times \mathbf{E} \approx \frac{e}{c} \frac{\mathbf{v} \times \mathbf{r}}{r^3}, \quad (20.10)$$

if it is also assumed that \mathbf{E} has approximately the electrostatic value. This last formula is the same as (20.5) of Part I.

The field produced by a moving charge was found by classical methods * even before the appearance of the theory of relativity. There is nothing surprising in this, since the Maxwell-Lorentz equations are relativistically invariant.

Let us apply the formulae obtained to the calculation of the force of interaction between two charges e_1 and e_2 moving with the same velocity v with respect to the laboratory system. In the reference frame connected with the charges the force is, obviously, equal to $\mathbf{F} = (e_1 e_2 / r^3) \mathbf{r}$ and is directed along the vector connecting the charges. We choose the direction of the vector \mathbf{v} to be the x -axis.

From the point of view of the laboratory system the field of charge e_1 is expressed by formulae (20.8) and (20.10). The charge e_2 is acted upon by the Lorentz force

* See, for example, R. Becker, *Electromagnetic fields and interactions*, Vol. I (Blackie, London, 1964) p. 267.

$$\begin{aligned} \mathbf{F} &= e_2 \left(\mathbf{E} + \frac{1}{c} \mathbf{v} \times \mathbf{H} \right) = e_2 \mathbf{E} + \frac{e_2}{c^2} \mathbf{v} \times (\mathbf{v} \times \mathbf{E}) = \\ &= e_2 \mathbf{E} + \frac{e_2}{c^2} \mathbf{v} (\mathbf{v} \cdot \mathbf{E}) - \frac{e_2}{c^2} v^2 \mathbf{E} = e_2 \left(1 - \frac{v^2}{c^2} \right) \mathbf{E} + e_2 \frac{\mathbf{v} v E_x}{c^2}. \end{aligned}$$

This force is no longer directed along the radius vector. The component of the force in the direction of motion is equal to

$$F_x = e_2 E_x = \frac{e_1 e_2 \left(1 - \frac{v^2}{c^2} \right) \cos \psi}{r^2 \left(1 - \frac{v^2}{c^2} \sin^2 \psi \right)^{3/2}}.$$

The component of the force in the perpendicular direction is equal to

$$F_y = e_2 \left(1 - \frac{v^2}{c^2} \right) E_y = \frac{e_1 e_2 \left(1 - \frac{v^2}{c^2} \right)^2 \sin \psi}{r^2 \left(1 - \frac{v^2}{c^2} \sin^2 \psi \right)^{3/2}}.$$

Before the appearance of the theory of relativity it was assumed that, by observing the interaction between moving charges, one could determine their absolute velocity with respect to the ether. However, attempts at such measurements did not lead to any positive results.

In the light of the theory of relativity the error in this reasoning is clear: only the common relative velocity \mathbf{v} of the two charges enters into the formula for the force measured in the laboratory system.

It is interesting to apply the result obtained to the motion of a uniformly charged sphere. In the proper reference frame moving together with the sphere the charge density is constant and the lines of field are normal to the surface. In the laboratory system the repulsion between the charges must lead to a non-uniform charge density distribution over the sphere. If the polar axis is drawn in the direction of motion, then the charge density must be largest at the poles of the sphere and a minimum in the equatorial plane.

From the non-relativistic point of view, the absolute velocity of motion of the sphere could be found by measuring this charge distribution. In reality this is not the case: from the point of view of the laboratory system a moving sphere must undergo a contraction and turn into an ellipsoid. Calculation

shows that the effect of contraction of the sphere compensates exactly for the effect of the charge accumulation at the poles. As a result the charge density measured in the laboratory system will be constant over the entire sphere.

This example is very interesting because it shows how the Maxwell-Lorentz theory, "correct" from the point of view of the theory of relativity, leads to false results in association with the classical notions of space and time. Only an alteration of the ideas of space and time in conjunction with the laws of electrodynamics allows one consequently to bring the theory into agreement with experiment.

In addition to the field of a uniformly moving charge it turns out to be possible to find the field of a charge performing an arbitrary motion.

In §25 of Part I we found an expression for the Liénard-Wiechert potentials and pointed out that the corresponding expressions do not lose their applicability even at velocities close to the velocity of light.

To convince ourselves of this, we write the Liénard-Wiechert potentials in the four-dimensional form.

We introduce the 4-vector R_α having the components $(\mathbf{r} - \mathbf{r}_0)$, $ic(t - \tau)$, where \mathbf{r} is the coordinate of the observation point, \mathbf{r}_0 is the coordinate of the charge, and $\tau = t - |\mathbf{r} - \mathbf{r}_0|/c$. The relation between the components of the vector R_α is given by the formula

$$R_\alpha^2 = 0.$$

Indeed, substituting into it the components of R_α , we have

$$(\mathbf{r} - \mathbf{r}_0)^2 - c^2(t - \tau)^2 = 0.$$

By means of the 4-vector R_α one can introduce the Liénard-Wiechert 4-potential by the relation

$$A_\alpha = -eu_\alpha/R_\beta u_\beta.$$

where the summation is carried out over the index β ($\beta = x, y, z, \tau$). Indeed, making use of the definition of the 4-velocity u_β (11.6), we have

$$\begin{aligned}
 R_\beta u_\beta &= R_x u_x + R_y u_y + R_z u_z + R_\tau u_\tau = \\
 &= (x - x_0) \frac{v_x}{\sqrt{1 - \frac{v^2}{c^2}}} + (y - y_0) \frac{v_y}{\sqrt{1 - \frac{v^2}{c^2}}} + \\
 &\quad + (z - z_0) \frac{v_z}{\sqrt{1 - \frac{v^2}{c^2}}} + ic(t - \tau) \frac{ic}{\sqrt{1 - \frac{v^2}{c^2}}} = \\
 &= \frac{c}{\sqrt{1 - \frac{v^2}{c^2}}} \left\{ \frac{(\mathbf{r} - \mathbf{r}_0) \cdot \mathbf{v}}{c} - c(t - \tau) \right\} = \\
 &= \frac{c}{\sqrt{1 - \frac{v^2}{c^2}}} \left\{ \frac{(\mathbf{r} - \mathbf{r}_0) \cdot \mathbf{v}}{c} - |\mathbf{r} - \mathbf{r}_0| \right\} = \\
 &= \frac{c}{\sqrt{1 - \frac{v^2}{c^2}}} \left\{ \frac{\mathbf{R}(\tau) \cdot \mathbf{v}}{c} - R(\tau) \right\},
 \end{aligned}$$

where, in correspondence with the notation of § 25 of Part I, $\mathbf{R}(\tau) = \mathbf{r} - \mathbf{r}_0$ is the radius vector drawn from an instantaneous position of the charge to the observation point at an instant τ .

Correspondingly, the components of A_α have the form

$$\begin{aligned}
 A_x &= - \frac{ev_x}{\sqrt{1 - \frac{v^2}{c^2}}} \frac{1}{\frac{c}{\sqrt{1 - \frac{v^2}{c^2}}} \left\{ \frac{\mathbf{R}(\tau) \cdot \mathbf{v}}{c} - R(\tau) \right\}} = \\
 &= \frac{ev_x}{c \left\{ R(\tau) - \frac{\mathbf{R}(\tau) \cdot \mathbf{v}}{c} \right\}} \quad (20.11)
 \end{aligned}$$

with analogous expressions for A_y and A_z ;

$$\begin{aligned}
 A_\tau = i\varphi &= \frac{iec}{\sqrt{1-\frac{v^2}{c^2}}} \frac{1}{\frac{c}{\sqrt{1-\frac{v^2}{c^2}}} \left\{ \frac{\mathbf{R}(\tau) \cdot \mathbf{v}}{c} - R(\tau) \right\}} = \\
 &= \frac{ie}{\left\{ R(\tau) - \frac{\mathbf{R}(\tau) \cdot \mathbf{v}}{c} \right\}}
 \end{aligned}$$

Hence

$$\varphi = \frac{e}{\left\{ R(\tau) - \frac{\mathbf{R}(\tau) \cdot \mathbf{v}}{c} \right\}} \quad (20.12)$$

Formulae (20.11) and (20.12) are identical with formulae (25.3) and (25.4) of Part I.

Thus, the Liénard-Wiechert potentials can be written in relativistically invariant form and, consequently, use can be made of them at an arbitrary value of the velocity of motion of the charge.

§21. The electromagnetic field tensor and Maxwell's equations

We now turn to the calculation of the components of the electric and magnetic fields.

Making use of the definition of the 4-potential and introducing the coordinates of the radius 4-vector, we can write the components of the electric field in the form

$$\begin{aligned}
 E_x &= i \left(\frac{\partial A_\tau}{\partial x} - \frac{\partial A_x}{\partial \tau} \right), \\
 E_y &= i \left(\frac{\partial A_\tau}{\partial y} - \frac{\partial A_y}{\partial \tau} \right), \\
 E_z &= i \left(\frac{\partial A_\tau}{\partial z} - \frac{\partial A_z}{\partial \tau} \right),
 \end{aligned} \quad (21.1)$$

while the components of the magnetic field are expressed in terms of the components of the vector potential by the usual relations

$$H_x = \left(\frac{\partial A_z}{\partial y} - \frac{\partial A_y}{\partial z} \right), \quad (21.2)$$

and analogously for H_y and H_z .

The symmetry of formulae (21.1) and (21.2) suggests that we try to write the whole set in the form of one general formula. To do this we introduce a tensor $F_{\alpha\beta}$ by means of the relation

$$F_{\alpha\beta} = \frac{\partial A_\beta}{\partial x_\alpha} - \frac{\partial A_\alpha}{\partial x_\beta}. \quad (21.3)$$

The tensor $F_{\alpha\beta}$ is antisymmetric by definition. The calculation of the components of $F_{\alpha\beta}$ leads to the result

$$F_{\alpha\beta} = \begin{vmatrix} 0 & H_z & -H_y & -iE_x \\ -H_z & 0 & H_x & -iE_y \\ H_y & -H_x & 0 & -iE_z \\ iE_x & iE_y & iE_z & 0 \end{vmatrix}. \quad (21.4)$$

We see that all components of the electric and magnetic field vectors prove to be components of one tensor quantity $F_{\alpha\beta}$. It turns out that Maxwell's equations represent a system of equations for the tensor $F_{\alpha\beta}$. That is, if we write for $F_{\alpha\beta}$ the equation

$$\frac{\partial F_{\alpha\beta}}{\partial x_\lambda} + \frac{\partial F_{\beta\lambda}}{\partial x_\alpha} + \frac{\partial F_{\lambda\alpha}}{\partial x_\beta} = 0, \quad (21.5)$$

then, assuming α, β and λ to be successively equal to 1, 2, 3 and 4 and making use of the definition (21.4), we find easily that the four-dimensional equation (21.5) represents a notation of the two Maxwell-Lorentz vector equations (8.1) and (8.2) in Part I.

Analogously, writing the four-dimensional equation

$$\frac{\partial F_{\alpha\beta}}{\partial x_\beta} = \frac{4\pi}{c} j_\alpha, \quad (21.6)$$

we can verify that it involves the two vector equations (8.3) and (8.4). Formulae (21.5) and (21.6) represent the relativistically invariant form of notation of the Maxwell-Lorentz system of equations. The indissoluble connection between the electric and magnetic fields appeared in the non-relativistic formulation of the theory of the electromagnetic field as a proposition which followed from the whole of the experimental data. In relativistic electrodynamics this connection proves to be inevitable and self-evident. From the very definition of the field it follows that its properties are characterized not by two vectors but by one antisymmetric tensor. The equations of the electromagnetic field are equations related to this tensor. The components of the fields \mathbf{E} and \mathbf{H} appear equivalently in the tensor $F_{\alpha\beta}$. Under Lorentz transformations, which we can now formulate, the fields \mathbf{E} and \mathbf{H} are expressed in terms of each other.

Indeed, according to formulae (11.21) we have (assuming $A_{xy} = H_z$, $A_{xz} = -H_y$, $A_{yz} = H_x$, $A_{x\tau} = -iE_x$, $A_{y\tau} = -iE_y$, $A_{z\tau} = -iE_z$):

$$E_x = E'_x, \quad E_y = \frac{E'_y - \frac{v}{c}H'_z}{\sqrt{1 - \frac{v^2}{c^2}}}, \quad E_z = \frac{E'_z + \frac{v}{c}H'_y}{\sqrt{1 - \frac{v^2}{c^2}}}, \quad (21.7)$$

$$H_x = H'_x, \quad H_y = \frac{H'_y + \frac{v}{c}E'_z}{\sqrt{1 - \frac{v^2}{c^2}}}, \quad H_z = \frac{H'_z - \frac{v}{c}E'_y}{\sqrt{1 - \frac{v^2}{c^2}}}. \quad (21.8)$$

We see that statements of the type "the field is of purely electric character" or "the field is of purely magnetic character" are relative. An electric or magnetic field can be equal to zero in one reference frame and different from zero in another. Hence it makes no sense to attribute physical reality to the electric field and magnetic field separately. It is their combination, expressed by the electromagnetic field tensor $F_{\alpha\beta}$, which is the physical reality.

It is natural to establish which quantities characterizing the electromagnetic field are invariant. Since the electromagnetic field is described by the antisymmetric tensor $F_{\alpha\beta}$ then according to the results presented in §11 these invariants are the quantities $F_{\alpha\beta}F_{\alpha\beta}$ and $F_{\alpha\lambda}F_{\lambda\mu}F_{\mu\nu}F_{\nu\alpha}$. The cube invariant $F_{\alpha\beta}F_{\beta\lambda}F_{\lambda\alpha}$ turns out to be equal to zero. A simple calculation gives

$$I_1 = F_{\alpha\beta} F_{\alpha\beta} = H^2 - E^2 = \text{invar} , \quad (21.9)$$

$$I_2 = F_{\alpha\lambda} F_{\lambda\mu} F_{\mu\nu} F_{\nu\alpha} = (\mathbf{E} \cdot \mathbf{H})^2 = \text{invar} . \quad (21.10)$$

The invariants I_1 and I_2 are the absolute characteristics of the field. The statement "the electromagnetic field is equal to zero" ($I_1 = I_2 = 0$) or "the electric and magnetic field have the same value and are perpendicular to each other" ($I_1 = I_2 = 0$) are examples of absolute statements.

It is also true that, if $I_2 = 0$, i.e. if the fields \mathbf{E} and \mathbf{H} are perpendicular to each other, then they will remain perpendicular to each other in all reference frames. If in this case $I_1 > 0$, then in all reference frames $|\mathbf{H}| > |\mathbf{E}|$. We can in such cases find a reference frame in which the electric (but not the magnetic) field is equal to zero. Analogously, if $I_1 < 0$, one can find a reference frame in which the magnetic field is absent.

In the limiting case $v \ll c$ the Lorentz transformation formulae are essentially simplified. Disregarding v^2/c^2 , they can be written in the form

$$\mathbf{E} = \mathbf{E}' - \frac{\mathbf{v} \times \mathbf{H}'}{c} , \quad \mathbf{H} = \mathbf{H}' + \frac{\mathbf{v} \times \mathbf{E}'}{c} . \quad (21.11)$$

These transformations had already been obtained in non-relativistic field theory.

In conclusion we note that the relation and resemblance between the fields \mathbf{E} and \mathbf{H} does not at the same time exclude the existence of an essential difference between them, which we have mentioned in §7 of Part I. In relativistic electrodynamics this difference manifests itself in the fact that the components of the electric field are the temporal (imaginary) components of the electromagnetic field tensor, whereas the components of the magnetic field form the set of its spatial (real) components.

§22. Some applications: Doppler effect, Mössbauer effect, observation of rapidly moving bodies, transformation of angles, intensities and cross sections

We have seen that the statement "the electromagnetic field is absent at a certain point of space at a particular instant of time" has an absolute character. From this it follows that the value of the phase α in the electromagnetic

$$\mathbf{E} = \mathbf{E}_0 e^{i\alpha} , \quad \mathbf{H} = \mathbf{H}_0 e^{i\alpha} ,$$

wave is an invariant. If, for example, the phase is equal to $\frac{1}{2}\pi$ or to an integer multiple of $\frac{1}{2}\pi$, so that $\mathbf{E} = \mathbf{H} = 0$, then this value of the phase must be conserved in all inertial reference frames.

Formally introducing the 4-vector k_α ,

$$k_\alpha = \left(\mathbf{k}, i \frac{\omega}{c} \right),$$

called the four-dimensional wave vector, one can write the phase of the wave in the form of the scalar product of two 4-vectors, k_α and r_α ,

$$\alpha = k_\alpha r_\alpha = (\mathbf{k} \cdot \mathbf{r} - \omega t).$$

Since the phase is invariant, the above formula shows that the quantity k_α , determined formally, is clearly a 4-vector.

The law of transformation of the components of a 4-vector also allows one to find the law of transformation of frequencies in the theory of relativity. That is to say, from the definition of the four-dimensional wave vector it follows that its fourth component transforms according to the law

$$k_r = \frac{k'_r + i \frac{v}{c} k'_x}{\sqrt{1 - \frac{v^2}{c^2}}}.$$

Expressing k_r in terms of the frequency ω , we find

$$\omega = \frac{\omega' + vk'_x}{\sqrt{1 - \frac{v^2}{c^2}}}.$$

Writing k'_x in the form $k'_x = (\omega'/c) \cos \theta'$, where $\cos \theta'$ is the direction cosine of the wave vector, we find

$$\omega = \frac{\omega' \left(1 + \frac{v}{c} \cos \theta' \right)}{\sqrt{1 - \frac{v^2}{c^2}}} \quad (22.1)$$

Analogously,

$$k_x = \frac{\omega}{c} n_x = \frac{k'_x - i k'_y \frac{v}{c}}{\sqrt{1 - \frac{v^2}{c^2}}} = \frac{\frac{\omega'}{c} \cos \theta' + \frac{v}{c^2} \omega'}{\sqrt{1 - \frac{v^2}{c^2}}}. \quad (22.2)$$

Expressing ω in terms of ω' , we find

$$\cos \theta = \frac{\cos \theta' + \frac{v}{c}}{1 + \frac{v}{c} \cos \theta'}, \quad (22.3)$$

$$\sin \theta = \sin \theta' \frac{\sqrt{1 - \frac{v^2}{c^2}}}{1 + \frac{v}{c} \cos \theta'},$$

The formulae for the inverse transformation from the reference frame K to the reference frame K' read:

$$\omega' = \frac{\omega \left(1 - \frac{v}{c} \cos \theta\right)}{\sqrt{1 - \frac{v^2}{c^2}}}, \quad (22.4)$$

$$\cos \theta' = \frac{\cos \theta - \frac{v}{c}}{1 - \frac{v}{c} \cos \theta}, \quad (22.5)$$

$$\sin \theta' = \sin \theta \frac{\sqrt{1 - \frac{v^2}{c^2}}}{1 - \frac{v}{c} \cos \theta}.$$

Formula (22.1) expresses the Doppler effect in the theory of relativity. As is well known, the Doppler effect consists in a change of the frequency emitted by a moving source in comparison with the frequency emitted by the same source at rest.

Formulae (22.3) and (22.5) give the law of angular transformation. The law of angular transformation given by these relations is the same as that following from (7.4). One can verify this most simply by dividing the lower formula in (22.3) by the upper one.

In these formulae ω' is the frequency measured in the reference frame moving together with the source of radiation, and ω is the frequency in the reference frame at rest. It is assumed that the source moves together with the reference frame K' along the x -axis. The angle θ' represents the angle between the direction of the emitted wave, characterized in the reference frame K' by a vector \mathbf{k}' , and the direction of motion of the source. In the transition to the reference frame at rest the angle θ' transforms into the angle θ between the vector \mathbf{k} and the direction of motion.

Formula (22.4), which can be written in the form

$$\omega = \frac{\omega' \sqrt{1 - \frac{v^2}{c^2}}}{1 - \frac{v}{c} \cos \theta}, \quad (22.6)$$

is the most important for practical use. Formula (22.6) allows one to find the frequency of light ω as a function of the frequency of light ω' emitted by the moving source in the proper reference frame K' and the angle θ measured in the reference frame K .

If the source of light approaches or moves away from the observer who is located, for example, at the origin of the reference frame K , then one speaks about the longitudinal Doppler effect. For the approaching case $\cos \theta = 1$ and the frequency $\omega > \omega'$, and for the receding case $\cos \theta = -1$ and the frequency $\omega < \omega'$.

It is interesting to compare the relativistic formula for the change in the frequency in the Doppler effect with the classical one. The latter is obtained from the elementary treatment of waves emitted by the moving source and reaching the observer, and has the form

$$\omega = \omega' \left(1 + \frac{v}{c} \cos \theta \right). \quad (22.7)$$

The value of the angle was assumed in classical physics to be invariant in all reference frames.

Comparing the classical and relativistic formula for the change in the frequency in the Doppler effect we see that the two formulae are the same when

the source of radiation is moving with a velocity $v \ll c$, so that it can be assumed that

$$\sqrt{1 - \frac{v^2}{c^2}} \approx 1$$

and

$$\frac{1}{1 - \frac{v}{c} \cos \theta} \approx 1 + \frac{v}{c} \cos \theta.$$

However, if the second order terms are taken into account, then an essential difference arises between these formulae. In particular, when the source is moving in a direction perpendicular to the direction of observation, i.e. when $\theta = \frac{1}{2}\pi$, the classical formula (22.7) shows that no change in the frequency takes place. On the contrary, according to the theory of relativity a change in the frequency does take place (the "transverse" Doppler effect) which is, according to (22.6), equal to

$$\omega = \omega' \sqrt{1 - \frac{v^2}{c^2}}. \quad (22.8)$$

The experimental study of the Doppler effect was of particularly great importance because the change in the frequency is connected directly with the change in time in the transition from one inertial reference frame to another. The experimental investigation of the Doppler effect made it possible to confirm to a high degree of accuracy the validity of the relativistic relations.

In Ives' experiments* the change in the frequency emitted by hydrogen atoms in canal rays was investigated. The velocity of the atoms was about $6 \times 10^{-3} c$. The main difficulty lay in the separation of the second order effect with respect to (v/c) , which is small in comparison with the ordinary (classical) line shift by an amount of the order of magnitude of v/c . To do this light rays emitted along and against the direction of motion were matched by means of mirrors. According to the relativistic formula (22.1) the value of the mean of the emitted frequencies of the lines is equal to

* Ives' and Stillwell's. See W. Pauli, *Theory of relativity* (Pergamon, London, 1958).

$$\begin{aligned}
 \bar{\omega} &= \frac{\omega_1 + \omega_2}{2} = \frac{\omega' \left(1 - \frac{v}{c}\right)}{2\sqrt{1 - \frac{v^2}{c^2}}} + \frac{\omega' \left(1 + \frac{v}{c}\right)}{2\sqrt{1 - \frac{v^2}{c^2}}} = \\
 &= \frac{\omega'}{\sqrt{1 - \frac{v^2}{c^2}}} \approx \omega' \left[1 + \frac{1}{2} \left(\frac{v}{c}\right)^2\right]. \quad (22.9)
 \end{aligned}$$

The classical result would be $\bar{\omega} = \omega'$.

Measurements confirmed to a high degree of accuracy the relativistic formula (22.9).

Ives' experiments, dating from 1938, appeared to be the first direct experimental confirmation of the relativistic law of change of time under Lorentz transformations. From this point of view they played a role analogous to Michelson's experiments. Taking these two experiments as a basis, one could have constructed the entire scheme of the theory of relativity, if both these experiments had preceded the development of the theory.

An extremely accurate measurement of the second order Doppler effect has recently become possible through the discovery of an important new phenomenon, the so-called Mössbauer effect. It is well known that γ -quanta emitted by nuclei are monochromatic to a high degree. The width of the corresponding spectral lines is smaller, by many orders of magnitude, than the natural width of the lines emitted by atoms in optical transitions. This fact was for a long time an obstacle to the observation of resonance absorption by nuclei, i.e. the absorption of γ -quanta of natural frequencies by the nuclei.

Nuclei, as well as atomic systems, absorb radiation of the same frequency which they themselves emit, very strongly. However, in contrast to emitting atomic systems, nuclei undergo a considerable recoil in emitting γ -quanta. This recoil changes the frequency of the emitted γ -quantum, which, owing to the very small width of the lines, leads to a complete shift from the resonance frequency.

Mössbauer showed that the situation is fundamentally changed if the nuclei emitting γ -quanta are in a crystal lattice. The forces of interaction between atoms and their neighbours in a crystal lattice is very large. Hence the recoil momentum acquired by the nucleus in emitting a γ -quantum is insufficient to pull the nucleus out of its position in the lattice. The recoil

momentum is transferred to the crystal as a whole. * The mass of the latter is very large and the emission of a γ -quantum takes place practically without a recoil. Gamma-rays emitted by nuclei in a crystal lattice have an unshifted frequency ν_0 . When γ -rays emitted by a crystal emitter without recoil are passed through an absorber containing the same nuclei as the emitter a resonance absorption is observed.

Although the emission of γ -quanta takes place without a recoil and the momentum of the crystal can be assumed to be equal to zero, the presence of thermal motion leads to a small change in the frequency. Namely, since the velocity of the emitter — an atomic nucleus performing thermal motion — differs from zero, a Doppler effect must occur.

To calculate the change in the frequency use can be made of the following.

If the nucleus emits radiation of frequency ν_0 , then the energy of the γ -quantum is equal to $h\nu_0$. The mass of the γ -quantum is equal to $h\nu_0/c^2$. As a result of the emission the mass of the nucleus is reduced by this amount. Let the mass of the nucleus before emission be equal to M . Then its kinetic energy is

$$E_{\text{kin}}^{(0)} = \sqrt{p^2 c^2 + M^2 c^4} - Mc^2 \approx p^2 / 2M.$$

In emission the mass of the nucleus is reduced by an amount $h\nu_0/c^2$ to

$$M' = M - \frac{h\nu_0}{c^2}$$

for a constant value of the momentum. Consequently the kinetic energy changes by an amount

$$\begin{aligned} \Delta E_{\text{kin}} &= (\sqrt{p^2 c^2 + M'^2 c^4} - M' c^2) - E_{\text{kin}}^{(0)} \approx \\ &\approx \frac{p^2}{2M'} - \frac{p^2}{2M} \approx \frac{p^2}{2M^2} \frac{h\nu_0}{c^2}. \end{aligned}$$

Replacing the true value p^2 by the mean value $M^2 \overline{v^2}$ for thermal motion, we obtain

* At least at a sufficiently low temperature. For more details about the conditions under which the momentum is transferred to the crystal as a whole see the articles: R.Mössbauer, Soviet Physics Uspekhi 3 (1961) 866; and F.L.Shapiro, Soviet Physics Uspekhi 3 (1961) 881.

$$\Delta E_{\text{kin}} \approx h\nu_0 \frac{\overline{v^2}}{2c^2}.$$

The increase in the kinetic energy of the moving emitting nucleus means that the γ -quantum takes away an energy $h\nu_0 - \Delta E_{\text{kin}} = h\nu_0(1 - \overline{v^2}/2c^2)$. This energy is smaller by an amount ΔE_{kin} than the energy of the γ -quantum emitted by the source at rest.

Thus, the thermal motion of emitting nuclei leads to a frequency shift from ν_0 to ν such that

$$\nu = \nu_0 \left(1 - \frac{\overline{v^2}}{2c^2}\right).$$

This expression for the shifted frequency is the same as the formula for the second order Doppler effect (taking into account terms of the order of v^2/c^2). The absence of the linear term in the formula for the Doppler effect is associated with the fact that the mean velocity of thermal motion is equal to zero.

The calculated shift of the emitted line by an amount of $\nu_0 \overline{v^2}/2c^2$ is in good agreement with experimental data.

Since the mean square velocity of a molecule in a crystal depends on the temperature, one can find the temperature dependence of the value of the shift $\nu - \nu_0$:

$$\frac{d\Delta\omega}{dT} = -\frac{\omega_0}{Mc^2} \frac{d}{dT} \frac{M\overline{v^2}}{2}.$$

But in a crystal the heat capacity at a temperature substantially higher than the Debye temperature is equal to (see (30.1) of Part III):

$$C_V = N \frac{d\bar{\epsilon}}{dT} = N \frac{d}{dT} \left(\frac{M\overline{v^2}}{2} + \frac{M\omega^2 \overline{q^2}}{2} \right) = N \frac{dM\overline{v^2}}{dT},$$

hence

$$\frac{d\Delta\omega}{dT} = -\frac{\omega_0}{2Mc^2N} C_V$$

The accuracy of the measurements using the Mössbauer effect is so high that this effect has also been measured. We cannot dwell here on a number of

Other very important results obtained in studying the Mössbauer effect. *

We shall now consider the formulae for the transformation of some quantities which play important roles in physics. We begin with the consideration of the radiation emitted by a particle moving with a velocity close to the velocity of light.

We assume that in the reference frame moving with the particle the emission can take place at a large angle to the direction of motion, i.e. $\cos \theta'$ varies in the range

$$0 \leq \cos \theta' \leq 1.$$

Let us find the angle at which the radiation will be emitted in the motionless (laboratory) reference frame.

It is convenient to transform with formula (22.3). Setting

$$v \approx c - \frac{c}{\alpha^2},$$

where

$$\alpha = - \frac{\sqrt{2}}{\sqrt{1 - \frac{v^2}{c^2}}}.$$

For v close to c the quantity $\alpha^2 \gg 1$. Introducing this notion, we obtain for $\alpha \gg 1$:

$$\begin{aligned} \cos \theta &= \frac{\cos \theta' + 1 - \frac{1}{\alpha^2}}{1 + \left(1 - \frac{1}{\alpha^2}\right) \cos \theta'} = \frac{1 - \frac{1}{\alpha^2(1 + \cos \theta')}}{1 - \frac{\cos \theta'}{\alpha^2(1 + \cos \theta')}} \approx \\ &\approx 1 + \frac{\cos \theta' - 1}{\cos \theta' + 1} \frac{1}{\alpha^2} = 1 - \frac{\tan^2 \frac{1}{2} \theta'}{\alpha^2}. \end{aligned}$$

* See F.L.Shapiro, Soviet Physics Uspekhi 3 (1961) §81; and also the articles by R.Mössbauer and R.V.Pound in the same volume.

Since $\alpha^2 \gg 1$, $\cos \theta$ is close to unity and the angle θ itself is given approximately by

$$\theta \sim \frac{\sqrt{2} \tan \frac{1}{2} \theta'}{\alpha} \sim \tan \frac{1}{2} \theta' \sqrt{1 - \frac{v^2}{c^2}},$$

and is very small for a sufficiently large value of α , i.e. for a small value of the difference $c - v$. This means that in the reference frame at rest the overall radiation is directed forward and is confined to a narrow cone of angle $\Delta \theta \sim \sqrt{1 - v^2/c^2}$. The aperture of this cone is smaller the closer the velocity v of the source is to the velocity of light.

We now obtain the formula for the transformation of an element of solid angle $d\Omega$, which is important for many applications. We have, by definition,

$$d\Omega = 2\pi \sin \theta \, d\theta = -2\pi \, d \cos \theta,$$

$$d\Omega' = -2\pi \, d \cos \theta'.$$

Hence

$$d\Omega = \frac{d \cos \theta}{d \cos \theta'} \, d\Omega'. \quad (22.10)$$

From formula (22.5) we find

$$1 + \frac{v}{c} \cos \theta' = \left(1 - \frac{v^2}{c^2}\right) \frac{1}{1 - \frac{v}{c} \cos \theta}. \quad (22.11)$$

Differentiating (22.11) with respect to $\cos \theta$, we find

$$\frac{d \cos \theta'}{d \cos \theta} = \frac{1 - \frac{v^2}{c^2}}{\left(1 - \frac{v}{c} \cos \theta\right)^2}$$

thus we finally obtain

$$d\Omega' = \frac{1 - \frac{v^2}{c^2}}{\left(1 - \frac{v}{c} \cos \theta\right)^2} d\Omega. \quad (22.12)$$

Let us find how to transform the energy in an electromagnetic wave. From the general relation (13.9) and formula (33.12) of Part I we have

$$E = \frac{E' + \frac{E'}{c} (\mathbf{n}' \cdot \mathbf{v})}{\sqrt{1 - \frac{v^2}{c^2}}} = E' \frac{1 + \frac{v}{c} \cos \theta'}{\sqrt{1 - \frac{v^2}{c^2}}} \quad (22.13)$$

By virtue of the relation (27.10) of Part I the invariant of the energy-momentum 4-vector for the electromagnetic field is equal to zero:

$$\text{invariant} = g^2 - \frac{E^2}{c^2} = 0. \quad (22.14)$$

We note that, writing down the formulae for the energy and momentum of the field, which were determined in Part I as the densities of the corresponding quantities, they are related to unit volume moving with the field, i.e. with the velocity of light. We should therefore define more precisely what such a volume means in the theory of relativity. *

Comparing (22.13) with formula (22.1) for the transformation of frequency, we arrive at the important equality:

$$\frac{E}{\omega} = \frac{E'}{\omega'} = \text{invar}. \quad (22.15)$$

We now find the expression for the transformation of the total power of the radiation:

$$I = - \frac{dE}{dt}.$$

Since the total momentum emitted by the system in that reference frame in which it was at rest at the moment of emission is equal to zero (see (28.5) of Part I), one can write

* This transformation can be found, for instance, in the book: W. Pauli, *Theory of relativity* (Pergamon, London, 1958), or in the repeatedly quoted book by R. Becker.

$$E = \frac{E'}{\sqrt{1 - \frac{v^2}{c^2}}}.$$

ence using (6.3)

$$\frac{dE}{dt} = \frac{d}{dt} \frac{E'}{\sqrt{1 - \frac{v^2}{c^2}}} = \frac{dE'}{\sqrt{1 - \frac{v^2}{c^2}}} \frac{\sqrt{1 - \frac{v^2}{c^2}}}{dt'} = \frac{dE'}{dt'},$$

and, consequently,

$$I = - \frac{dE}{dt} = - \frac{dE'}{dt'} = \text{invar}. \quad (22.16)$$

Thus, the total power radiated (the energy emitted per unit time) is an invariant. The radiated power in a solid angle element $d\Omega$ transforms according to the formula

$$dI = I(\theta) d\Omega = I'(\theta') d\Omega' = \text{invar},$$

from which it follows that

$$I(\theta) = I'(\theta') \frac{d\Omega'}{d\Omega} = I'(\theta') \frac{1 - \frac{v^2}{c^2}}{\left(1 - \frac{v}{c} \cos \theta\right)^2}. \quad (22.17)$$

Combining formulae (22.4) and (22.12) we also obtain the expression

$$\omega^2 d\Omega = \omega'^2 d\Omega' = \text{invar} \quad (22.18)$$

In practice one often has to consider the law of transformation of the quantities dk_x, dk_y, dk_z . From (22.2) we find

$$dk'_x = \frac{dk'_x + \frac{v d\omega'}{c^2}}{\sqrt{1 - \frac{v^2}{c^2}}} = \frac{dk'_x \left(1 + \frac{v}{c^2} \frac{d\omega'}{dk'_x}\right)}{\sqrt{1 - \frac{v^2}{c^2}}}.$$

Taking into account that $\omega' = c\sqrt{k_x'^2 + k_y'^2 + k_z'^2}$, we have

$$\frac{d\omega'}{dk'_x} = \frac{k'_x c^2}{\omega'}$$

so that

$$dk'_x = \frac{dk'_x \left(1 + \frac{vk'_x}{\omega'}\right)}{\sqrt{1 - \frac{v^2}{c^2}}} = \frac{dk'_x}{\omega'} \frac{\omega' + vk'_x}{\sqrt{1 - \frac{v^2}{c^2}}} = \frac{dk'_x}{\omega'} \omega'.$$

In addition

$$dk'_y = dk_y, \quad dk'_z = dk_z,$$

whence we find

$$\frac{dk_x dk_y dk_z}{\omega} = \frac{dk'_x dk'_y dk'_z}{\omega'} = \text{invar}, \quad (22.19)$$

or, in spherical coordinates,

$$\frac{k^2 dk d\Omega}{\omega} = \frac{k'^2 dk' d\Omega'}{\omega'} = \text{invar}. \quad (22.20)$$

An important problem in the contemporary physics of high-energy particles is that of transformation of the total scattering cross section in the transition from one inertial reference frame to another.

In §43 of Part I we have seen that the total cross section in classical physics is an invariant. In the theory of relativity the cross section in general is not an invariant.

According to (43.2) and (43.4) of Part I the total number of particles scat-

tered by a volume V in a time dt in the reference frame K in which the scatterer is at rest is equal to

$$dN = \sigma I_0 \rho V dt,$$

where ρ is the particle density of the scatterer, and

$$I_0 = n |\mathbf{v}_2 - \mathbf{v}_1| = n v_{\text{rel}},$$

and n is the density of particles in the beam to be scattered, \mathbf{v}_2 is the velocity of particles to be scattered, and \mathbf{v}_1 is the velocity of the particles of the target, equal to zero in the reference frame K .

In a reference frame K' let the target move with a velocity \mathbf{v}_1 . Then in view of the invariance of the number of particles dN we have

$$dN = \sigma I_0 \rho V dt = \sigma' V' I_0' \rho' dt',$$

where

$$I_0' = n' |\mathbf{v}_2' - \mathbf{v}_1'|.$$

Hence it follows that

$$\sigma n \rho |\mathbf{v}_2 - \mathbf{v}_1| V dt = \sigma' n' \rho' |\mathbf{v}_2' - \mathbf{v}_1'| V' dt'.$$

From formulae (6.2) and (6.3) the product $V dt$ is an invariant. The density of the incident beam of particles n and the density of the particles of the target ρ satisfy the continuity equation. In accordance with this, we can construct the 4-vectors $(\rho \mathbf{v}_1, i c \rho)$ and $(n \mathbf{v}_2, i c n)$. We form their scalar product, which is an invariant. We have, obviously

$$(\rho \mathbf{v}_1, i c \rho) \cdot (n \mathbf{v}_2, i c n) = n' \rho' \mathbf{v}_2' \cdot \mathbf{v}_1' - c^2 \rho' n' = -c^2 \rho n,$$

since in the reference frame K the target is at rest and $\mathbf{v}_1 = 0$.

On transforming we have

$$\rho' n' \left(1 - \frac{\mathbf{v}_1' \cdot \mathbf{v}_2'}{c^2} \right) = \rho n.$$

Thus, we can write that

$$\sigma |v_2 - v_1| = \sigma v_{rel} = \frac{\sigma' |v'_2 - v'_1|}{1 - \frac{v'_1 \cdot v'_2}{c^2}}.$$

Since $v_1 = 0$, the last formula can be written in symmetric form:

$$\frac{\sigma |v_2 - v_1|}{1 - \frac{v_1 \cdot v_2}{c^2}} = \frac{\sigma' |v'_2 - v'_1|}{1 - \frac{v'_1 \cdot v'_2}{c^2}}. \quad (22.21)$$

We see that the total scattering cross section is not an invariant.

In the particular case when the velocities of the incident particles and the target are in the same direction or in opposite directions we can choose the direction of motion as an axis and make use of the formula for the addition of velocities. According to the inverse of (7.1) we have

$$v_2 = \frac{v'_2 - v'_1}{1 - \frac{v'_1 v'_2}{c^2}}.$$

Thus, in this particular case

$$\sigma = \sigma' = \text{invar}. \quad (22.22)$$

A question of interest is, what is the form in which rapidly moving objects appear when they are recorded on a photographic plate or when they are observed visually? In other words, will the Lorentz contraction be noticeable? For example, will a sphere be seen in the form of an ellipsoid, and a cube in the form of a parallelepiped, and so on? The corresponding investigation has recently been carried out by Terrel *. It turns out that rapidly moving objects are seen not as flattened but as having undergone a rotation through some angle depending on the velocity of the object with respect to the observer and the angle of observation. In order to understand this, at first sight unexpected, result, we shall define more precisely the difference between the results of a measurement of the form of a rapidly moving body and the special case of recording this form on a photographic plate. In general, to measure the form of a body, for example by recording the radiation appearing

* J. Terrel, Phys. Rev. 116 (1950) 1041. See also V. Weisskopf, Physics Today 13 (1960) 24.

Fig. II.6

simultaneously from different points of its surface, we have to take into account the finite value of the velocity of light.

Different points of the object of observation — a moving body — are located at different distances from the recording device. Hence electromagnetic waves emitted by different points of the surface of the body traverse different paths for different times before arriving at the device. To obtain the true form of the object of observation it is necessary to introduce corresponding corrections into the measurement data.

The situation is different in photographing or observing a body visually. A photographic plate (or an eye) records the radiation reaching it at a given instant. Consequently, a photographic plate simultaneously records electromagnetic waves emitted by different points of the object of observation at different times. Let a photographic plate $\alpha\alpha$ be at rest (fig. II.6) in a certain reference frame. We assume that an extended body is moving in a direction towards it. We denote by v the velocity of the body (and the reference frame K' connected with it). The angle ϑ between a straight line drawn from the photographic plate to the body and the velocity vector v will be called the observation angle.

The radiation from the body can be characterized by a wave vector k' in the reference frame K' connected with the body. The observation angle in the reference frame K' will be equal to ϑ' . The angle θ' , formed by the wave vector k' with the velocity v is obviously equal to $\theta' = \pi - \vartheta'$.

In the reference frame K the wave vector forms an angle $\theta = \pi - \vartheta$ with the vector v . We assume that the solid angle subtended by the object of observation is sufficiently small. The radiation emitted by different points of the object can then be characterized by one value of the wave vector k . The image of the body on the photographic plate obtained at a certain instant will be called "the picture". Let us see how the picture is obtained, i.e. how elec-

tromagnetic waves emitted by different points A, B, C of the surface of the body are recorded (see fig. II.6). The waves emitted by the points A and B at the instant when they were respectively in the positions A' and B' reach the plate at the same time as the wave emitted by the point C on the surface of the body. In other words, radiation emitted by the points A, B, C is recorded simultaneously on the photographic plate at the points A'', B'', C''. However, the waves coming from the more distant points A and B were emitted at earlier times. Let us find the relation between the observation angles ϑ and ϑ' .

Taking into account the above mentioned relation between the observation angles ϑ , ϑ' and the emission angles θ , θ' and formula (22.5), we can write

$$\sin \vartheta' = \frac{\sqrt{1 - \frac{v^2}{c^2}} \sin \vartheta}{1 + \frac{v \cos \vartheta}{c}}. \quad (22.23)$$

In formula (22.5) we have replaced the angles θ and θ' by $\pi - \vartheta$, $\pi - \vartheta'$. The dependence $\vartheta' = f(\vartheta)$ is presented graphically in fig. II.7. The dotted line in the same drawing shows the straight line $\vartheta' = \vartheta$, corresponding to the case $v = 0$, i.e. to the recording on the photographic plate of an object which is at rest with respect to it. Consider first the case $\vartheta = \pi$. This means that the body to be photographed is moving directly towards the photographic plate. In this case $\vartheta' = \pi$, i.e. we obtain the image of the front surface of the body on the photographic plate.

Fig. II.7

Now let the angle ϑ have a value smaller than $\pi - \sqrt{1 - v^2/c^2}$. This means that the observation angle lies outside a narrow cone about the direction of motion.

From formula (22.23) and the graph in fig. 11.7 it is seen that for $v \approx c$ there correspond to the values of the observation angle $\frac{1}{2}\pi < \vartheta < \pi - \sqrt{1 - v^2/c^2}$ values of the angle ϑ' close to zero. To angles ϑ' close to zero there correspond angles ϑ' close to π . This means that at velocities of motion of the body close to the velocity of light the radiation from the back of the body arrives at the photographic plate.

It should be stressed that this result refers to a body moving in a direction towards the photographing device ($\vartheta > \frac{1}{2}\pi$). In this case the intensity observed can be found from formula (22.17). Namely, we have

$$I_0(\vartheta) = I'_0(\vartheta') \frac{d\Omega'}{d\Omega} = I'_0(\vartheta') \frac{1 - \frac{v^2}{c^2}}{\left(1 + \frac{v}{c} \cos \vartheta\right)^2}.$$

If the angle $\vartheta < \pi - \sqrt{1 - v^2/c^2}$, then the observed intensity of light is small. This result has a simple meaning: for $v \sim c$ in the reference frame K the radiation is concentrated in a narrow cone with an aperture $\Delta\theta \sim \sqrt{1 - v^2/c^2}$ in the direction of the velocity of the body.

In general it can be said that if the object to be photographed moves with a velocity v and is observed at a certain angle ϑ , then one obtains the same picture as in photographing the object at rest but seen at an angle ϑ' . Thus, the image of a moving object on a photographic plate turns out to be the same as on a plate which is at rest with respect to the object. However, the object turns out to have undergone a rotation through an angle $\vartheta' - \vartheta$. Thus, in photographing a sphere one must obtain a circle on a photographic plate, in photographing a cube one must obtain a cube turned at a different angle, and so on.

Fig. 11.8 shows schematically how the image of a cube on a photographic plate must change as the relative velocity approaches the velocity of light. To the points A, B, C, D of the cube there correspond the points A', B', C', D' on the photographic plate. We see how the image progressively "rotates".

These considerations make particularly clear the lack of meaning of the terminology "an apparent contraction" in relation to the Lorentz contraction.

It should be noted that the entire picture becomes more complex if the object observed subtends a large solid angle. In this case to each point of the

Fig. II.8

object there corresponds a proper observation angle ϑ and, consequently, also a proper rotation. However, in this case also the image of a sphere on a photographic plate must be a circle.

§ 23. The Lorentz force; the Lagrangian and the Hamiltonian for a particle moving in an electromagnetic field

In electrodynamics an expression was given for the force acting on a charge moving in an electromagnetic field. This force, called the Lorentz force, was deduced from experimental data. We shall now present a simple derivation of

the formula for the Lorentz force, based on the transformations of the electromagnetic field vectors.

Consider a charge e , moving with an arbitrary velocity \mathbf{v} with respect to the reference frame K . In the reference frame moving with the charge let there be an electric field \mathbf{E}' . Then the charge in the reference frame K' is acted upon by the force

$$\mathcal{F}' = e\mathbf{E}' \quad (23.1)$$

Our problem is to find the force acting on the charge in the reference frame K (in which it moves with the velocity \mathbf{v}). For this it is necessary to express the field \mathbf{E}' in terms of the electromagnetic field \mathbf{E} , and the force \mathcal{F}' in terms of the force \mathcal{F} in the reference frame K . The first transformation is given directly by the formulae of §21.

The formulae for the transformation of the force can be obtained in the following way. We find, first of all, the formulae for the transformation of the components of the Minkowski force (§12). The Minkowski force is a 4-vector, and its components transform according to the general formulae (11.1) – (11.4). In our case, in the reference frame moving with the charge the velocity $\mathbf{v}' = 0$ and, hence, $F'_4 = 0$. In this case

$$F_1 = \frac{F'_1}{\sqrt{1 - \frac{v^2}{c^2}}}, \quad F_2 = F'_2, \quad F_3 = F'_3.$$

The components of the Minkowski force are connected with the components of the ordinary force \mathcal{F} by relations of the type (12.5).

In the reference frame moving with the charge $\mathbf{v}' = 0$, and

$$F'_1 = \mathcal{F}'_x, \quad F'_2 = \mathcal{F}'_y, \quad F'_3 = \mathcal{F}'_z.$$

In the reference frame K , by definition from §12,

$$F_1 = \frac{\mathcal{F}_x}{\sqrt{1 - \frac{v^2}{c^2}}}, \quad F_2 = \frac{\mathcal{F}_y}{\sqrt{1 - \frac{v^2}{c^2}}}, \quad F_3 = \frac{\mathcal{F}_z}{\sqrt{1 - \frac{v^2}{c^2}}}.$$

Hence we find easily *

$$\mathcal{F}_x = \mathcal{F}'_x, \quad \mathcal{F}_y = \mathcal{F}'_y \sqrt{1 - \frac{v^2}{c^2}}, \quad \mathcal{F}_z = \mathcal{F}'_z \sqrt{1 - \frac{v^2}{c^2}}. \quad (23.2)$$

Combining (23.1), (23.2) and the transformation formulae (21.7)–(21.8), we find the expression for the components of the force:

$$\mathcal{F}_x = \mathcal{F}'_x = eE'_x = eE_x, \quad (23.3)$$

$$\mathcal{F}_y = \mathcal{F}'_y \sqrt{1 - \frac{v^2}{c^2}} = eE'_y \sqrt{1 - \frac{v^2}{c^2}} = e \left(E_y - \frac{vH_z}{c} \right), \quad (23.4)$$

$$\mathcal{F}_z = \mathcal{F}'_z \sqrt{1 - \frac{v^2}{c^2}} = eE'_z \sqrt{1 - \frac{v^2}{c^2}} = e \left(E_z + \frac{vH_y}{c} \right). \quad (23.5)$$

In vector form

$$\mathcal{F} = e \left\{ \mathbf{E} + \frac{1}{c} \mathbf{v} \times \mathbf{H} \right\}. \quad (23.6)$$

Thus, the expression for the Lorentz force is obtained in a purely mathematical way from the general relations of the theory of relativity.

Let us write the equations of motion (12.3) for the case of the motion of a charged particle in an external electromagnetic field.

The first three equations are of the form

$$\frac{d\mathbf{p}}{dt} = e \left\{ \mathbf{E} + \frac{1}{c} \mathbf{v} \times \mathbf{H} \right\}. \quad (23.7)$$

In finding the fourth equation it must be taken into account that the work done by the force in the magnetic field is equal to zero (since $\mathbf{v} \cdot (\mathbf{v} \times \mathbf{H}) = \mathbf{H} \cdot (\mathbf{v} \times \mathbf{v}) = 0$) and, consequently

$$\frac{dE}{dt} = \mathcal{F} \cdot \mathbf{v} = e\mathbf{E} \cdot \mathbf{v}. \quad (23.8)$$

In the following paragraphs we shall consider some particular cases of the

* It should be stressed that the formulae presented are valid only for the transition from the reference frame K' moving together with the particle to the reference frame K .

motion of a particle in an electric and magnetic field. For what follows we shall need an expression for the Lorentz force in terms of electromagnetic potentials.

We have

$$\mathcal{F} = e \left\{ -\nabla\varphi - \frac{1}{c} \frac{\partial \mathbf{A}}{\partial t} + \frac{1}{c} \mathbf{v} \times (\nabla \times \mathbf{A}) \right\}$$

We make use of the formula (I.47) of vector analysis:

$$\begin{aligned} \nabla(\mathbf{A} \cdot \mathbf{v}) &= (\mathbf{A} \cdot \nabla)\mathbf{v} + (\mathbf{v} \cdot \nabla)\mathbf{A} + \mathbf{v} \times (\nabla \times \mathbf{A}) + \mathbf{A} \times (\nabla \times \mathbf{v}) = \\ &= (\mathbf{v} \cdot \nabla)\mathbf{A} + \mathbf{v} \times (\nabla \times \mathbf{A}). \end{aligned}$$

Here we have taken into account that the differentiation with respect to coordinates is carried out at a constant value of the velocity \mathbf{v} .

Making use of this formula, we rewrite \mathcal{F} in the form

$$\begin{aligned} \mathcal{F} &= e \left\{ -\nabla\varphi - \frac{1}{c} \frac{\partial \mathbf{A}}{\partial t} + \frac{1}{c} \nabla(\mathbf{A} \cdot \mathbf{v}) - \frac{1}{c} (\mathbf{v} \cdot \nabla)\mathbf{A} \right\} = \\ &= e \nabla \left(\frac{\mathbf{A} \cdot \mathbf{v}}{c} - \varphi \right) - \frac{e}{c} \frac{d\mathbf{A}}{dt}, \end{aligned}$$

where the total derivative (see I.18) is

$$\frac{d\mathbf{A}}{dt} = \frac{\partial \mathbf{A}}{\partial t} + (\mathbf{v} \cdot \nabla)\mathbf{A}.$$

The equations of motion assume the form

$$\frac{d}{dt} \frac{m\mathbf{v}}{\sqrt{1 - \frac{v^2}{c^2}}} = e \nabla \left\{ \frac{\mathbf{A} \cdot \mathbf{v}}{c} - \varphi \right\} - \frac{e}{c} \frac{d\mathbf{A}}{dt}. \quad (23.9)$$

These can be considered the Lagrange equations, if the Lagrangian is of the form

$$L = -mc^2 \sqrt{1 - \frac{v^2}{c^2}} - e\varphi + \frac{e}{c} \mathbf{A} \cdot \mathbf{v}. \quad (23.10)$$

Indeed, in this case the generalized momentum is

$$\mathbf{P} = \frac{\partial L}{\partial \mathbf{v}} = \frac{m\mathbf{v}}{\sqrt{1 - \frac{v^2}{c^2}}} + \frac{e}{c} \mathbf{A} = \mathbf{p} + \frac{e}{c} \mathbf{A}. \quad (23.11)$$

Correspondingly the generalized force is

$$\mathbf{Q} = \frac{\partial L}{\partial \mathbf{r}} = \frac{e}{c} \nabla (\mathbf{A} \cdot \mathbf{v}) - e \nabla \varphi.$$

The Lagrange equation reads:

$$\frac{d}{dt} \frac{\partial L}{\partial \mathbf{v}} = \frac{\partial L}{\partial \mathbf{r}},$$

or

$$\frac{d}{dt} \mathbf{P} = \mathbf{Q}. \quad (23.12)$$

The substitution of the value \mathbf{P} and \mathbf{Q} into (23.12) again leads us to (23.9).

In the non-relativistic approximation the Lagrangian assumes the form

$$L \approx -mc^2 \left(1 - \frac{v^2}{2c^2} \right) + \frac{e}{c} \mathbf{A} \cdot \mathbf{v} - e\varphi = \frac{mv^2}{2} - e\varphi + \frac{e}{c} \mathbf{A} \cdot \mathbf{v}. \quad (23.13)$$

Here we have dropped the constant $(-mc^2)$, since Lagrange's equations include only the derivatives of L , and L itself is significant only with regard to its total derivative with respect to time. *

Comparing the Lagrangian of a particle in an electromagnetic field with the expression for the Lagrangian in an ordinary field of force,

$$L = \frac{mv^2}{2} - U,$$

we see that for the electromagnetic field the Lagrangian contains one more term, depending on the velocity and vector potential. Hence even in the non-relativistic approximation the Lagrangian of the electromagnetic field cannot

* L.D.Landau and E.M.Lifshitz, *Mechanics* (Pergamon, Oxford, 1960).

be written in the form of the difference between the kinetic and potential energy.

Let us find the Hamiltonian of a charged particle in an electromagnetic field. Obviously, we have

$$\begin{aligned}
 H = \sum_{i=x,y,z} \dot{q}_i P_i - L = \mathbf{v} \cdot \mathbf{P} - L = \mathbf{v} \cdot \left(\frac{m\mathbf{v}}{\sqrt{1 - \frac{v^2}{c^2}}} + \frac{e}{c} \mathbf{A} \right) + \\
 + mc^2 \sqrt{1 - \frac{v^2}{c^2}} + e\varphi - \frac{e}{c} \mathbf{A} \cdot \mathbf{v} = \frac{mc^2}{\sqrt{1 - \frac{v^2}{c^2}}} + e\varphi. \quad (23.14)
 \end{aligned}$$

In order to obtain the Hamiltonian the velocity \mathbf{v} should be expressed in terms of the generalized momentum \mathbf{P} . This is done most simply by means of the equations

$$(H - e\varphi)^2 = \frac{m^2 c^4}{1 - \frac{v^2}{c^2}}, \quad (23.15)$$

$$\frac{m^2 v^2}{1 - \frac{v^2}{c^2}} = \left(\mathbf{P} - \frac{e}{c} \mathbf{A} \right)^2, \quad (23.16)$$

which are obtained by raising (23.14) and (23.11) to the second power. Rewriting (23.16) in the form

$$\frac{m^2 v^2}{1 - \frac{v^2}{c^2}} + m^2 c^2 - m^2 c^2 = \frac{m^2 c^2}{1 - \frac{v^2}{c^2}} - m^2 c^2 = \left(\mathbf{P} - \frac{e}{c} \mathbf{A} \right)^2,$$

and comparing with (23.15), we obtain

$$(H - e\varphi)^2 = m^2 c^4 + \left(\mathbf{P} - \frac{e}{c} \mathbf{A} \right)^2 c^2,$$

or

$$H = \sqrt{m^2 c^4 + \left(\mathbf{P} - \frac{e}{c} \mathbf{A} \right)^2 c^2} + e\varphi. \quad (23.17)$$

As was to be expected from general considerations, the Hamiltonian in an electromagnetic field is, essentially, the same as the Hamiltonian in an electrostatic field: the magnetic field does not change the energy of the particle. In the non-relativistic approximation we obtain from (23.17)

$$H = mc^2 \sqrt{1 + \frac{\left(\mathbf{P} - \frac{e}{c} \mathbf{A}\right)^2}{m^2 c^2}} + e\varphi \approx mc^2 + \frac{\left(\mathbf{P} - \frac{e}{c} \mathbf{A}\right)^2}{2m} + e\varphi. \quad (23.18)$$

The last expression, if the rest energy is not taken into account, is the same as the classical expression for the Hamiltonian of a particle in an electromagnetic field (see (41.4) of Part I).

§ 24. The motion of particles in constant electric and magnetic fields

The simplest case of the motion of relativistic particles is their motion in constant electric and magnetic fields. At the same time, the motion of charged particles in electric and magnetic fields is of very great practical interest. It is sufficient to quote some examples: the investigation of the motion of electrons in such fields made it possible to test to a high degree of accuracy the relativistic expression for momentum; the relativistic formulae determining the law of motion of particles in electric and magnetic fields represent the basis for the design of contemporary nuclear particle accelerators, allowing one to obtain particles of relativistic energies. The investigation of the motion of very fast particles in a Wilson cloud chamber placed in a magnetic field allows the determination of their momentum. The combination of the measurements of the momentum and the energy (carried out, for example, on the basis of the ionization produced by the particles) makes it possible to determine the mass of the particles.

Consider, first of all, the motion of a relativistic particle in an electric field \mathbf{E} which is constant in time and uniform in space. We choose the direction of the vector \mathbf{E} to be the x -axis. According to § 12, the equations of motion are of the form

$$\frac{dp_x}{dt} = eE_x,$$

$$\frac{dp_y}{dt} = \frac{dp_z}{dt} = 0,$$

$$\frac{dE}{dt} = eE_x v_x = eE_x \frac{dx}{dt}.$$

As the first example we shall consider the motion of a charge in a transverse electric field. At the time $t = 0$ let the charge be at the point $x = 0$ and have a momentum $p_x = 0, p_y = p_0, p_z = 0$ and energy

$$E_0 = \sqrt{p_0^2 c^2 + m^2 c^4}.$$

This means that at the initial instant the charge was moving in a direction perpendicular to the field. The integration of the equations for the components of the momentum in the constant electric field is carried out directly and, taking into account the initial conditions, gives

$$p_x = eE_x t, \quad p_y = p_0, \quad p_z = 0. \quad (24.1)$$

The equation for the energy is also integrated directly:

$$E = eE_x x + E_0.$$

On the other hand,

$$\begin{aligned} E &= \sqrt{(p_x^2 + p_y^2 + p_z^2)c^2 + m^2 c^4} = \\ &= \sqrt{[(eE_x t)^2 + p_0^2]c^2 + m^2 c^4} = \sqrt{(ecE_x t)^2 + E_0^2}. \end{aligned}$$

Comparing the two expressions for the energy, we can write

$$\sqrt{(ecE_x t)^2 + E_0^2} = eE_x x + E_0. \quad (24.2)$$

Formulae (24.1) show that the motion is planar and takes place in the (xy) -plane. In order to find the trajectory one can write the relation

$$\frac{p_x}{p_y} = \frac{mv_x}{\sqrt{1-v^2/c^2}} \frac{\sqrt{1-v^2/c^2}}{mv_y} = \frac{v_x}{v_y} = \frac{dx}{dy}. \quad (24.3)$$

Substituting the value of p_x/p_y from (24.1) into (24.3), we obtain

$$\frac{dx}{dy} = \frac{eE_x t}{p_0}. \quad (24.4)$$

To eliminate the time we make use of formula (24.2), which gives

$$t = \frac{\sqrt{(eE_x x + E_0)^2 - E_0^2}}{ecE_x}.$$

Substituting this expression into (24.4), we arrive at the differential equation for the trajectory:

$$\frac{dx}{dy} = \frac{\sqrt{(eE_x x + E_0)^2 - E_0^2}}{cp_0}.$$

Integration gives the equation of the trajectory

$$\frac{y}{cp_0} = \int \frac{dx}{\sqrt{(eE_x x + E_0)^2 - E_0^2}} = \frac{1}{eE_x} \operatorname{arccosh} \frac{eE_x x}{E_0},$$

or

$$x = \frac{E_0}{eE_x} \cosh \frac{eE_x y}{cp_0}. \quad (24.5)$$

Eq. (24.5) shows that in the transverse electric field the charge moves on a catenary. For $v \ll c$ we can write

$$E_0 \approx mc^2, \quad p_0 \approx mv_0 \quad \text{and} \quad x \approx \frac{mc^2}{eE_x} \cosh \frac{eE_x y}{mv_0 c}. \quad (24.6)$$

If the argument of the hyperbolic cosine, containing c in the denominator, is small, then, expanding (24.6) into a series we arrive at the classical formula for the trajectory, which we have already found earlier (see § 39 of Part I).

The second important case is the motion of a charge in the direction of the electric field, i.e. the case of the initial conditions

$$p_x^{(0)} = 0, \quad p_y^{(0)} = 0, \quad p_z^{(0)} = 0, \quad E^{(0)} = mc^2.$$

In this case the field will be considered to be constant in time, but varying arbitrarily in space along the x -axis.

The integration of the equations for the components of the momentum gives

$$p_x = eE_x(x)t, \quad p_y = 0, \quad p_z = 0. \quad (24.7)$$

We write the equation for the energy in the form

$$\frac{dE}{dt} = -e \frac{d\varphi}{dx} \frac{dx}{dt} = -e \frac{d\varphi}{dt},$$

where φ is the electrostatic potential. Whence we find the integral of the energy:

$$E + e\varphi = \text{const} = mc^2 + e\varphi_0,$$

or

$$\Delta E = mc^2 \left[\frac{1}{\sqrt{1 - \frac{v^2}{c^2}}} - 1 \right] = eV, \quad (24.8)$$

where V is the difference of potential through which the particle has passed, and ΔE is the corresponding change in the energy. The velocity of the particle which has passed through the difference of potential V is equal to

$$v = \sqrt{\frac{2eV}{m} \frac{1 + \frac{e}{m} \frac{V}{2c^2}}{\left(1 + \frac{e}{m} \frac{V}{c^2}\right)^2}}. \quad (24.9)$$

This expression is used in practice for the calculation of the velocity of a particle accelerated by an electric field (fig. II.9).

For $eV/mc^2 \ll 1$ formula (24.9) reduces to the classical expression (39.1) of Part I. On the contrary, for $eV/mc^2 \gg 1$ the velocity of the particle tends to a constant limit $v \rightarrow c$ as the potential increases.

If the field is uniform in space, then the dependence of the velocity and coordinate on time is obtained directly from (24.7). Namely, from (24.7) we have

Fig. 11.9

$$v = \frac{c \left(\frac{eE_x t}{mc} \right)}{\sqrt{1 + \left(\frac{eE_x t}{mc} \right)^2}}. \quad (24.10)$$

Formula (24.10) gives the law of uniformly-accelerated motion in relativistic mechanics. A uniformly accelerated motion in the theory of relativity is understood to be the following: Let us introduce a number of inertial reference frames K'_1, K'_2, K'_3, \dots , moving with velocities equal to those of the motion of the particle at different instants. Each of the reference frames K' is called a frame instantaneously accompanying the particle. In such a reference frame accompanying the particle its velocity is equal to zero for an instant.

Hence, according to (11.12) and (11.16), the components of the 4-acceleration in K' are equal to

$$w'_x = \dot{v}'_x = \dot{v} = \frac{eE_x}{m}, \quad w'_\tau = 0.$$

By virtue of (11.1) and (11.13), we have in a reference frame at rest

$$w_x = \frac{w'_x}{\sqrt{1 - \frac{v^2}{c^2}}} = \frac{eE_x}{m \sqrt{1 - \frac{v^2}{c^2}}} = \frac{\dot{v}}{1 - \frac{v^2}{c^2}} + \frac{v^2 \dot{v}}{c^2 \left(1 - \frac{v^2}{c^2} \right)^2}.$$

Whence we find the quantity \dot{v} , which we shall call the acceleration:

$$\dot{v} = \frac{eE_x}{m} \left(1 - \frac{v^2}{c^2}\right)^{3/2}. \quad (24.11)$$

Integrating (24.11) we again arrive at formula (24.10). Integrating (24.10) we obtain the law for motion

$$x - x_0 = \frac{mc^2}{eE_x} \sqrt{1 + \left(\frac{eE_x}{mc} t\right)^2}. \quad (24.12)$$

This is the equation of a hyperbola. Hence in relativistic mechanics the motion in a constant field is often called hyperbolic, as distinct from the parabolic trajectory of classical mechanics.

Finally, consider the motion of a particle in a constant and uniform magnetic field \mathbf{H} . We choose the direction of the latter to be the z -axis. Then the equations of motion take the form

$$\frac{dp_x}{dt} = \frac{e}{c} v_y H, \quad \frac{dp_y}{dt} = -\frac{e}{c} v_x H, \quad \frac{dp_z}{dt} = 0, \quad \frac{dE}{dt} = 0. \quad (24.13)$$

Integrating the equation for energy, we have

$$E = \text{const} = E_0.$$

By means of (13.2) we obtain

$$\frac{dp_x}{dt} = \frac{d}{dt} \left(\frac{E}{c^2} v_x \right) = \frac{E_0}{c^2} \frac{dv_x}{dt}, \quad \frac{dp_y}{dt} = \frac{E_0}{c^2} \frac{dv_y}{dt}.$$

Hence the equations for the x and y components of the momentum can be written in the form

$$\begin{aligned} \frac{1}{v_y} \frac{dv_x}{dt} &= \frac{ecH}{E_0}, \\ \frac{1}{v_x} \frac{dv_y}{dt} &= -\frac{ecH}{E_0}. \end{aligned} \quad (24.14)$$

Eqs. (24.14) can be satisfied by setting

$$v_x = a \cos(\omega t + \alpha), \quad v_y = -a \sin(\omega t + \alpha). \quad (24.15)$$

For ω we find

$$\omega = \frac{ecH}{E_0}. \quad (24.16)$$

From (24.15)

$$v_x^2 + v_y^2 = a^2 = (v_{\perp})^2 = (v_{\perp})_0^2 = \text{const.}$$

The quantity $(v_{\perp})_0$, which represents the initial velocity of motion of a particle in the (xy) -plane, remains constant in time.

The second integration leads to the equation of the trajectory in the (xy) -plane

$$x = x_0 + \frac{(v_{\perp})_0}{\omega} \sin(\omega t + \alpha), \quad y = y_0 + \frac{(v_{\perp})_0}{\omega} \cos(\omega t + \alpha).$$

The particle moves with a constant velocity along the z -axis, as is seen from (24.13):

$$z = z_0 + (v_z)_0 t.$$

If, in particular, at the initial instant the charge had no velocity along the z -axis, i.e. $(v_z)_0 = 0$, then its trajectory represents a circle in the plane (xy) the radius of which is equal to

$$R = \frac{(v_{\perp})_0}{\omega} = \frac{(v_{\perp})_0 E_0}{ecH} = \frac{cp_0}{eH}, \quad (24.17)$$

where p_0 is the initial momentum.

The frequency ω of rotation in the circle is proportional to the strength of the magnetic field and depends on the energy E_0 which remains constant during the motion. At small energies

$$E_0 \approx mc^2 \quad \text{and} \quad \omega \approx eH/mc, \quad (24.18)$$

i.e. ω reduces to the cyclotron frequency determined in §39 of Part I, which does not depend on the energy of the particle.

Formulae (24.16) and (24.17) are of very great importance in contemporary nuclear physics and technology.

The measurement of the deflection of particles in a magnetic field allows one to find their momentum by means of formula (24.17).

Formula (24.16) is the basis for the design of contemporary cyclotrons, which allow one to obtain heavy particles (protons, deuterons and α -particles) with relativistic velocities.

As is well known, in the cyclotron particles move in circles in a magnetic field between two dees to which an alternating voltage is applied. Particles pass through the gap between the dees in an accelerating electric field. Thus, after describing a semicircle with a constant velocity the particle is accelerated and describes the next semicircle with a new value of the velocity, and so on. For continuous acceleration the field in the accelerating gap must be in a definite phase at the instant when the particle enters it. So long as the particles do not acquire relativistic velocities the frequency of the electric field applied to the dees is determined by formula (24.18) and does not depend on the energy of the particle. If, however, the velocity of the particles attains relativistic values, then, according to (24.16), the frequency of their rotation turns out to vary with energy. Hence, for a further acceleration of the particles, it is necessary to change the frequency of the accelerating field in correspondence with formula (24.16). Cyclotrons operating in this varying frequency mode are called relativistic cyclotrons or synchrotrons.

The design of synchrotrons was first suggested in 1944 by V.I. Veksler, who showed that owing to the particular properties of the motion of charged particles (the so-called phase stability), the synchrotron accelerates particles arriving at the accelerator chamber with different initial phases of motion.

The acceleration of light particles — e.g. electrons — takes place in the relativistic mode at relatively small energies.

One of the most important types of accelerators is the induction accelerator or the betatron. In the betatron electrons move in a magnetic field with axial symmetry between the poles of an electromagnet. If the magnetic field were constant in time, then the motion of an electron with constant velocity would take place on a circle of radius R given by formula (24.17). In the betatron, however, the strength of the magnetic field varies in time. For concreteness we shall assume that the strength of the magnetic field increases in time. This variation of the strength of the magnetic field entails:

- 1) The appearance of an induced electric field with a strength E determined by the formula

$$\oint \mathbf{E} \, d\mathbf{l} = -\frac{1}{c} \frac{\partial}{\partial t} \int \mathbf{H} \cdot d\mathbf{S},$$

or

$$E_{\varphi} = -\frac{1}{2\pi R c} \frac{d\Phi}{dt},$$

where $\Phi = \int \mathbf{H} \cdot d\mathbf{S}$ is the flux of induction through the area of a circular orbit of radius R . It is clear that, because of the axial symmetry of the magnetic field, the electric field is directed along a tangent to the circle of radius R . Consequently, the electron will be acted upon by a force $(-eE_{\varphi})$, which is also directed along a tangent to this circle. According to (24.17), the increase in the momentum of the electron will correspond to an increase in the radius of the orbit, i.e. to a tendency of the electron to move outwards on a spiral.

2) A decrease in the radius of the circle in (24.17) as the strength \mathbf{H} increases. This corresponds to a tendency of the electron to move inwards on a spiral.

If the rate of change of \mathbf{H} in time (and, as will be seen from what follows, in space) is chosen in such a way that the two tendencies exactly compensate each other, the electron will move on a circle of constant radius R with increasing momentum. This is the so-called betatron mode of the motion of a particle.

We now consider the conditions under which such a mode will occur.

The change of the momentum of the electron can be written in the form

$$\frac{dp}{dt} = -eE_{\varphi} = \frac{e}{2\pi c R} \frac{d\Phi}{dt}. \quad (24.19)$$

If it is assumed that the electron moves on a circle of constant radius, then on integrating (24.19) we obtain

$$p = \frac{e}{2\pi c R} \Phi.$$

The integration constant is set equal to zero under the assumption that the conditions $H = 0$ and $v = 0$ hold at the instant $t = 0$.

If p is substituted into (24.17), then the condition of constancy of the radius of the orbit in time can be written in the form

$$R = \frac{cp}{eH} = \frac{1}{2\pi} \frac{\Phi}{RH}. \quad (24.20)$$

The flux of magnetic induction through the area of the orbit is equal to

$$\Phi = \pi R^2 \bar{H},$$

where \bar{H} is the mean field inside the orbit.

Then the condition (24.20) reduces to the equality

$$H_{r=R} = \frac{1}{2} \bar{H}.$$

This indicates that for the motion of an accelerated electron on a circular orbit it is necessary to produce a magnetic field not only varying in time but also non-uniform in space. The field on the orbit must be equal to one half of the mean strength inside the orbit. For this requirement to be fulfilled the field must decrease with increasing radius r . It is clear that the acceleration of particles in the betatron is of intermittent character — it takes place only when the magnetic field increases in time. We cannot consider here the problems of the stability of the motion of particles in a betatron orbit and the details of the design of actual accelerators. *

§25. A system of weakly interacting charged particles

We can now return to a system of particles in relativistic mechanics and consider the case mentioned in §15: that of particles connected by the electromagnetic interaction. **

We have already shown that a potential energy of interaction cannot be introduced for a system of interacting particles, since the retarded interaction depends not on the relative position of the particles at a given instant but on their motion during the preceding time. Moreover, in an accelerated motion charged particles emit radiation and a part of the energy leaves the system, so that the system as a whole is non-conservative.

However, it turns out that if the motion of the particles is sufficiently slow, so that $v \ll c$, then to a certain approximation one can introduce the

* See, for example: A.P.Grünberg, *Metody uskoreniya zaryazhonykh chastits (Methods of accelerating charged particles)* (Gostekhizdat, Moscow, 1960); M.S.Livingston and J.P.Blewett, *Particle accelerators* (McGraw-Hill, New York, 1962).

** V.A.Foek, *The theory of space, time and gravitation* (Pergamon, London, 1964); L.D.Landau and E.M.Lifshitz, *The classical theory of fields* (Pergamon, London, 1962).

notion of the interaction of a system of charges which depends only on their mutual separations. This allows one to characterize the state of a system of moving charges by means of mechanical quantities and to consider the motion of the system, according to the laws of mechanics without a direct connection with the state of the electromagnetic field.

Indeed, if the charges are moving with small velocities, so that the retardation can be completely disregarded, then their energy of interaction is expressed by the formula of electrostatics:

$$U = \sum_{i < k} \frac{e_i e_k}{r_{ik}}, \quad (25.1)$$

where r_{ik} is the fixed distance between the charges i and k . For an arbitrarily chosen k th charge the Lagrangian can be written in the form

$$L_k = \frac{1}{2} m_k v_k^2 - e_k \varphi_k, \quad (25.2)$$

where φ_k is the potential of the field acting on the charge k .

The Lagrangian of a system of charges is obtained by a simple summation:

$$L = \sum_k L_k = \sum_k \left(\frac{1}{2} m_k v_k^2 - e_k \varphi_k \right). \quad (25.3)$$

Knowing the Lagrangian, one can find the equations of motion of the system.

Further calculations will show also that in successive approximations of the expansion in powers of the ratio v/c , up to terms of the order of v^2/c^2 , the Lagrangian of the system can be found. This will also allow us to carry out the programme of a purely mechanical description of a system of charges previously mentioned.

At the same time it is clear that, if terms of the order of $(v/c)^3$ are not discarded, then such a description will, generally speaking, become impossible. Indeed, according to the results of § 27 of Part I, the dipole radiation of a system is determined by a quantity of the order of $1/c^3$. The retention of the higher terms of the expansion of potentials corresponds to taking account of the dipole radiation. This makes the mechanical approach to the treatment of the state of the system illegitimate.

In systems in which there is no dipole radiation the expansion of the potentials can be carried out up to terms of a low order of magnitude as follows. We write the Lagrangian of the k th particle taking into account the motion of the charges in the system (see eq. 23.10):

$$L_k = -m_k c^2 \sqrt{1 - \frac{v_k^2}{c^2}} - e_k \varphi_k + \frac{e_k}{c} (\mathbf{v}_k \cdot \mathbf{A}_k), \quad (25.4)$$

where φ_k and \mathbf{A}_k are the potentials of the field at that point where the k th charge is located. These potentials, taking into account the finiteness of the velocity of propagation of interaction, can be written in the form of retarded potentials (see §24 of Part I):

$$\varphi(\mathbf{r}_k, t) = \int \frac{\rho\left(\mathbf{r}', t - \frac{|\mathbf{r}_k - \mathbf{r}'|}{c}\right)}{|\mathbf{r}_k - \mathbf{r}'|} dV',$$

$$\mathbf{A}(\mathbf{r}_k, t) = \frac{1}{c} \int \frac{\mathbf{j}\left(\mathbf{r}', t - \frac{|\mathbf{r}_k - \mathbf{r}'|}{c}\right)}{|\mathbf{r}_k - \mathbf{r}'|} dV'.$$

For a slow motion ($v \ll c$) the charge density and current density can be expanded in a series of powers of the delay time. An important difference of this expansion from the analogous formulae of §26 of Part I lies in the fact that we are interested in potentials at a point \mathbf{r}_k located within the limits of the system of charges considered. Hence the total delay time cannot be resolved into the proper retardation and the retardation of the system, and the expansion must be carried out with respect to the total retardation:

$$\tau = \frac{|\mathbf{r}_k - \mathbf{r}|}{c}.$$

We then have

$$\begin{aligned} \rho\left(\mathbf{r}', t - \frac{|\mathbf{r}_k - \mathbf{r}'|}{c}\right) &\approx \rho(\mathbf{r}', t) - \frac{|\mathbf{r}_k - \mathbf{r}'|}{c} \frac{\partial}{\partial t} \rho(\mathbf{r}', t) + \\ &+ \frac{1}{2} \frac{|\mathbf{r}_k - \mathbf{r}'|^2}{c^2} \frac{\partial^2}{\partial t^2} \rho(\mathbf{r}', t), \\ \mathbf{j}\left(\mathbf{r}', t - \frac{|\mathbf{r}_k - \mathbf{r}'|}{c}\right) &= \mathbf{j}(\mathbf{r}', t) + O(1/c). \end{aligned}$$

Terms $O(1/c)$ are neglected because of the factors $1/c$ in $\mathbf{A}(\mathbf{r}_k, t)$ above and in eq. (25.4). Hence

$$\begin{aligned}
 \varphi(\mathbf{r}_k, t) &\approx \int \frac{\rho(\mathbf{r}', t)}{|\mathbf{r}_k - \mathbf{r}'|} dV' - \frac{1}{c} \int \frac{\partial \rho(\mathbf{r}', t)}{\partial t} dV' + \\
 &\quad + \frac{1}{2c^2} \int |\mathbf{r}_k - \mathbf{r}'| \frac{\partial^2 \rho(\mathbf{r}', t)}{\partial t^2} dV' = \\
 &\int \frac{\rho(\mathbf{r}', t)}{|\mathbf{r}_k - \mathbf{r}'|} dV' - \frac{1}{c} \frac{\partial}{\partial t} \int \rho(\mathbf{r}', t) dV' + \frac{1}{2c^2} \frac{\partial^2}{\partial t^2} \int |\mathbf{r}_k - \mathbf{r}'| \rho(\mathbf{r}', t) dV'.
 \end{aligned}$$

The order of the differentiation and integration can be changed, since the vector \mathbf{r}_k is fixed, and \mathbf{r}' is a set of three independent variables.

Since the integral in the second term is taken at a time t , it represents the total charge of the system. Correspondingly,

$$\frac{\partial}{\partial t} \int \rho(\mathbf{r}', t) dV' = \frac{\partial e}{\partial t} = 0.$$

Finally, we find

$$\varphi(\mathbf{r}_k, t) = \int \frac{\rho(\mathbf{r}', t)}{|\mathbf{r}_k - \mathbf{r}'|} dV' + \frac{1}{2c^2} \frac{\partial^2}{\partial t^2} \int |\mathbf{r}_k - \mathbf{r}'| \rho(\mathbf{r}', t) dV' \quad (25.5)$$

$$\mathbf{A}(\mathbf{r}_k, t) = \frac{1}{c} \int \frac{\mathbf{j}(\mathbf{r}', t)}{|\mathbf{r}_k - \mathbf{r}'|} dV' \quad (25.6)$$

Further calculations become clearer if one considers point charges. Let

$$\rho(\mathbf{r}', t) = \sum_i' e_i \delta(\mathbf{r}' - \mathbf{r}_i(t)). \quad (25.7)$$

The prime on the summation sign indicates that in the sum the term $i = k$ is absent since we do not take into account the field due to the k th charge itself. In what follows we shall omit the prime on the sum so as not to encumber the formulae, but shall imply it in all summations over charges.

Substituting the expression (25.7) for $\rho(\mathbf{r}', t)$ into (25.5), we have

$$\begin{aligned}
\varphi(\mathbf{r}_k, t) &= \sum \varphi_i = \\
&= \sum \frac{e_i}{|\mathbf{r}_k - \mathbf{r}_i(t)|} + \frac{1}{2c^2} \frac{\partial^2}{\partial t^2} \sum e_i |\mathbf{r}_k - \mathbf{r}_i(t)| = \\
&= \sum \frac{e_i}{|\mathbf{r}_k - \mathbf{r}_i(t)|} + \frac{1}{2c^2} \sum e_i \frac{\partial^2}{\partial t^2} |\mathbf{r}_k - \mathbf{r}_i(t)|. \quad (25.8)
\end{aligned}$$

We stress that as a result of integration (elimination of the δ -function) the radius vector of the i th charge $\mathbf{r}_i(t)$, depending explicitly on time, appears instead of \mathbf{r}' in the corresponding expressions. Hence the result of integration with respect to the variables \mathbf{r}' must be differentiated with respect to time.

Analogously, assuming

$$\mathbf{j}(\mathbf{r}', t) = \sum_i' e_i \mathbf{v}_i \delta(\mathbf{r}' - \mathbf{r}_i(t)), \quad (25.9)$$

we have from (25.6)

$$\mathbf{A}(\mathbf{r}_k, t) = \sum \mathbf{A}_i = \sum \frac{e_i \mathbf{v}_i}{c |\mathbf{r}_k - \mathbf{r}_i|}. \quad (25.10)$$

Here φ_i and \mathbf{A}_i are the potentials produced at an instant t at a point \mathbf{r}_k by the i th charge.

The expression (25.8) for the scalar potential taking into account the retardation (the second term) contains the second derivative with respect to time of the vector \mathbf{r}_i , i.e. the acceleration of the i th particle producing a field at the point \mathbf{r}_k . However, only the coordinates and velocities of the particles can enter into the Lagrangian. Hence it is advisable to carry out the gauge transformation (see §11 of Part I) and to choose the function ψ in such a way that the second term will be absent in the scalar potential. That is to say, assuming

$$\begin{aligned}
\varphi_i &\rightarrow \varphi_i' + \frac{1}{c} \frac{\partial \psi_i}{\partial t}, \\
\mathbf{A}_i &\rightarrow \mathbf{A}_i' - \nabla \psi_i,
\end{aligned}$$

where, using (I.12'),

$$\begin{aligned}
 \psi_i &= \frac{e_i}{2c} \frac{\partial}{\partial t} |\mathbf{r}_k - \mathbf{r}_i(t)| = \frac{e_i}{2c} \nabla_{\mathbf{r}_i} |\mathbf{r}_k - \mathbf{r}_i| \cdot \frac{\partial \mathbf{r}_i}{\partial t} = \\
 &= \frac{e_i}{2c} \left\{ -\frac{(\mathbf{r}_k - \mathbf{r}_i)}{|\mathbf{r}_k - \mathbf{r}_i|} \right\} \frac{\partial \mathbf{r}_i}{\partial t} = -\frac{e_i}{2c} \frac{(\mathbf{r}_k - \mathbf{r}_i) \cdot \mathbf{v}_i}{|\mathbf{r}_k - \mathbf{r}_i|}, \quad (25.11)
 \end{aligned}$$

we find from (25.5)

$$\varphi' = \sum \varphi'_i = \sum_i \frac{e_i}{|\mathbf{r}_k - \mathbf{r}_i|}. \quad (25.12)$$

In differentiating with respect to time, the position of the observation point \mathbf{r}_k is fixed, the gradient is directed from the charge i to the observation point, and \mathbf{v}_i denotes the velocity of motion of the i th charge at an instant t .

Correspondingly, for A' we obtain

$$A'_i = A_i + \nabla_{\mathbf{r}_k} \psi_i = \sum_i \frac{e_i \mathbf{v}_i}{c |\mathbf{r}_k - \mathbf{r}_i|} - \nabla \frac{e_i}{2c} \frac{(\mathbf{r}_k - \mathbf{r}_i) \cdot \mathbf{v}_i}{|\mathbf{r}_k - \mathbf{r}_i|} \quad (25.13)$$

According to the formula

$$\nabla_{\mathbf{r}_k} \frac{(\mathbf{r}_k - \mathbf{r}_i) \cdot \mathbf{a}}{|\mathbf{r}_k - \mathbf{r}_i|} = \frac{\mathbf{a}}{|\mathbf{r}_k - \mathbf{r}_i|} - \frac{(\mathbf{r}_k - \mathbf{r}_i) \cdot \mathbf{a}}{|\mathbf{r}_k - \mathbf{r}_i|^3} (\mathbf{r}_k - \mathbf{r}_i),$$

where \mathbf{a} is a constant vector, we find

$$\nabla_{\mathbf{r}_k} \frac{(\mathbf{r}_k - \mathbf{r}_i) \cdot \mathbf{v}_i}{|\mathbf{r}_k - \mathbf{r}_i|} = \frac{\mathbf{v}_i}{|\mathbf{r}_k - \mathbf{r}_i|} - \frac{(\mathbf{r}_k - \mathbf{r}_i) \cdot \mathbf{v}_i}{|\mathbf{r}_k - \mathbf{r}_i|^3} (\mathbf{r}_k - \mathbf{r}_i).$$

Hence for the total vector potential we obtain

$$A'(\mathbf{r}_k, t) = \sum A'_i = \sum_i \left(\frac{e_i \mathbf{v}_i}{2c |\mathbf{r}_k - \mathbf{r}_i|} + \frac{e_i}{2c} \frac{(\mathbf{r}_k - \mathbf{r}_i) \cdot \mathbf{v}_i}{|\mathbf{r}_k - \mathbf{r}_i|^3} (\mathbf{r}_k - \mathbf{r}_i) \right). \quad (25.14)$$

The expression (25.12) and (25.14) which have been found for φ' and A' must be substituted into the Lagrangian (25.4) of the k th particle. One must first expand the first term in it in a series in powers of v^2/c^2 and retain terms of the same low order of magnitude as the terms retained in φ' and A' . This gives

$$m_k c^2 \sqrt{1 - \frac{v_k^2}{c^2}} \approx m_k c^2 \left(1 - \frac{v_k^2}{2c^2} - \frac{1}{8} \frac{v_k^4}{c^4} \right). \quad (25.15)$$

As a result we find

$$\begin{aligned} L_k &= -m_k c^2 + \frac{m_k v_k^2}{2} + \frac{1}{8} \frac{m_k v_k^4}{c^2} - e_k \varphi' + \frac{e_k (\mathbf{v}_k \cdot \mathbf{A}')}{c} = \\ &= -m_k c^2 + \frac{m_k v_k^2}{2} + \frac{1}{8} \frac{m_k v_k^4}{c^2} - \sum_i \left\{ \frac{e_i e_k}{|\mathbf{r}_k - \mathbf{r}_i|} - \right. \\ &\quad \left. - \frac{1}{2c^2} \frac{e_i e_k \mathbf{v}_i \cdot \mathbf{v}_k}{|\mathbf{r}_k - \mathbf{r}_i|} - \frac{e_i e_k [(\mathbf{r}_k - \mathbf{r}_i) \cdot \mathbf{v}_i] [(\mathbf{r}_k - \mathbf{r}_i) \cdot \mathbf{v}_k]}{2c^2 |\mathbf{r}_k - \mathbf{r}_i|^3} \right\}. \end{aligned} \quad (25.16)$$

The first term of the Lagrangian L_k refers to the particle at rest, the second term has the meaning of the kinetic energy in the approximation of classical mechanics, and the third term has the meaning of the relativistic correction to the kinetic energy. The term in the brackets depends only on the instantaneous positions and velocities of the particles.

The quantity

$$U_{ik} = \frac{e_i e_k}{|\mathbf{r}_k - \mathbf{r}_i|} - \frac{1}{2c^2} \frac{e_i e_k \mathbf{v}_i \cdot \mathbf{v}_k}{|\mathbf{r}_k - \mathbf{r}_i|} - \frac{e_i e_k [(\mathbf{r}_k - \mathbf{r}_i) \cdot \mathbf{v}_i] [(\mathbf{r}_k - \mathbf{r}_i) \cdot \mathbf{v}_k]}{2c^2 |\mathbf{r}_k - \mathbf{r}_i|^3}, \quad (25.17)$$

depending on the distance between the i th and k th particle at a given instant can be considered as the generalized energy of interaction between the particles. The first term has an obvious meaning: it is the potential energy of interaction between two charges, the i th one and the k th one, at rest. The other two terms, proportional to $\mathbf{v}_i \cdot \mathbf{v}_k / c^2$, represent the correction to the energy of interaction taking into account the motion of the charges and the retardation. However, it is clear that, although U_{ik} is the energy of interaction, it does not have the meaning of a potential energy depending only on the position of the particles.

The expression (25.17) is completely symmetrical in the two charges. Hence it is easy to write the Lagrangian for a system of particles. Namely,

$$L = \sum_k \left\{ -m_k c^2 + \frac{m_k v_k^2}{2} + \frac{m_k v_k^4}{8c^2} \right\} - \sum_{k>i} \left\{ \frac{e_i e_k}{|\mathbf{r}_k - \mathbf{r}_i|} - \frac{e_i e_k}{2c^2} \frac{\mathbf{v}_i \cdot \mathbf{v}_k}{|\mathbf{r}_k - \mathbf{r}_i|} - \frac{e_i e_k}{2c^2} \frac{[(\mathbf{r}_k - \mathbf{r}_i) \cdot \mathbf{v}_i][(\mathbf{r}_k - \mathbf{r}_i) \cdot \mathbf{v}_k]}{|\mathbf{r}_k - \mathbf{r}_i|^3} \right\} = L_1 + L_2, \quad (25.18)$$

where L_1 is the Lagrangian of a system of charges when relativistic corrections and the retardation are disregarded, given by formula (25.3), and L_2 is an addition to it, found with an accuracy up to terms of order less than $(v/c)^3$:

$$L_2 = \frac{1}{4c^2} \left\{ \sum_k \frac{m_k v_k^4}{2} + 2 \sum_{k>i} e_i e_k \left[\frac{\mathbf{v}_i \cdot \mathbf{v}_k}{|\mathbf{r}_k - \mathbf{r}_i|} + \frac{[(\mathbf{r}_k - \mathbf{r}_i) \cdot \mathbf{v}_i][(\mathbf{r}_k - \mathbf{r}_i) \cdot \mathbf{v}_k]}{|\mathbf{r}_k - \mathbf{r}_i|^3} \right] \right\} \quad (25.19)$$

Knowing the Lagrangian, one can find the energy, mass and momentum of the system.

The energy of the system is found according to the usual rules and is equal to

$$E_{\text{tot}} = \sum_k \mathbf{v}_k \cdot \frac{\partial L}{\partial \mathbf{v}_k} - L = E_0 + E_1 + E_2, \quad (25.20)$$

where

$$E_0 = \sum_k m_k c^2, \quad E_1 = \frac{1}{2} \sum_k m_k v_k^2 + \sum_{k>i} \frac{e_i e_k}{|\mathbf{r}_k - \mathbf{r}_i|},$$

and E_2 is the relativistic correction to the energy, which is equal to

$$E_2 = \frac{3}{8} \sum_k \frac{m_k v_k^4}{c^2} + \frac{1}{2c^2} \left\{ \sum_{k>i} e_i e_k \left[\frac{\mathbf{v}_i \cdot \mathbf{v}_k}{|\mathbf{r}_k - \mathbf{r}_i|} + \frac{[(\mathbf{r}_k - \mathbf{r}_i) \cdot \mathbf{v}_i][(\mathbf{r}_k - \mathbf{r}_i) \cdot \mathbf{v}_k]}{|\mathbf{r}_k - \mathbf{r}_i|^3} \right] \right\} \quad (25.21)$$

We see, first of all, that the energy of the system cannot be written in the form of a sum of the kinetic and potential energies. The relativistic correc-

tion to the energy E_2 depends both on the coordinates and on the velocities, so that taking account of this correction a potential energy for the system does not exist. Only for charges at rest or, more precisely, charges moving so slowly that quantities of the order of v^2/c^2 can completely be disregarded, can the quantity E_2 be discarded and use be made of the potential energy (25.1).

With the usual definition of mass, we find the mass of the system

$$M = \frac{E_{\text{tot}}}{c^2} = \sum_k m_k + \frac{E_1 + E_2}{c^2}. \quad (25.22)$$

Thus, the mass of the system is made up of the rest masses of the particles and the masses due to the kinetic energy of interaction of the particles of the system (in the approximation of charges at rest — the potential energy). The mass M obviously possesses no additive properties and is not equal to the sum of the masses of individual particles. The energy E of the system and its mass M are conserved. However, a conservation law cannot be written for individual terms entering into E_{tot} and M .

The momentum \mathbf{P} of the system is by definition equal to

$$\mathbf{P} = \sum_k \frac{\partial L_k}{\partial \mathbf{v}_k} = \mathbf{P}_1 + \mathbf{P}_2, \quad (25.23)$$

where $\mathbf{P}_1 = \sum_k m_k \mathbf{v}_k$ is the usual value of the momentum in classical mechanics and \mathbf{P}_2 is the relativistic correction to it:

$$\begin{aligned} \mathbf{P}_2 = & \frac{1}{2c^2} \sum m_k v_k^2 \mathbf{v}_k + \frac{1}{2c^2} \sum_{k>i} e_i e_k \left[\frac{\mathbf{v}_i}{|\mathbf{r}_k - \mathbf{r}_i|} + \right. \\ & \left. + \frac{(\mathbf{r}_k - \mathbf{r}_i) \cdot \mathbf{v}_i}{|\mathbf{r}_k - \mathbf{r}_i|^3} (\mathbf{r}_k - \mathbf{r}_i) \right]. \end{aligned} \quad (25.24)$$

We see that the correction \mathbf{P}_2 to the momentum depends on the coordinates of the particles of the system.

It is easy to show that in the approximation considered one can introduce the notion of the centre of mass of the system, which does not exist in an arbitrary system of interacting particles. From the definition of the velocity of the centre of mass (15.16) $\mathbf{V}_{\text{c.m.}} = c^2 \mathbf{P} / E_{\text{tot}}$ it can be seen that the vector $\mathbf{V}_{\text{c.m.}}$ can be written in the form of the derivative of the radius vector of the

centre of mass with respect to time:

$$\mathbf{R}_{\text{c.m.}} \approx \frac{\sum_k \left(m_k c^2 + \frac{1}{2} m_k v_k^2 + e_k \sum_i' \frac{e_i}{|\mathbf{r}_k - \mathbf{r}_i|} \right) \mathbf{r}_k}{E_0 + E_1}. \quad (25.25)$$

One can convince oneself of this by a direct verification of the equality

$$\mathbf{V}_{\text{c.m.}} = \frac{d\mathbf{R}_{\text{c.m.}}}{dt} = \frac{\mathbf{P}c^2}{E_{\text{tot}}},$$

which is valid with an accuracy up to quantities of the order of v^2/c^2 .

In addition to the energy and momentum, a system of material points possesses angular momentum

$$\mathbf{L} = \sum_k \mathbf{r}_k \times \frac{\partial \mathbf{L}}{\partial \mathbf{v}_k} = \mathbf{L}_0 + \mathbf{L}_1, \quad (25.26)$$

where \mathbf{L}_0 is the angular momentum of classical mechanics, and \mathbf{L}_1 is the relativistic correction depending on the velocities and coordinates of all points of the system.

We see that in this approximation (taking account of the corrections v^2/c^2) in the relativistic mechanics of the system one can introduce the same basic notions as in classical mechanics. However, in this approximation also the system possesses no potential energy.

Thus, in addition to the case of a system of particles interacting via collisions as discussed in § 15, one can construct the general mechanics of a system of interacting charged particles in the theory of relativity. However, in this case the theory has an approximate character and the highest terms retained in it are of the order of v^2/c^2 . The account of subsequent terms of the expansion in powers of (v/c) is possible only on concrete systems possessing no dipole radiation (the terms $(v/c)^3$), no quadrupole radiation $((v/c)^4)$ and so on.

In what follows we shall need another representation of the energy of interaction in the case where the system consists of two particles. Writing the Lagrangian of the first particle in the form

$$L_1 = -m_1 c^2 \sqrt{1 - \frac{v_1^2}{c^2}} - e_1 \varphi_1 + \frac{e_1}{c} (\mathbf{v}_1 \cdot \mathbf{A}_1),$$

we shall consider φ_1 and A_1 to be the potentials of the field produced by the second particle at the point where the first particle is located at an instant t . Taking account of the retardation and for an arbitrary law of motion the potentials φ_1 and A_1 represent Liénard-Wiechert potentials. The Liénard-Wiechert potentials φ_1 and A_1 are related by formula (25.5) of Part I:

$$A_1 = \frac{\mathbf{v}_2 \varphi_1}{c}.$$

Hence

$$L_1 = -m_1 c^2 \sqrt{1 - \frac{v_1^2}{c^2}} - e \left(1 - \frac{\mathbf{v}_1 \cdot \mathbf{v}_2}{c^2} \right) \varphi_1.$$

Thus it follows that for the energy of interaction of two particles one can write the expression

$$U_{\text{interac}} = e \left(1 - \frac{\mathbf{v}_1 \cdot \mathbf{v}_2}{c^2} \right) \varphi, \quad (25.27)$$

where φ is the field potential depending only on the instantaneous distance $R(\tau)$ between the charges.

§26. The radiation emitted by a moving charge

Formula (28.4) of Part I for the radiation emitted by a moving charge is applicable only at velocities which are small in comparison with the velocity of light. In order to obtain an analogous expression valid at velocities close to the velocity of light, we introduce into the treatment a set of accompanying reference frames in one of which the particle is at rest at each instant. In every one of these reference frames the formula (28.4) of Part I for the radiation is valid. The radiation described by this formula has the character of spherical waves, so that the total momentum of the emitted electromagnetic waves is equal to zero. The energy emitted per unit time by a charge is, according to (22.16), an invariant:

$$-\frac{dE}{dt} = -\frac{dE'}{dt'} = \dots = \text{invar}. \quad (26.1)$$

The rate of loss of energy due to radiation can be written, according to (28.4) of Part I,

$$\frac{dE'}{dt'} = -\frac{2e^2}{3c^3} (w')^2 = -\frac{2e^2}{3c^2} (w'_\alpha)^2, \quad (26.2)$$

since in the accompanying reference frame $w'_\tau = 0$. The rate of loss of momentum due to radiation is, according to (28.5) of Part I, equal to zero:

$$\frac{dp'}{dt'} = 0. \quad (26.3)$$

To find the radiation in an arbitrary (unprimed) reference frame one need only transform the square of the acceleration $(w'_\alpha)^2$ according to formula (11.17) to the acceleration in the unprimed reference frame.

We then have

$$\frac{dE}{dt} = \frac{dE'}{dt'} = -\frac{2e^2}{3c^3} \frac{\dot{v}^2 - \left[\frac{\mathbf{v} \times \dot{\mathbf{v}}}{c} \right]^2}{\left(1 - \frac{v^2}{c^2} \right)^3} = -\frac{2e^2}{3c^3} \frac{\dot{v}^2 \left(1 - \frac{v^2}{c^2} \right) + \frac{1}{c^2} (\mathbf{v} \cdot \dot{\mathbf{v}})^2}{\left(1 - \frac{v^2}{c^2} \right)^3} \quad (26.4)$$

In this case we obtain for the change in the momentum per unit time using (13.6) and (26.4)

$$\frac{d\mathbf{p}}{dt} = \frac{\mathbf{v}}{c^2} \frac{dE'}{dt'} \frac{1}{\sqrt{1 - \frac{v^2}{c^2}}} = -\frac{2e^2}{3c^3} \frac{\dot{v}^2 \left(1 - \frac{v^2}{c^2} \right) + \frac{1}{c^2} (\mathbf{v} \cdot \dot{\mathbf{v}})^2}{\left(1 - \frac{v^2}{c^2} \right)^3} \frac{\mathbf{v}}{c^2} \quad (26.5)$$

It is obvious that for $v/c \ll 1$ formulae (26.4) and (26.5) reduce to (26.2) and (26.3).

Formulae (26.4) and (26.5) allow one to find in an arbitrary reference frame, for example the laboratory system, the energy and momentum of the radiation field produced by a charge with an accelerated motion.

As a rule, an accelerated motion of rapidly moving particles is associated with the action of the electromagnetic field on them. To transform formulae (26.4) and (26.5) in this particular case we make use of the expression (12.14) for the acceleration of a particle in an electromagnetic field. Putting in the value of the Lorentz force, we find

$$\mathbf{w} = \dot{\mathbf{v}} = \frac{e}{m} \sqrt{1 - \frac{v^2}{c^2}} \left\{ \mathbf{E} + \frac{1}{c} \mathbf{v} \times \mathbf{H} - \frac{\mathbf{v}}{c^2} (\mathbf{v} \cdot \mathbf{E}) \right\} \quad (26.6)$$

Making use of this expression for the acceleration, we have

$$\begin{aligned} \dot{v}^2 \left(1 - \frac{v^2}{c^2}\right) + \frac{1}{c^2} (\mathbf{v} \cdot \dot{\mathbf{v}})^2 &= \frac{e^2}{m^2} \left(1 - \frac{v^2}{c^2}\right)^2 \left\{ \left(\mathbf{E} + \frac{1}{c} \mathbf{v} \times \mathbf{H}\right)^2 + \right. \\ &\quad \left. + \frac{v^2}{c^4} (\mathbf{v} \cdot \mathbf{E})^2 - \frac{2(\mathbf{v} \cdot \mathbf{E})^2}{c^2} \right\} + \frac{e^2}{m^2} \left(1 - \frac{v^2}{c^2}\right)^3 \frac{(\mathbf{v} \cdot \mathbf{E})^2}{c^2} = \\ &= \frac{e^2}{m^2} \left(1 - \frac{v^2}{c^2}\right)^2 \left\{ \left(\mathbf{E} + \frac{\mathbf{v} \times \mathbf{H}}{c}\right)^2 - \frac{(\mathbf{v} \cdot \mathbf{E})^2}{c^2} \right\}. \quad (26.7) \end{aligned}$$

The rate of emission of energy by a charge moving in an electromagnetic field is equal to

$$\begin{aligned} \frac{dE}{dt} &= - \frac{2e^4}{3m^2c^3} \frac{\left(\mathbf{E} + \frac{1}{c} \mathbf{v} \times \mathbf{H}\right)^2 - \frac{1}{c^2} (\mathbf{v} \cdot \mathbf{E})^2}{1 - \frac{v^2}{c^2}} = \\ &= - \frac{2e^4}{3m^4c^7} \left[\frac{mc^2}{\sqrt{1 - \frac{v^2}{c^2}}} \right]^2 \left\{ \left(\mathbf{E} + \frac{1}{c} \mathbf{v} \times \mathbf{H}\right)^2 - \frac{1}{c^2} (\mathbf{v} \cdot \mathbf{E})^2 \right\} = \\ &= - \frac{2e^4}{3m^4c^7} E^2 \left\{ \left(\mathbf{E} + \frac{1}{c} \mathbf{v} \times \mathbf{H}\right)^2 - \frac{1}{c^2} (\mathbf{v} \cdot \mathbf{E})^2 \right\}. \quad (26.8) \end{aligned}$$

Consider several cases of formula (26.8) for the ultrarelativistic case $v \approx c$. Let there be an electric field only (i.e. $\mathbf{H} = 0$). Then

$$\frac{1}{E^2} \frac{dE}{dt} = - \frac{2e^4}{3m^4c^7} \left\{ (\mathbf{E})^2 - \frac{(\mathbf{v} \cdot \mathbf{E})^2}{c^2} \right\}. \quad (26.9)$$

For $\mathbf{v} \perp \mathbf{E}$ the rate of energy loss is

$$\frac{dE}{dt} = - \frac{2e^4}{3m^4c^7} (\mathbf{E})^2 E^2 \quad (26.10)$$

For $\mathbf{v} \parallel \mathbf{E}$ the rate of energy loss is

$$\frac{dE}{dt} = -\frac{2e^4 E^2}{3m^4 c^7} (E)^2 \left(1 - \frac{v^2}{c^2}\right) = -\frac{2e^4}{3m^2 c^3} (E)^2, \quad (26.11)$$

and does not depend on the energy.

For the motion in a magnetic field perpendicular to the direction of the velocity ($\mathbf{v} \perp \mathbf{H}$) and $\mathbf{E} = 0$ we find

$$\frac{dE}{dt} = -\frac{2e^4}{3m^2 c^5} \frac{v^2 (\mathbf{H})^2}{1 - \frac{v^2}{c^2}} = -\frac{2e^4}{3m^4 c^5} p^2 (\mathbf{H})^2 \approx -\frac{2e^4}{3m^4 c^7} E^2 (\mathbf{H})^2, \quad (26.12)$$

where p is the momentum of the particle.

Formulae (26.9)–(26.12) are used in nuclear physics for the determination of energy losses by ultrarelativistic particles moving in electric and magnetic fields. The motion of charged particles in cosmic rays in the Earth's magnetic field and in the magnetic field of a betatron are examples of the motion of ultrarelativistic particles in a magnetic field. Calculations have shown that energy losses due to radiation in a magnetic field determine the upper limit of the energy of particles which can reach the Earth's surface, as well as the upper limit of energies to which electrons can be accelerated in a betatron.

An important application of the formulae obtained is in the calculation of the bremsstrahlung of ultrarelativistic particles in the electric field of a nucleus. An ultrarelativistic electron passing by a nucleus undergoes a very small deflection. Its velocity can be assumed to be constant, and the acceleration can be assumed to be perpendicular to the direction of velocity and equal to $w_{\perp} = eE_{\perp}/m$, where

$$E_{\perp} = Ze\rho/r^3$$

is the component of the nuclear field perpendicular to the velocity (we choose the direction of the latter as the x -axis). For the transverse acceleration use can be made of the non-relativistic expression, since the corresponding velocity component is very small. As in §43 in Part I, ρ is the impact parameter, and r is the distance between the nucleus and the electron. For a motion with constant velocity it can be assumed that

$$r = (\rho^2 + v^2 t^2)^{1/2}$$

Formula (26.10) gives for the rate of energy loss

$$\begin{aligned}\frac{dE}{dt} &= -\frac{2e^2}{3m^2c^3} \frac{1}{1-\frac{v^2}{c^2}} (E_{\perp})^2 = \\ &= -\frac{2Z^2e^4}{3m^2c^3} \frac{1}{1-\frac{v^2}{c^2}} \frac{\rho^2}{(\rho^2 + v^2t^2)^3}.\end{aligned}$$

Integrating with respect to the transit time, we obtain the total energy loss due to bremsstrahlung by an ultrarelativistic particle:

$$\Delta E = -\frac{2Z^2e^4}{3m^2c^3} \frac{\rho^2}{\left(1-\frac{v^2}{c^2}\right)} \int_{-\infty}^{\infty} \frac{dt}{(\rho^2 + v^2t^2)^3}.$$

We have, obviously,

$$\int_{-\infty}^{\infty} \frac{dt}{\left(1 + \frac{v^2t^2}{\rho^2}\right)^3} = 2 \int_0^{\infty} \frac{dt}{\left(1 + \frac{v^2}{\rho^2}t^2\right)^3} = 2\frac{\rho}{v} \int_0^{\pi/2} \cos^4 z \, dz = \frac{3}{8} \frac{\pi\rho}{v},$$

Hence

$$\Delta E = -\frac{\pi}{4} \frac{Z^2e^4}{m^2c^3v} \frac{1}{\left(1-\frac{v^2}{c^2}\right)} \frac{1}{\rho^3}. \quad (26.13)$$

The magnitude of the energy loss increases rapidly with increasing atomic number Z of the matter in which the particle is moving. Formula (26.13) determines the energy loss of one particle passing by a nucleus at a distance ρ . It shows that the loss increases rapidly with decreasing ρ .

In practice the particle may pass by the nucleus at any distance. Multiplying (26.13) by $2\pi\rho \, d\rho n$, where n is the density of the beam, and integrating over all values of ρ , we find the effective radiation of a beam of particles:

$$\begin{aligned}
 E_{\text{eff}} &= -\frac{\pi^2}{2} \frac{Z^2 e^4}{m^2 c^3 v} \frac{n}{\left(1 - \frac{v^2}{c^2}\right)} \int_{\rho_{\min}}^{\infty} \frac{d\rho}{\rho^2} = \\
 &= -\frac{\pi^2}{2} \frac{Z^2 e^4}{m^2 c^3 v} \frac{n}{\left(1 - \frac{v^2}{c^2}\right)} \frac{1}{\rho_{\min}}.
 \end{aligned} \tag{26.14}$$

In formula (26.14) the closest distance of approach of the electron to the nucleus, ρ_{\min} , is introduced, since the integral diverges at the lower limit. The introduction of this unknown quantity means that the classical theory of radiation turns out to be inapplicable for the calculation of bremsstrahlung.

In quantum mechanics it will be shown that the classical treatment of the motion of the electron is inapplicable at small distances. A quantum-mechanical calculation leads to the value

$$\rho_{\min} = \frac{h}{mc} \frac{1}{\sqrt{1 - \frac{v^2}{c^2}}},$$

so that

$$E_{\text{eff}} = -\frac{\pi^2}{2} \frac{Z^2 e^4}{mc^2 v h} \frac{1}{\sqrt{1 - \frac{v^2}{c^2}}}. \tag{26.15}$$

Formula (26.15) allows one to find the losses due to bremsstrahlung when very fast particles pass through matter.

The comparison of (26.15) with the formula for energy loss due to ionization shows that bremsstrahlung is the basic factor determining the deceleration of fast electrons in matter. Losses due to the bremsstrahlung are important for electrons at energies of the order of $200 mc^2$ (100 MeV) in air and $20 mc^2$ (10 MeV) in lead. For heavy particles, for example protons, almost all losses are associated with the ionization up to very large energies.

In conclusion it should be noted that one cannot pass directly from formula (26.14) to the non-relativistic formula (43.37) of Part I, assuming $v \ll c$. Formula (26.14) is found for $v \approx c$, and not for the general case of an arbitrary velocity.

Vector Analysis

Assuming that the reader is familiar with vector analysis, we summarize below the basic formulae used in this book.

Vector algebra

$$\mathbf{a} = a_x \mathbf{i} + a_y \mathbf{j} + a_z \mathbf{k} = a_0 \mathbf{a}_0,$$

where \mathbf{i} , \mathbf{j} , \mathbf{k} are unit vectors directed along the x -axis, y -axis and z -axis respectively, and \mathbf{a}_0 is the unit vector in the direction of \mathbf{a} .

$$\mathbf{a} \cdot \mathbf{b} = \mathbf{b} \cdot \mathbf{a} = ab \cos(\widehat{\mathbf{a}, \mathbf{b}}) = a_x b_x + a_y b_y + a_z b_z; \quad (1.1)$$

$$\begin{aligned} \mathbf{a} \times \mathbf{b} = -\mathbf{b} \times \mathbf{a} &= \begin{vmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ a_x & a_y & a_z \\ b_x & b_y & b_z \end{vmatrix} = \\ &= (a_y b_z - a_z b_y) \mathbf{i} + (a_z b_x - a_x b_z) \mathbf{j} + (a_x b_y - a_y b_x) \mathbf{k}, \end{aligned} \quad (1.2)$$

$$|\mathbf{a} \times \mathbf{b}| = ab \sin(\widehat{\mathbf{a}, \mathbf{b}}), \quad (1.2')$$

$$\mathbf{a} \cdot (\mathbf{b} \times \mathbf{c}) = \mathbf{b} \cdot (\mathbf{c} \times \mathbf{a}) = \mathbf{c} \cdot (\mathbf{a} \times \mathbf{b}), \quad (1.3)$$

$$\mathbf{a} \times (\mathbf{b} \times \mathbf{c}) = \mathbf{b}(\mathbf{a} \cdot \mathbf{c}) - \mathbf{c}(\mathbf{a} \cdot \mathbf{b}), \quad (1.4a)$$

$$(\mathbf{a} \times \mathbf{b}) \times \mathbf{c} = \mathbf{b}(\mathbf{c} \cdot \mathbf{a}) - \mathbf{a}(\mathbf{c} \cdot \mathbf{b}) \quad (1.4b)$$

$$(\mathbf{a} \times \mathbf{b}) \cdot (\mathbf{c} \times \mathbf{d}) = (\mathbf{a} \cdot \mathbf{c})(\mathbf{b} \cdot \mathbf{d}) - (\mathbf{a} \cdot \mathbf{d})(\mathbf{b} \cdot \mathbf{c}). \quad (1.5)$$

$$\begin{aligned} \mathbf{a}(\mathbf{b} \cdot \mathbf{c}) &= \frac{1}{2} \{ \mathbf{a}(\mathbf{b} \cdot \mathbf{c}) - \mathbf{b}(\mathbf{a} \cdot \mathbf{c}) \} + \frac{1}{2} \{ \mathbf{a}(\mathbf{b} \cdot \mathbf{c}) + \mathbf{b}(\mathbf{a} \cdot \mathbf{c}) \} = \\ &= \frac{1}{2} \mathbf{c} \times (\mathbf{a} \times \mathbf{b}) + \frac{1}{2} \{ \mathbf{a}(\mathbf{b} \cdot \mathbf{c}) + \mathbf{b}(\mathbf{a} \cdot \mathbf{c}) \}. \end{aligned} \quad (1.6)$$

The basic formula of spherical trigonometry is easily derived from (1.5). Let \mathbf{r}_1 , \mathbf{r}_2 and \mathbf{r}_3 be the unit radius vectors of the apices of a spherical triangle ABC with angles α , β , γ as in fig. A.1. If in (1.5) we set $\mathbf{a} = \mathbf{r}_1$, $\mathbf{b} = \mathbf{r}_2$, $\mathbf{c} = \mathbf{r}_3$, $\mathbf{d} = \mathbf{r}_1$, we find

$$(\mathbf{r}_1 \times \mathbf{r}_2) \cdot (\mathbf{r}_1 \times \mathbf{r}_3) = \mathbf{r}_2 \cdot \mathbf{r}_3 - (\mathbf{r}_1 \cdot \mathbf{r}_2)(\mathbf{r}_1 \cdot \mathbf{r}_3). \quad (1.5')$$

By definition

$$\mathbf{r}_1 \cdot \mathbf{r}_2 = \cos \gamma, \quad \mathbf{r}_2 \cdot \mathbf{r}_3 = \cos \alpha, \quad \mathbf{r}_3 \cdot \mathbf{r}_1 = \cos \beta,$$

$$|\mathbf{r}_1 \times \mathbf{r}_2| = \sin \gamma, \quad |\mathbf{r}_1 \times \mathbf{r}_3| = \sin \beta,$$

$$(\mathbf{r}_1 \times \mathbf{r}_3) \cdot (\mathbf{r}_1 \times \mathbf{r}_2) = \sin \beta \sin \gamma \cos \delta,$$

where δ is the angle between the planes OAB and OAC.

Fig. A.1

The substitution of these expressions into (I.5') gives the basic formula of spherical trigonometry:

$$\cos \alpha = \cos \beta \cos \gamma + \sin \beta \sin \gamma \cos \delta \quad (1.7)$$

Vectors which do not change under the inversion of the coordinate axes $\mathbf{r} \rightarrow (-\mathbf{r})$ are called polar vectors. The velocity vector, force vector etc. are polar vectors. Vectors which change sign under the inversion, i.e.

$$\mathbf{a}(\mathbf{r}) = -\mathbf{a}(-\mathbf{r})$$

are called axial vectors or pseudo-vectors.

The vector expressing the cross product of two polar vectors is an axial vector.

Scalar field

A scalar field $\varphi(\mathbf{r})$ is characterized by defining the scalar φ at every point of space. The spatial rate of change of the scalar $\varphi(\mathbf{r})$ is characterized by the derivative with respect to a given direction \mathbf{l} :

$$\begin{aligned} \frac{\partial \varphi}{\partial l} &= \frac{\partial \varphi}{\partial x} \cos(\widehat{\mathbf{l}, \mathbf{i}}) + \frac{\partial \varphi}{\partial y} \cos(\widehat{\mathbf{l}, \mathbf{j}}) + \frac{\partial \varphi}{\partial z} \cos(\widehat{\mathbf{l}, \mathbf{k}}) \\ &= |\mathbf{l}| |\nabla \varphi| \cos(\widehat{\mathbf{l}, \nabla \varphi}), \end{aligned} \quad (1.8)$$

where the gradient of the scalar φ ,

$$\nabla \varphi = \frac{\partial \varphi}{\partial x} \mathbf{i} + \frac{\partial \varphi}{\partial y} \mathbf{j} + \frac{\partial \varphi}{\partial z} \mathbf{k}, \quad (1.9)$$

represents the vector which is oriented in the direction of the most rapid increase of φ and is equal to the derivative of φ with respect to this direction.

The magnitude of the gradient is equal to

$$|\nabla \varphi| = \sqrt{\left(\frac{\partial \varphi}{\partial x}\right)^2 + \left(\frac{\partial \varphi}{\partial y}\right)^2 + \left(\frac{\partial \varphi}{\partial z}\right)^2} \quad (1.10)$$

The Hamiltonian differential operator "del" ∇ is defined by the relation

$$\nabla \equiv \mathbf{i} \frac{\partial}{\partial x} + \mathbf{j} \frac{\partial}{\partial y} + \mathbf{k} \frac{\partial}{\partial z}. \quad (\text{I.11})$$

∇ is not represented as a vector. The Hamiltonian operator is a symbol indicating operations which must be done on the functions of coordinates standing in front of it. For example, $\nabla \varphi$ means that one has to take the partial derivatives of the function φ and construct a vector whose components are equal to these partial derivatives.

From the definition (I.11) it follows that

$$\nabla r = \mathbf{i} \frac{\partial r}{\partial x} + \mathbf{j} \frac{\partial r}{\partial y} + \mathbf{k} \frac{\partial r}{\partial z} = \frac{\mathbf{r}}{r}. \quad (\text{I.12})$$

$$\nabla \varphi(r) = \frac{d\varphi}{dr} \nabla r = \frac{d\varphi}{dr} \frac{\mathbf{r}}{r}, \quad (\text{I.13})$$

$$\nabla (\varphi + \psi) = \nabla \varphi + \nabla \psi, \quad (\text{I.14})$$

$$\nabla \varphi \psi = \psi \nabla \varphi + \varphi \nabla \psi, \quad (\text{I.15})$$

$$\nabla f(\varphi) = \frac{df}{d\varphi} \nabla \varphi. \quad (\text{I.16})$$

In calculating the gradient of functions which depend on the distance r between two given points,

$$r = \sqrt{(x - x_0)^2 + (y - y_0)^2 + (z - z_0)^2},$$

one has to distinguish between the gradients with respect to coordinates (x, y, z) and (x_0, y_0, z_0) .

We have

$$\nabla r = \frac{\mathbf{i}(x - x_0) + \mathbf{j}(y - y_0) + \mathbf{k}(z - z_0)}{r}, \quad (\text{I.12}')$$

$$\nabla_0 r = - \frac{\mathbf{i}(x - x_0) + \mathbf{j}(y - y_0) + \mathbf{k}(z - z_0)}{r}.$$

Consequently,

$$\nabla_0 \varphi(r) = - \nabla \varphi(r) . \quad (I.17)$$

The differentiation of a vector which depends on a scalar argument:

$$\frac{da(x)}{dx} = \frac{d}{dx} a_0(x) a(x) = a_0 \frac{da}{dx} + a \frac{da_0}{dx} = a_0 \frac{da}{dx} + b ,$$

where $a_0(x) = a(x)/|a(x)|$, $b = a\omega b_0$, $b_0 \perp a_0$, and $\omega = |da_0/dx|$ is the rate of change of the angle φ , which determines the orientation of the vector a .

The total derivative of $A(x, y, z, t)$ with respect to time is equal to

$$\begin{aligned} \frac{dA}{dt} &= \frac{\partial A}{\partial t} + \frac{\partial A}{\partial x} \frac{dx}{dt} + \frac{\partial A}{\partial y} \frac{dy}{dt} + \frac{\partial A}{\partial z} \frac{dz}{dt} = \\ &= \frac{\partial A}{\partial t} + v_x \frac{\partial A}{\partial x} + v_y \frac{\partial A}{\partial y} + v_z \frac{\partial A}{\partial z} = \frac{\partial A}{\partial t} + (\mathbf{v} \cdot \nabla) A . \end{aligned} \quad (I.18)$$

The line integral of a vector along a path is defined by the relation

$$\int_L \mathbf{a} \cdot d\mathbf{l} = \int (a_x dl_x + a_y dl_y + a_z dl_z) .$$

The integral over a closed path is called the circulation:

$$\oint \mathbf{a} \cdot d\mathbf{l} .$$

If the vector \mathbf{a} can be written in the form

$$\mathbf{a} = \nabla \varphi ,$$

then it is called a potential, or irrotational, vector, and φ is called the potential.

The circulation of a potential vector is equal to zero:

$$\oint \nabla \varphi \cdot d\mathbf{l} = 0 . \quad (I.19)$$

The line integral of a potential vector along the path L between two points \mathbf{r}_1 and \mathbf{r}_2 is

$$\int_L \nabla \varphi \cdot d\mathbf{l} = \varphi(\mathbf{r}_1) - \varphi(\mathbf{r}_2), \quad (1.20)$$

where $\varphi(\mathbf{r}_1)$ and $\varphi(\mathbf{r}_2)$ are the potentials at the end points of the line L .

The scalar field is represented geometrically by plotting equipotential surfaces $\varphi = \text{const}$. The vector $\nabla \varphi$ is normal to the surface $\varphi = \text{const}$. The more rapid the variation of the function φ , the larger $\nabla \varphi$ and the smaller the separation between the equipotential surfaces.

The integral

$$\int \varphi(\mathbf{r}) dS = \int \varphi \mathbf{n} dS = \lim_{\substack{N \rightarrow \infty \\ \Delta S_i \rightarrow 0}} \sum_{i=1}^N \varphi_i \Delta S_i$$

is called the surface integral of the function $\varphi(\mathbf{r})$. The integral over a closed surface is denoted in this book by $\oint \varphi dS$.

Let us consider the integral over the surface of an infinitesimal parallelepiped of volume $V \rightarrow 0$. We assume that the faces of the parallelepiped are infinitesimal areas $(dx dy)$, $(dx dz)$, $(dy dz)$ in the coordinate planes (xy) , (xz) and (yz) at the origin.

We have, obviously,

$$\begin{aligned} \oint_{V \rightarrow 0} \varphi dS &= i \{ \varphi(0 + dx) dy dz - \varphi(0) dy dz \} + \\ &+ j \{ \varphi(0 + dy) dx dz - \varphi(0) dx dz \} + \\ &+ k \{ \varphi(0 + dz) dx dy - \varphi(0) dx dy \} = \\ &= \left(i \frac{\partial \varphi}{\partial x} + j \frac{\partial \varphi}{\partial y} + k \frac{\partial \varphi}{\partial z} \right) dx dy dz \\ &= \left(i \frac{\partial \varphi}{\partial x} + j \frac{\partial \varphi}{\partial y} + k \frac{\partial \varphi}{\partial z} \right) V, \end{aligned}$$

whence we find the equality

$$\nabla \varphi = i \frac{\partial \varphi}{\partial x} + j \frac{\partial \varphi}{\partial y} + k \frac{\partial \varphi}{\partial z} = \lim_{V \rightarrow 0} \frac{\oint \varphi \mathbf{n} dS}{V} \quad (1.21)$$

Formula (I.21) allows one to give another, integral, definition of the Hamiltonian operator:

$$\nabla = \lim_{V \rightarrow 0} \frac{\oint \mathbf{n} dS}{V}, \quad (I.22)$$

which is equivalent with (I.11).

We emphasize that, since the integration surface reduces to a point as V tends to zero, the integral operator (I.22) does not depend on the form of this surface.

The following integral relation results from (I.21):

$$\oint \varphi dS = \int \nabla \varphi dV. \quad (I.23)$$

This relation connects the surface integral of the scalar φ with the volume integral of the vector $\nabla \varphi$. The volume of integration on the right-hand side of (I.23) is bounded by the surface φ over which the surface integration on the left-hand side of (I.23) is carried out.

In order to prove formula (I.23), we divide the finite volume into infinitesimal volumes, formula (I.21) being valid for each of these. We carry out the summation over all these volumes. The integration over all internal surfaces which represent interfaces of the volumes is carried out twice. In this case the directions of the external normals will be opposite, and the integrals over the internal surfaces will cancel out. There will remain only the integrals over all external surfaces, which form in the sum the integral over the surface bounding the volume V .

Vector field

The region of space in which the value of a vector $\mathbf{a}(\mathbf{r})$ is defined at each point is called a vector field. The vector field is represented graphically by means of field lines. The vector $\mathbf{a}(\mathbf{r}_0)$ is in the direction of a tangent to the field line at the point \mathbf{r}_0 . The field lines are drawn in such a way that the density of lines is proportional to the absolute value $|\mathbf{a}|$.

For the vector field one can define the flux of the vector through an area characterized by the vector $d\mathbf{S}$ in the form

$$dJ = \mathbf{a} \cdot d\mathbf{S}. \quad (I.24)$$

By the surface integral of a vector \mathbf{a} we mean the quantity

$$\begin{aligned} j &= \int_S \mathbf{a} \cdot d\mathbf{S} = \int_S \mathbf{a} \cdot \mathbf{n} dS = \int_S a_n dS \\ &= \int a_x dy dz + \int a_y dx dz + \int a_z dx dy, \end{aligned} \quad (1.25)$$

where $dy dz = dS \cos(\widehat{\mathbf{n}}, \widehat{\mathbf{i}})$, and so on.

The surface integral represents the flux of the vector \mathbf{a} through the surface S .

If the surface S is closed, then the surface integral is denoted by $\oint \mathbf{a} \cdot d\mathbf{S}$. For the surface integral over a closed surface the Gauss-Ostrogradsky theorem

$$\oint \mathbf{a} \cdot d\mathbf{S} = \int \left(\frac{\partial a_x}{\partial x} + \frac{\partial a_y}{\partial y} + \frac{\partial a_z}{\partial z} \right) dV \quad (1.26)$$

holds.

The integration in (1.26) is carried out over the volume bounded by the surface of integration of the surface integral.

The proof is obtained by dividing the volume into infinitesimal volumes. It can formally be performed by means of the definition (1.22) of the Hamiltonian operator.

Namely,

$$\nabla \cdot \mathbf{a} = \lim_{V \rightarrow 0} \frac{\oint \mathbf{a} \cdot \mathbf{n} dS}{V}, \quad (1.27)$$

whence, as in deriving (1.23), summing the elementary volumes we obtain

$$\int \nabla \cdot \mathbf{a} dV = \oint \mathbf{a} \cdot d\mathbf{S}.$$

Making use of the definition (1.11), we arrive at theorem (1.26).

The scalar quantity which may be expressed by two equivalent representations

$$\nabla \cdot \mathbf{a} = \frac{\partial a_x}{\partial x} + \frac{\partial a_y}{\partial y} + \frac{\partial a_z}{\partial z}, \quad (1.28)$$

$$\nabla \cdot \mathbf{a} = \lim_{V \rightarrow 0} \frac{\oint \mathbf{a} \cdot \mathbf{n} dS}{V}, \quad (1.29)$$

which are based on different forms of the Hamiltonian operator is called the divergence of the vector \mathbf{a} . The Gauss-Ostrogradsky theorem can be rewritten in the form

$$\oint \mathbf{a} \cdot d\mathbf{S} = \int \nabla \cdot \mathbf{a} dV. \quad (1.30)$$

The divergence plays an important role in the theory of the vector field (see §2 of Part I of the book).

From expression (1.29) it follows that $\nabla \cdot \mathbf{a}$ represents the flux per unit volume of the vector $\mathbf{a}(\mathbf{r})$ through an infinitesimal surface surrounding the given point \mathbf{r} of the field.

A vector field is called solenoidal, if at each point of the field

$$\nabla \cdot \mathbf{a} = 0.$$

This means that the flux of the vector through a transverse section of a tube formed by a group of field lines has a constant value along the tube. At those points of the field at which $\nabla \cdot \mathbf{a} \neq 0$ there are sources ($\nabla \cdot \mathbf{a} > 0$) or sinks ($\nabla \cdot \mathbf{a} < 0$) of the field. The numerical value of $\nabla \cdot \mathbf{a}$ is called the intensity or abundance of sources of the field.

The following obvious formulae hold:

$$\begin{aligned} \nabla \cdot (\mathbf{a}_1 + \mathbf{a}_2) &= \nabla \cdot \mathbf{a}_1 + \nabla \cdot \mathbf{a}_2, \\ \nabla \cdot (c\mathbf{a}) &= c(\nabla \cdot \mathbf{a}) \quad (c = \text{const}), \\ \nabla \cdot \mathbf{a}(\mathbf{r}) &= -\nabla_0 \cdot \mathbf{a}(\mathbf{r}), \end{aligned} \quad (1.31)$$

where $r = \sqrt{(x-x_0)^2 + (y-y_0)^2 + (z-z_0)^2}$; and the index 0 denotes differentiation with respect to the coordinates x_0, y_0, z_0 .

Let $\mathbf{a}(u)$ be a vector depending only on the scalar quantity u . Then

$$\nabla \cdot \mathbf{a}(u) = \frac{d\mathbf{a}}{du} \cdot \nabla u = \dot{\mathbf{a}} \cdot \nabla u, \quad (1.32)$$

where the dot over \mathbf{a} denotes differentiation with respect to the argument u .

Besides the operation $\nabla \cdot \mathbf{a}$ corresponding to the scalar product of the vectors ∇ and \mathbf{a} , one can consider the operation forming the vector

$$\nabla \times \mathbf{a} \equiv \text{curl } \mathbf{a}. \quad (1.33)$$

The vector representing the cross product of the Hamiltonian operator ∇ and the vector \mathbf{a} is called the curl of the vector \mathbf{a} .

A calculation according to formula (1.2), taking into account (1.11), gives

$$\begin{aligned}\nabla \times \mathbf{a} &= \begin{vmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ \frac{\partial}{\partial x} & \frac{\partial}{\partial y} & \frac{\partial}{\partial z} \\ a_x & a_y & a_z \end{vmatrix} = \\ &= \mathbf{i} \left(\frac{\partial a_z}{\partial y} - \frac{\partial a_y}{\partial z} \right) + \mathbf{j} \left(\frac{\partial a_x}{\partial z} - \frac{\partial a_z}{\partial x} \right) + \mathbf{k} \left(\frac{\partial a_y}{\partial x} - \frac{\partial a_x}{\partial y} \right). \quad (1.34)\end{aligned}$$

Making use now of the integral expression (1.22) for the Hamiltonian operator, we have another representation of the vector:

$$\nabla \times \mathbf{a} = \lim_{V \rightarrow 0} \frac{\oint \mathbf{n} \times \mathbf{a} dS}{V}. \quad (1.35)$$

From the definition (1.35), in an analogous way to (1.23) and (1.30), it follows that

$$\int \nabla \times \mathbf{a} dV = \oint \mathbf{dS} \times \mathbf{a}. \quad (1.36)$$

Let us now consider the projection of the vector $\nabla \times \mathbf{a}$ on to an arbitrary direction characterized by unit vector \mathbf{N} . From the definition (1.35) it follows that

$$\mathbf{N} \cdot (\nabla \times \mathbf{a}) = \lim_{V \rightarrow 0} \frac{\mathbf{N} \cdot \oint (\mathbf{n} \times \mathbf{a}) dS}{V} = \lim_{V \rightarrow 0} \frac{\oint \mathbf{a} \cdot (\mathbf{N} \times \mathbf{n}) dS}{V}.$$

Since the result obtained after passing to the limit does not depend on the form of the surface, the latter can be chosen arbitrarily. If we direct the z -axis along \mathbf{N} and choose a cylinder with base S and height h as the surface, then

$$\oint \mathbf{a} \cdot (\mathbf{N} \times \mathbf{n}) dS = \oint \mathbf{a} \cdot d\mathbf{l} h.$$

The integration in the expression on the right is carried out with respect to the lateral surface of the cylinder, since at its bases $\mathbf{n} \parallel \mathbf{N}$ and their cross product reduces to zero. A length element at the lateral surface perpendicular to the vectors \mathbf{n} and \mathbf{N} is denoted by $d\mathbf{l}$.

Hence it follows that

$$\bar{\mathbf{N}} \cdot (\nabla \times \mathbf{a}) = \lim_{V \rightarrow 0} \frac{h}{Sh} \oint \mathbf{a} \cdot d\mathbf{l} = \lim_{S \rightarrow 0} \frac{1}{S} \oint \mathbf{a} \cdot d\mathbf{l}.$$

Dividing an arbitrary volume into small volumes as previously and carrying out the summation over them, we find that the surface integrals over the internal surfaces and the line integrals over the edges of adjacent cells cancel out, so that

$$\oint \mathbf{a} \cdot d\mathbf{l} = \int (\nabla \times \mathbf{a}) \cdot d\mathbf{S}. \quad (1.37)$$

Formula (1.37), connecting the line integral of the vector \mathbf{a} over an arbitrary closed contour with the surface integral of $\nabla \times \mathbf{a}$, is called Stokes' theorem.

From the derivation of the theorem it is clear that the integration is carried out over an arbitrary surface bounded by the contour of integration.

The geometrical meaning of the idea of curl becomes clear from Stokes' theorem. In order that the integral of the vector \mathbf{a} over a closed path be different from zero it is necessary that certain lines (even field lines) have the character of closed curves. Such lines, for example, are the lines of the vector of the velocity of rotation of a solid body, or the flow lines of a liquid performing a circulatory motion. Hence the term curl.

From Stokes' theorem it follows that:

1) If $\mathbf{a} = \nabla \varphi$, then $\oint \mathbf{a} \cdot d\mathbf{l} = 0$. Consequently,

$$\nabla \times \mathbf{a} = \nabla \times \nabla \varphi = 0, \quad (1.38)$$

i.e. if \mathbf{a} is a potential vector, then the field of the vector \mathbf{a} is irrotational. Conversely, any vector whose field is irrotational is a potential vector.

2) If the vector \mathbf{a} is solenoidal, so that

$$\nabla \cdot \mathbf{a} = 0,$$

then it can be written in the form of the curl of a certain vector \mathbf{c} :

$$\mathbf{a} = \nabla \times \mathbf{c}.$$

Conversely, if a vector field \mathbf{a} can be written as the curl of a field \mathbf{c} , then the field \mathbf{a} has solenoidal character.

$$\nabla \cdot (\nabla \times \mathbf{c}) = 0.$$

Sources and sinks are absent in a solenoidal field. The proof of these statements is obtained by a direct calculation. For example,

$$\nabla \cdot (\nabla \times \mathbf{c}) = \mathbf{c} \cdot (\nabla \times \nabla) = 0.$$

The formation of the scalar $\nabla \cdot \mathbf{a}$ and the vector $\nabla \times \mathbf{a}$ are the basic operations of differentiation of a vector.

The divergence and curl of a vector \mathbf{a} determine the vector field (see §2 of Part I).

In calculating the divergence and curl of a vector $\mathbf{a}(u)$ which depends on the scalar argument u it turns out that

$$\nabla \cdot \mathbf{a}(u) = \nabla u \cdot \frac{d\mathbf{a}}{du} = \nabla u \cdot \dot{\mathbf{a}}, \quad (1.39)$$

$$\nabla \times \mathbf{a}(u) = \nabla u \times \frac{d\mathbf{a}}{du} = (\nabla u) \times \dot{\mathbf{a}}, \quad (1.40)$$

where the dot over \mathbf{a} denotes differentiation with respect to the scalar u .

Calculation of the derivatives of a product and repeated derivatives. These operations are carried out most simply by means of the Hamiltonian operator. In this case the following two rules are to be adhered to:

1. The Hamiltonian operator must act successively on each scalar and vector following it.

2. The Hamiltonian operator can be treated as an ordinary vector, but it cannot be transposed with the quantity on which it acts. For clarity, in carrying out intermediate transformations we shall indicate the quantity acted upon by the Hamiltonian operator by a subscript, for example, ∇_φ or $\nabla_{\mathbf{a}}$.

The most important examples are:

$$1. \quad \nabla(\varphi\psi) = \varphi \nabla_\psi \psi + \psi \nabla_\varphi \varphi = \varphi \nabla \psi + \psi \nabla \varphi. \quad (1.41)$$

$$2. \quad \nabla \cdot (\varphi \mathbf{a}) = \mathbf{a} \cdot \nabla_\varphi \varphi + \varphi \nabla_{\mathbf{a}} \cdot \mathbf{a} = \mathbf{a} \cdot \nabla \varphi + \varphi \nabla \cdot \mathbf{a}. \quad (1.42)$$

In particular

$$\nabla \cdot \left(\frac{\mathbf{r}}{r} \right) \equiv \nabla \cdot \mathbf{n} = \left(\frac{1}{r} \right) \nabla \cdot \mathbf{r} + \mathbf{r} \cdot \nabla \left(\frac{1}{r} \right) = \frac{3}{r} - \frac{1}{r} = \frac{2}{r},$$

$$\nabla \times (\varphi \mathbf{a}) = \varphi (\nabla_{\mathbf{a}} \times \mathbf{a}) + (\nabla_{\varphi} \varphi) \times \mathbf{a} = \varphi (\nabla \times \mathbf{a}) + (\nabla \varphi) \times \mathbf{a}. \quad (1.43)$$

$$\begin{aligned} 3. \quad \nabla \cdot (\mathbf{a} \times \mathbf{b}) &= \nabla_{\mathbf{a}} \cdot (\mathbf{a} \times \mathbf{b}) + \nabla_{\mathbf{b}} \cdot (\mathbf{a} \times \mathbf{b}) = \\ &= \mathbf{b} \cdot (\nabla_{\mathbf{a}} \times \mathbf{a}) - \nabla_{\mathbf{b}} \cdot (\mathbf{b} \times \mathbf{a}) = \\ &= \mathbf{b} \cdot (\nabla_{\mathbf{a}} \times \mathbf{a}) - \mathbf{a} \cdot (\nabla_{\mathbf{b}} \times \mathbf{b}) = \\ &= \mathbf{b} \cdot (\nabla \times \mathbf{a}) - \mathbf{a} \cdot (\nabla \times \mathbf{b}). \end{aligned} \quad (1.44)$$

We have carried out a cyclic permutation of the vectors. In the second term the order of vector multiplication has been changed. Otherwise rule 2 would be violated in the cyclic permutation: the vector \mathbf{b} would be moved behind the symbol $\nabla_{\mathbf{b}}$.

$$\begin{aligned} 4. \quad \nabla \times (\mathbf{a} \times \mathbf{b}) &= \nabla_{\mathbf{a}} \times (\mathbf{a} \times \mathbf{b}) + \nabla_{\mathbf{b}} \times (\mathbf{a} \times \mathbf{b}) = \\ &= (\nabla_{\mathbf{a}} \cdot \mathbf{b})\mathbf{a} - (\nabla_{\mathbf{a}} \cdot \mathbf{a})\mathbf{b} + (\nabla_{\mathbf{b}} \cdot \mathbf{b})\mathbf{a} - (\nabla_{\mathbf{b}} \cdot \mathbf{a})\mathbf{b} = \\ &= (\mathbf{b} \cdot \nabla_{\mathbf{a}})\mathbf{a} - \mathbf{b}(\nabla_{\mathbf{a}} \cdot \mathbf{a}) + \mathbf{a}(\nabla_{\mathbf{b}} \cdot \mathbf{b}) - (\mathbf{a} \cdot \nabla_{\mathbf{b}})\mathbf{b} = \\ &= (\mathbf{b} \cdot \nabla)\mathbf{a} - (\mathbf{a} \cdot \nabla)\mathbf{b} + \mathbf{a}(\nabla \cdot \mathbf{b}) - \mathbf{b}(\nabla \cdot \mathbf{a}). \end{aligned} \quad (1.45)$$

Here $\mathbf{a} \cdot \nabla$ is the scalar differential operator

$$\mathbf{a} \cdot \nabla = a_x \frac{\partial}{\partial x} + a_y \frac{\partial}{\partial y} + a_z \frac{\partial}{\partial z}. \quad (1.46)$$

$$\begin{aligned} 5. \quad \nabla (\mathbf{a} \cdot \mathbf{b}) &= \nabla_{\mathbf{a}} (\mathbf{a} \cdot \mathbf{b}) + \nabla_{\mathbf{b}} (\mathbf{a} \cdot \mathbf{b}) = \\ &= (\mathbf{b} \cdot \nabla_{\mathbf{a}})\mathbf{a} + \mathbf{b} \times (\nabla_{\mathbf{a}} \times \mathbf{a}) + (\mathbf{a} \cdot \nabla_{\mathbf{b}})\mathbf{b} + \mathbf{a} \times (\nabla_{\mathbf{b}} \times \mathbf{b}) = \\ &= (\mathbf{b} \cdot \nabla)\mathbf{a} + (\mathbf{a} \cdot \nabla)\mathbf{b} + \mathbf{b} \times (\nabla \times \mathbf{a}) + \mathbf{a} \times (\nabla \times \mathbf{b}). \end{aligned} \quad (1.47)$$

$$6. \quad \nabla \cdot \frac{1}{2} a^2 = (\mathbf{a} \cdot \nabla)\mathbf{a} + \mathbf{a} \times (\nabla \times \mathbf{a}). \quad (1.48)$$

$$7. \quad \nabla \cdot \nabla \varphi = \nabla^2 \varphi = \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \right) \varphi. \quad (1.49)$$

$$\begin{aligned}
 8. \quad \nabla \times (\nabla \times \mathbf{a}) &= \nabla(\nabla \cdot \mathbf{a}) - (\nabla \cdot \nabla) \mathbf{a} = \\
 &= \nabla(\nabla \cdot \mathbf{a}) - \nabla^2 \mathbf{a}.
 \end{aligned} \tag{I.50}$$

$$9. \quad \nabla \cdot (\mathbf{a}\mathbf{b}) = \mathbf{b}(\nabla \cdot \mathbf{a}) + (\mathbf{a} \cdot \nabla) \mathbf{b}. \tag{I.51}$$

The product $(\mathbf{a}\mathbf{b})$ of the two vectors \mathbf{a} and \mathbf{b} is known as dyadic. The properties of dyadics are treated in books on vector analysis.

From the integral representation of the Hamiltonian operator the formula

$$\nabla \cdot (\mathbf{a}\mathbf{b}) = \lim_{V \rightarrow 0} \frac{1}{V} \oint (\mathbf{n} \cdot \mathbf{a}) \mathbf{b} dS$$

follows, from which one obtains directly

$$\int \nabla \cdot (\mathbf{a}\mathbf{b}) dV = \oint (\mathbf{n} \cdot \mathbf{a}) \mathbf{b} dS, \tag{I.52}$$

or by virtue of (I.51),

$$\oint (\mathbf{n} \cdot \mathbf{a}) \mathbf{b} dS = \int \mathbf{b}(\nabla \cdot \mathbf{a}) dV + \int (\mathbf{a} \cdot \nabla) \mathbf{b} dV \tag{I.53}$$

We obtain also another integral equality:

$$\int \mathbf{b} \times (\nabla \times \mathbf{a}) dV + \int (\mathbf{a} \times \nabla) \times \mathbf{b} dV = - \oint (\mathbf{n} \times \mathbf{a}) \times \mathbf{b} dS. \tag{I.54}$$

From the integral representation of the Hamiltonian operator the formula

$$(\nabla \times \mathbf{a}) \times \mathbf{b} = \lim_{V \rightarrow 0} \frac{1}{V} \oint (\mathbf{n} \times \mathbf{a}) \times \mathbf{b} dS$$

follows, whence

$$\int (\nabla \times \mathbf{a}) \times \mathbf{b} dV = \oint (\mathbf{n} \times \mathbf{a}) \times \mathbf{b} dS. \tag{I.55}$$

On the other hand, we have

$$(\nabla \times \mathbf{a}) \times \mathbf{b} = (\nabla_a \times \mathbf{a}) \times \mathbf{b} + (\nabla_b \times \mathbf{a}) \times \mathbf{b} = -\mathbf{b} \times (\nabla \times \mathbf{a}) - (\mathbf{a} \times \nabla) \times \mathbf{b}.$$

Substituting this into (I.55), we arrive at (I.54).

Representation of vector operations in curvilinear coordinates

In addition to Cartesian coordinates it is often convenient to make use of curvilinear coordinates q_1, q_2, q_3 . To each point r there corresponds a set of quantities q_1, q_2 and q_3 , i.e.

$$\mathbf{r} = \mathbf{r}(q_1, q_2, q_3). \quad (1.56)$$

Since vector operations are not connected with any particular coordinate system, the relations of vector analysis remain valid in all coordinate representations. However, the actual expression of vector operations in curvilinear coordinates is, naturally, not the same as that in Cartesian coordinates.

In this book only orthogonal coordinates are used. Let us call the three surfaces

Fig. A.2

$$q_i = q_i(x, y, z) = \text{const} \quad (i = 1, 2, 3), \quad (1.57)$$

the coordinate surfaces, and the lines of their intersection the coordinate lines. It is obvious that the set of three coordinate surfaces is a generalization of the coordinate trihedron in the Cartesian coordinate system. The directions of the coordinate lines are characterized by unit vectors $\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3$ (fig. A.2). Reference frames in which the vectors $\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3$ are mutually perpendicular are called orthogonal coordinate systems.

The derivative with respect to coordinates q_i is equal to

$$\frac{\partial \mathbf{r}}{\partial q_i} = \frac{\partial \mathbf{r}(q_1, q_2, q_3)}{\partial q_i} = H_i \mathbf{e}_i \quad (i = 1, 2, 3). \quad (1.58)$$

The vector $\partial \mathbf{r} / \partial q_i$ is directed along a tangent to the coordinate line q_i , and its value H_i is a function of the coordinates q_1, q_2, q_3 . Obviously,

$$H_i^2 = \left(\frac{\partial \mathbf{r}}{\partial q_i} \right)^2 = \left(\frac{\partial x}{\partial q_i} \right)^2 + \left(\frac{\partial y}{\partial q_i} \right)^2 + \left(\frac{\partial z}{\partial q_i} \right)^2 \quad (1.59)$$

The three quantities H_i ($i = 1, 2, 3$) are called the Lamé coefficients. By means of them one can write

$$d\mathbf{r} = H_1 dq_1 \mathbf{e}_1 + H_2 dq_2 \mathbf{e}_2 + H_3 dq_3 \mathbf{e}_3, \quad (1.60)$$

or, in components

$$(d\mathbf{r})_1 = H_1 dq_1; \quad (d\mathbf{r})_2 = H_2 dq_2; \quad (d\mathbf{r})_3 = H_3 dq_3. \quad (1.61)$$

Squaring (1.60), we find the square of the length in orthogonal coordinates

$$(d\mathbf{r})^2 = ds^2 = H_1^2 dq_1^2 + H_2^2 dq_2^2 + H_3^2 dq_3^2 \quad (1.62)$$

An element of area is easily found by considering an infinitesimal parallelepiped formed by the coordinate surfaces. The areas of its faces are

$$\begin{aligned} dS_1 &= H_2 H_3 dq_2 dq_3, & dS_2 &= H_1 H_3 dq_1 dq_3, \\ dS_3 &= H_1 H_2 dq_1 dq_2. \end{aligned} \quad (1.63)$$

The volume of the parallelepiped is equal to

$$dV = H_1 H_2 H_3 dq_1 dq_2 dq_3. \quad (1.64)$$

The most important orthogonal coordinates are cylindrical and spherical polar coordinates.

In spherical polar coordinates

$$q_1 = r, \quad q_2 = \theta, \quad q_3 = \psi. \quad (1.65)$$

Obviously, we have

$$(dr)_r = dr, \quad (dr)_\theta = r d\theta, \quad (dr)_\psi = r \sin \theta d\psi \quad (1.66)$$

Comparison with (1.61) gives

$$\begin{aligned} H_r &= 1, \quad H_\theta = r, \quad H_\psi = r \sin \theta; \\ dV &= r^2 \sin \theta dr d\theta d\psi. \end{aligned} \quad (1.67)$$

In the cylindrical polar coordinate system

$$\begin{aligned} q_1 &= \rho, \quad q_2 = \psi, \quad q_3 = z, \\ (dr)_\rho &= d\rho, \quad (dr)_\psi = \rho d\psi, \quad (dr)_z = dz, \end{aligned} \quad (1.68)$$

and from (1.61)

$$\begin{aligned} H_\rho &= 1, \quad H_\psi = \rho, \quad H_z = 1, \\ dV &= \rho d\rho d\psi dz. \end{aligned} \quad (1.69)$$

Expressions for vector operations are obtained from their definitions, taking into account the relations which have been written out:

$$1. \quad \nabla \varphi = \frac{\mathbf{e}_1}{H_1} \frac{\partial \varphi}{\partial q_1} + \frac{\mathbf{e}_2}{H_2} \frac{\partial \varphi}{\partial q_2} + \frac{\mathbf{e}_3}{H_3} \frac{\partial \varphi}{\partial q_3} \quad (1.70)$$

In particular, in spherical and cylindrical polar coordinate systems we have respectively:

$$\nabla \varphi = \mathbf{e}_r \frac{\partial \varphi}{\partial r} + \frac{\mathbf{e}_\theta}{r} \frac{\partial \varphi}{\partial \theta} + \frac{\mathbf{e}_\psi}{r \sin \theta} \frac{\partial \varphi}{\partial \psi}, \quad (1.71)$$

$$\nabla \varphi = \mathbf{e}_\rho \frac{\partial \varphi}{\partial \rho} + \frac{\mathbf{e}_\psi}{\rho} \frac{\partial \varphi}{\partial \psi} + \mathbf{e}_z \frac{\partial \varphi}{\partial z}. \quad (1.72)$$

$$2. \nabla \cdot \mathbf{a} = \frac{1}{H_1 H_2 H_3} \left\{ \frac{\partial}{\partial q_1} (a_1 H_2 H_3) + \frac{\partial}{\partial q_2} (a_2 H_3 H_1) + \frac{\partial}{\partial q_3} (a_3 H_1 H_2) \right\}. \quad (1.73)$$

In spherical and cylindrical polar coordinates respectively:

$$\nabla \cdot \mathbf{a} = \frac{1}{r^2} \frac{\partial(r^2 a_r)}{\partial r} + \frac{1}{r \sin \theta} \frac{\partial(\sin \theta a_\theta)}{\partial \theta} + \frac{1}{r \sin \theta} \frac{\partial a_\psi}{\partial \psi}, \quad (1.74)$$

$$\nabla \cdot \mathbf{a} = \frac{1}{\rho} \frac{\partial(\rho a_\rho)}{\partial \rho} + \frac{1}{\rho} \frac{\partial a_\psi}{\partial \psi} + \frac{\partial a_z}{\partial z}. \quad (1.75)$$

$$3. (\nabla \times \mathbf{a})_1 = \frac{1}{H_2 H_3} \left\{ \frac{\partial(a_3 H_3)}{\partial q_2} - \frac{\partial(a_2 H_2)}{\partial q_3} \right\}. \quad (1.76)$$

Other projections are obtained by the cyclic permutation of the coordinates 1, 2, 3.

In spherical and cylindrical coordinates respectively:

$$(\nabla \times \mathbf{a})_r = \frac{1}{r \sin \theta} \frac{\partial(a_\psi \sin \theta)}{\partial \theta} - \frac{1}{r \sin \theta} \frac{\partial a_\theta}{\partial \psi}, \quad (1.77)$$

$$(\nabla \times \mathbf{a})_\theta = \frac{1}{r \sin \theta} \frac{\partial a_r}{\partial \psi} - \frac{1}{r} \frac{\partial(r a_\psi)}{\partial r}, \quad (1.78)$$

$$(\nabla \times \mathbf{a})_\psi = \frac{1}{r} \frac{\partial a_\theta r}{\partial r} - \frac{1}{r} \frac{\partial a_r}{\partial \theta}, \quad (1.79)$$

$$(\nabla \times \mathbf{a})_\rho = \frac{1}{\rho} \frac{\partial a_z}{\partial \psi} - \frac{\partial a_\psi}{\partial z}, \quad (1.80)$$

$$(\nabla \times \mathbf{a})_\psi = \frac{\partial a_\rho}{\partial z} - \frac{\partial a_z}{\partial \rho}, \quad (1.81)$$

$$(\nabla \times \mathbf{a})_z = \frac{1}{\rho} \frac{\partial(a_\psi \rho)}{\partial \rho} - \frac{1}{\rho} \frac{\partial a_\rho}{\partial \psi}. \quad (1.82)$$

4. The Laplacian operator is

$$\nabla^2 = \frac{1}{H_1 H_2 H_3} \left\{ \frac{\partial}{\partial q_1} \left(\frac{H_2 H_3}{H_1} \frac{\partial}{\partial q_1} \right) + \frac{\partial}{\partial q_2} \left(\frac{H_3 H_1}{H_2} \frac{\partial}{\partial q_2} \right) + \frac{\partial}{\partial q_3} \left(\frac{H_1 H_2}{H_3} \frac{\partial}{\partial q_3} \right) \right\}. \quad (1.83)$$

In spherical and cylindrical coordinates respectively:

$$\nabla^2 = \frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial}{\partial r} \right) + \frac{1}{r^2 \sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial}{\partial \theta} \right) + \frac{1}{r^2 \sin^2 \theta} \frac{\partial^2}{\partial \psi^2}, \quad (1.84)$$

$$\nabla^2 = \frac{1}{\rho} \frac{\partial}{\partial \rho} \left(\rho \frac{\partial}{\partial \rho} \right) + \frac{1}{\rho^2} \frac{\partial^2}{\partial \psi^2} + \frac{\partial^2}{\partial z^2}. \quad (1.85)$$

The Fourier Integral

Any function which is periodic in the region $l = 2\pi/\omega$, i.e. a function satisfying the condition

$$f(t + l) = f\left(t + \frac{2\pi}{\omega}\right) = f(t),$$

can be expanded in a Fourier series:

$$f(t) = \sum_{n=0}^{\infty} (a_n \cos n\omega t + b_n \sin n\omega t) \equiv \sum_{n=-\infty}^{\infty} f_n e^{in\omega t}.$$

The Fourier coefficients are given by the formula

$$f_n(\omega) = \frac{\omega}{2\pi} \int_{-\pi/\omega}^{\pi/\omega} e^{-in\omega\tau} f(\tau) d\tau$$

The expansion in a Fourier series means that an arbitrary periodic function with a period $2\pi/\omega$ can be written in the form of a superposition (spectrum) of an infinitely large number of monochromatic functions with periods $2\pi/\omega$, $2\pi/2\omega$, ..., $2\pi/n\omega$ or frequencies ω , 2ω , ..., $n\omega$ and so on.

Conditions under which the expansion in a Fourier series is possible are usually fulfilled in physical applications.

Passing to the limit where the period increases indefinitely (i.e. $\omega \rightarrow 0$) and the frequencies draw nearer together, one can obtain the expansion in a Fourier integral:

$$f(t) = \int_{-\infty}^{\infty} F(\omega) e^{i\omega t} d\omega. \quad (\text{II.1})$$

The function $F(\omega)$, called the Fourier transform of the function $f(t)$, is given by the formula

$$F(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} f(t) e^{-i\omega t} dt. \quad (\text{II.2})$$

The expansion in a Fourier integral is possible if the properties of $f(t)$ ensure the convergence of (II.1)–(II.2). In physical applications $f(t)$ usually tends to zero as $t \rightarrow \pm \infty$, which ensures the convergence of these expressions.

The Fourier integral can be written in a more symmetric form:

$$f(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} e^{i\omega t} F(\omega) d\omega, \quad (\text{II.3})$$

$$F(\omega) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} e^{-i\omega t} f(t) dt. \quad (\text{II.4})$$

If $f(t)$ is a real function, then $F(\omega)$ is a complex function, and

$$F^*(\omega) = F(-\omega). \quad (\text{II.5})$$

Formulae (II.3) and (II.4) can be combined in the form

$$f(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{i\omega t} d\omega \int_{-\infty}^{\infty} d\tau e^{-i\omega \tau} f(\tau), \quad (\text{II.6})$$

which is also often called the Fourier integral.

Formula (II.3) shows that $f(t)$ represents the sum of monochromatic terms $e^{i\omega t}$ which are taken with weights (amplitudes) $F(\omega) d\omega/\sqrt{2\pi}$

The complex amplitude $F(\omega)$ can be written in the form

$$F(\omega) = A(\omega) e^{i\varphi(\omega)}, \quad (\text{II.7})$$

where $A(\omega)$ is the modulus and $\varphi(\omega)$ is the phase of the function $F(\omega)$; they are real functions of the frequency ω . In such a representation for the Fourier integral we have

$$f(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} A(\omega) e^{i(\omega t + \varphi(\omega))} d\omega. \quad (\text{II.8})$$

We prove an important equality which is sometimes called the Parseval relation for the Fourier integral:

$$\int_{-\infty}^{\infty} (f(t))^2 dt = \int_{-\infty}^{\infty} |F(\omega)|^2 d\omega. \quad (\text{II.9})$$

Now,

$$\begin{aligned} \int_{-\infty}^{\infty} (f(t))^2 dt &= \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} f(t) \left\{ \int_{-\infty}^{\infty} A(\omega) e^{i(\omega t + \varphi(\omega))} d\omega \right\} dt \\ &= \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} A(\omega) e^{i\varphi(\omega)} \left\{ \int_{-\infty}^{\infty} f(t) e^{i\omega t} dt \right\} d\omega. \end{aligned}$$

But, by the definition (II.4),

$$\frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} f(t) e^{i\omega t} dt = F^*(\omega) = A(\omega) e^{-i\varphi(\omega)}$$

Hence

$$\int_{-\infty}^{\infty} (f(t))^2 dt = \int_{-\infty}^{\infty} (A(\omega))^2 d\omega = \int_{-\infty}^{\infty} |F(\omega)|^2 d\omega ,$$

which was to be proved.

The Delta-function and its Properties

The δ -function was introduced by Dirac * and proved to be very useful in considering many problems of theoretical physics.

The δ -function is defined by the relations

$$\delta(x) = 0 \quad \text{for} \quad x \neq 0 ,$$

$$\delta(x) = \infty \quad \text{for} \quad x = 0 ,$$

so that

$$\int_a^b \delta(x) dx = 1 , \quad \text{where } a < 0 < b . \quad (\text{III.1})$$

The basic property of the δ -function

$$\int_a^b f(x) \delta(x) dx = f(0) , \quad a < 0 < b , \quad (\text{III.2})$$

* P.A.M.Dirac, *The principles of quantum mechanics* (Clarendon Press, Oxford, 1958).

(where $f(x)$ is an arbitrary continuous function of x) follows immediately from the definition (III.1).

Indeed, because of the properties of the δ -function, only the neighbourhood of the point $x = 0$ is of importance in the integral (III.2). Then for the point $x = 0$ the function $f(x)$ can be brought out of the integral, and the remaining integral is equal to unity by virtue of (III.1). The integral (III.2) can also be rewritten in the form

$$\int f(x) \delta(x - x_0) dx = f(x_0). \quad (\text{III.3})$$

The range of integration in (III.3) must include the point $x = x_0$, otherwise the integral reduces to zero:

$$\int_a^b f(x) \delta(x - x_0) dx = 0, \quad \begin{cases} x_0 > b, \\ x_0 < a \end{cases} \quad (\text{III.3}')$$

The delta-function cannot be contained in any final expression. When the δ -function is written a subsequent integration with respect to the variables on which it depends is always implied; the δ -function can be considered as a limit of consistency for analytical functions.

In particular, such properties are possessed by the expression

$$F(\alpha, x) = \frac{\sin \alpha x}{\pi x},$$

which behaves as $\delta(x)$ when $\alpha \rightarrow \infty$. Indeed, for $x = 0$, $F(\alpha, x)|_{x=0}$ is equal to α/π and diverges as $\alpha \rightarrow \infty$. For $x \neq 0$, $F(\alpha, x)$ strongly oscillates about the zero value with a damped amplitude. Finally,

$$\int_{-\infty}^{\infty} \frac{\sin \alpha x}{\pi x} dx = 1$$

for any α . Consequently, we see that

$$\lim_{\alpha \rightarrow \infty} \frac{\sin \alpha x}{\pi x} = \delta(x). \quad (\text{III.4})$$

The integral of the form

$$\int_{-\infty}^{\infty} e^{ikx} dk,$$

which is often encountered and which should be understood as

$$\lim_{\alpha \rightarrow \infty} \int_{-\alpha}^{\alpha} e^{ikx} dk = \lim_{\alpha \rightarrow \infty} \frac{2}{x} \sin \alpha x$$

can be expressed in terms of the δ -function. Comparing with (III.4), we obtain

$$\int_{-\infty}^{\infty} e^{ikx} dk = 2\pi\delta(x). \quad (\text{III.5})$$

Other representations of the δ -function are

$$\delta(x) = \frac{1}{\pi} \lim_{\alpha \rightarrow 0} \frac{\alpha}{x^2 + \alpha^2}, \quad (\text{III.4}')$$

$$\delta(x) = \frac{1}{\sqrt{\pi}} \lim_{\alpha \rightarrow 0} \alpha e^{-x^2/\alpha^2}, \quad (\text{III.4}'')$$

$$\delta(x) = - \lim_{\alpha \rightarrow 0} \frac{e^{x/\alpha}}{\alpha(e^{x/\alpha} + 1)^2}. \quad (\text{III.4}''')$$

The delta-function can also be defined as the derivative of a particular discontinuous function $\epsilon(x)$:

$$\begin{aligned} \epsilon(x) &= 0, & x < 0, \\ \epsilon(x) &= 1, & x > 0. \end{aligned} \quad (\text{III.6})$$

It is obvious that $\epsilon'(x) = 0$ for $x \neq 0$. We show that the equality (III.2) also

holds:

$$\begin{aligned}\int_a^b f(x) \epsilon'(x) dx &= f(x) \epsilon(x) \Big|_a^b - \int_a^b \epsilon(x) f'(x) dx \\ &= f(b) - \int_0^b f'(x) dx = f(0) .\end{aligned}$$

Consequently,

$$\epsilon'(x) = \delta(x) . \quad (\text{III.7})$$

We list certain basic properties of the δ -function:

$$\begin{aligned}\delta(-x) &= \delta(x) , \\ \delta'(-x) &= -\delta'(x) , \\ x\delta(x) &= 0 , \\ x\delta'(x) &= -\delta(x) , \\ \delta(ax) &= \frac{1}{a} \delta(x) , \quad a > 0 , \\ \delta(x^2 - a^2) &= \frac{1}{2a} [\delta(x - a) + \delta(x + a)] , \\ \int \delta(a - x) \delta(x - b) dx &= \delta(a - b) , \\ f(x) \delta(x - a) &= f(a) \delta(x - a) , \\ \int f(x) \delta'(x - a) dx &= -f'(a) , \\ \delta(f) df &= \delta(x) dx , \\ \delta[f(x)] &= \frac{1}{|df/dx|} \delta(x - x_0) ,\end{aligned} \quad (\text{III.8})$$

where x_0 are the roots of the equation $f(x_0) = 0$,

$$\int \varphi(x) \delta[f(x) - \alpha] = \left\{ \frac{\varphi(x)}{|df/dx|} \right\}_{f(x)=\alpha},$$

$$\delta(\mathbf{r} - \mathbf{r}_0) = \delta(x - x_0) \delta(y - y_0) \delta(z - z_0), \quad (\text{III.8'})$$

$$\delta(r - vt) = \frac{1}{2\pi} \int e^{i(kr - \omega t)} \delta(\omega - kv) dk d\omega.$$

Since the δ -function has a meaning only provided that integration with respect to its argument is implied, then these equalities also mean that, multiplying the left-hand side of each of them by the continuous function $f(x)$ and integrating with respect to x , we shall arrive at the same results as those which will be given by the right-hand sides. Let us prove, for example, the third relation. For this we consider the integral

$$\int f(x) x \delta(x) dx = f(x) x|_{x=0} = 0$$

and the relation is proved.

The δ -function often proves to be useful in considering Fourier transforms. Thus, if we have the expansion of a certain function $f(x)$ in a Fourier transform

$$f(x) = \int_{-\infty}^{\infty} c(k) e^{ikx} dk, \quad (\text{III.9})$$

then, making use of (III.5), we immediately obtain the expression for the inverse Fourier transform. Indeed, multiplying the left-hand and right-hand sides of the equality (III.9) by $e^{-ik'x}$ and integrating with respect to x , we obtain

$$\begin{aligned} \int_{-\infty}^{\infty} f(x) e^{-ik'x} dx &= \int_{-\infty}^{\infty} c(k) e^{i(k-k')x} dk dx = \\ &= \int_{-\infty}^{\infty} c(k) dk \int_{-\infty}^{\infty} e^{i(k-k')x} dx = \\ &= \int_{-\infty}^{\infty} c(k) 2\pi \delta(k-k') dk = 2\pi c(k'). \end{aligned}$$

Consequently, we have

$$c(k') = \frac{1}{2\pi} \int f(x) e^{-ik'x} dx. \quad (\text{III.10})$$

Analogous relations are also obtained in more complex cases. Formula (III.5) can be considered as the expansion of the δ -function in a Fourier transform.

We now consider the Legendre polynomial expansion of the δ -function:

$$\delta(1 - \xi) = \sum_l B_l P_l(\xi).$$

We find the coefficients B_l by multiplying the left-hand and right-hand sides of the equality by $P_l(\xi)$ and integrating with respect to ξ . Taking into account that

$$\int_{-1}^{+1} P_l(\xi) P_l(\xi) d\xi = \frac{2}{2l+1} \delta_{ll},$$

and

$$P_l(1) = 1,$$

we obtain

$$B_l = \frac{1}{2} (2l+1).$$

Finally we have:

$$\delta(1 - \xi) = \frac{1}{2} \sum_l (2l+1) P_l(\xi). \quad (\text{III.11})$$

Let us prove the following relation:

$$\nabla^2 \left(\frac{1}{r} \right) = -4\pi \delta(\mathbf{r}), \quad (\text{III.12})$$

where

$$\delta(\mathbf{r}) = \delta(x) \delta(y) \delta(z).$$

For this we expand the function $1/r$ in a three-dimensional Fourier integral:

$$\frac{1}{r} = \int c(\mathbf{k}) e^{i\mathbf{k} \cdot \mathbf{r}} dk_x dk_y dk_z. \quad (\text{III.13})$$

Correspondingly, for the function $c(\mathbf{k}) \equiv c(k_x, k_y, k_z)$ we have, making use of (III.10),

$$c(\mathbf{k}) = \frac{1}{(2\pi)^3} \int \frac{1}{r} e^{-i\mathbf{k} \cdot \mathbf{r}} dV \quad (\text{III.14})$$

In formula (III.14) we integrate first with respect to the angle, choosing the polar axis in the direction of the vector \mathbf{k} :

$$\begin{aligned} c(\mathbf{k}) &= \frac{1}{(2\pi)^2} \int_0^\infty \frac{1}{r} r^2 dr \int_0^\pi e^{-ikr \cos \vartheta} \sin \vartheta d\vartheta \\ &= \frac{1}{(2\pi)^2} \frac{i}{k} \int_0^\infty (e^{-ikr} - e^{ikr}) dr. \end{aligned}$$

The last integral is usually calculated by multiplying the integrand by the factor $e^{-\alpha r}$ and by subsequently letting $\alpha \rightarrow 0$. We obtain finally

$$c(\mathbf{k}) = \frac{1}{(2\pi)^2} \frac{2}{k^2}.$$

Substituting $c(\mathbf{k})$ into (III.13), we have

$$\frac{1}{r} = \frac{2}{(2\pi)^2} \int \frac{1}{k^2} e^{i\mathbf{k} \cdot \mathbf{r}} d\mathbf{k}.$$

Taking the Laplacian of the left-hand and right-hand sides, we obtain

$$\nabla^2 \left(\frac{1}{r} \right) = - \frac{2}{(2\pi)^2} \int e^{i\mathbf{k} \cdot \mathbf{r}} d\mathbf{k},$$

and, consequently (see III.5)

$$\nabla^2 \left(\frac{1}{r} \right) = - \frac{2}{(2\pi)^2} (2\pi)^3 \delta(x) \delta(y) \delta(z) = -4\pi \delta(\mathbf{r}). \quad (\text{III.15})$$

In conclusion we note that, as follows from (III.1), the δ -function is a function with dimensions, its dimensionality being the inverse of that of its argument.

It is often convenient to make use of the sign function $\operatorname{sgn} x$ which is defined as

$$\operatorname{sgn} x = \begin{cases} +1 & x > 0, \\ -1 & x < 0 \end{cases} \quad (\text{III.16})$$

Its Fourier transform F_{sgn} and the integral representation is:

$$\begin{aligned} F_{\operatorname{sgn}}(\omega) &= \lim_{\alpha \rightarrow 0} \frac{1}{2\pi} \int_{-\infty}^{\infty} \operatorname{sgn} x e^{-\alpha|x|} e^{i\omega x} dx = \\ &= \lim_{\alpha \rightarrow 0} \frac{i}{\pi} \frac{\omega}{\omega^2 + \alpha^2} = \frac{i}{\pi} P\left(\frac{1}{\omega}\right), \end{aligned} \quad (\text{III.17})$$

where P denotes the principal value of the function $1/\omega$:

$$P(1/x) = \begin{cases} 1/x & x \neq 0, \\ 0 & x = 0. \end{cases} \quad (\text{III.18})$$

In this case

$$\int f(x) P\left(\frac{1}{x}\right) dx = P \int \frac{f(x)}{x} dx, \quad (\text{III.19})$$

where $P \int$ is the principal value of the integral.

The inversion gives

$$\operatorname{sgn} x = \frac{i}{\pi} P \int_{-\infty}^{\infty} \frac{e^{-i\omega x}}{\omega} d\omega. \quad (\text{III.20})$$

FOREWORD

The first Russian edition of 'Theoretical Physics', which appeared in 1962, has been widely used as a textbook.

Numerous comments from colleagues, lecturers and students have been taken into account in preparing this new edition, which is the first one in English and which will also appear as the second Russian edition.

The material has now been divided into 4 volumes covering the following subjects

Volume 1

- Part I Theory of the Electromagnetic Field
- Part II Theory of Relativity

Volume 2

- Part III Statistical Physics
- Part IV Electromagnetic Processes in Matter

Volume 3

- Part V Quantum Mechanics

Volume 4

- Part VI Quantum Statistics and Physical Kinetics

The rapid development of physics and the present wide interest in non-equilibrium and non-stationary processes has compelled us to expand the section on physical kinetics. It has also been transferred to the end of Volume 4 as it is practically impossible to expound this topic without using quantum mechanics.

Part IV – 'Electromagnetic Processes in Matter' – has been substantially revised. Interest in this field has increased recently, mainly in connection with the study of plasmas and plasma-like media, which now have sections devoted to them.

The methods of calculating electrostatic and direct-current fields, and other problems of classical electrodynamics in a medium, are covered very briefly as we have assumed that students will be able to consult the many monographs and handbooks on general physics, electrical- and radio-technology, and the equations of mathematical physics.

As for other modifications and additions, we should draw attention to the introduction of tensor notation, to new ideas in the theories of relativity and electromagnetic fields, the broadening of the introduction to the theory of probability, a brief presentation of the method of correlation functions in statistical physics, the exposition of the thermodynamic theory of ferromagnetism and the theory of propagation of electromagnetic waves in plasma. A number of paragraphs have been rewritten. We have tried to bring the content of the book even closer to the interests of present-day theoretical physics.

The general level of the book has been preserved and it is still intended to form an introduction to theoretical physics. Problems requiring the use of cumbersome or special mathematical apparatus are still excluded, and the most difficult sections are marked by an asterisk. These may be skipped at will, since there is no reference to them in the main text.

In conclusion we would like to express our gratitude to all those who helped us in preparing this book, in particular to A.M. Brodsky, A.M. Golovin, B.M. Grafov, R.R. Dogonadze, V.S. Krylov and especially V.S. Markin and V.V. Tolmachev. I.V. Savelyev discovered a number of misprints which have now been corrected.

L.D. Konkina helped us in editing the manuscript.

We are grateful to the readers and students who used the first Russian edition of the book for sending us their valuable comments which have been taken into account in this edition.

August 1970

FOREWORD TO THE FIRST RUSSIAN EDITION

The continuous development of theoretical physics and the regular expansion of its areas of application create increasing demand for textbooks and manuals.

The rapid development and the complexity of the most recent experimental methods of physical investigation, and the corresponding development and extension of the mathematical apparatus of theoretical physics, have meant that one man usually cannot combine the two methods of investigation. The end of the 19th century and particularly the 20th century therefore saw physicists divided into 'experimentalists' and 'theoreticians', the latter studying physical laws by means of the mathematical methods of theoretical physics.

Obviously, a background in theoretical physics is essential in the education of experimental as well as theoretical physicists.

The experimental and theoretical methods of physical investigation have penetrated into a number of branches of science related to physics (physical chemistry, biophysics, geophysics, astrophysics, and so on) and into technology (metal physics and metallurgical science, thermophysics, electrical technology, radiotechnology, computation, the instrument-making industry etc.). Workers in these branches of science and technology also need a certain minimum knowledge of theoretical physics.

The compilation of a modern textbook on theoretical physics is inevitably associated with certain logical and methodological difficulties. It is impossible at present to divide theoretical physics into classical and quantum parts so that it is also impossible to divide it into separate chapters and sections. For example, the exposition of statistical physics without taking into account the quantum properties of atomic systems is impossible, for it would mean that the general theory remained without practical application. In the theory of electromagnetic processes in matter one has of necessity to make use of the ideas of statistical physics, and so on. It may be that the maximum consistency of composition would be obtained if the book were founded on

quantum mechanics but this is completely inadmissible in a book intended as an introductory treatise. Quantum mechanics requires a certain preparedness and the student must be convinced of the necessity of renouncing obvious classical representations. Compromise solutions, which have justified themselves during many years of teaching theoretical physics at the Moscow Engineering-Physical Institute and Moscow State University, are therefore inevitable.

The following general principles have been applied.

(1) The book is written as an introduction to theoretical physics so that aspects requiring the use of cumbersome or special mathematical apparatus have not been included.

(2) As it is to be used for a systematic study of the subject the course is a unique whole and all material necessary for understanding the later sections is contained in the earlier ones.

(3) It would not be feasible to elucidate experimental facts in addition to problems concerning purely theoretical physics. However, physics is a single science, and an attempt to expound the theoretical aspects without taking experiment into account would be quite wrong. The reader is assumed to have some basic experimental knowledge from university courses in general and atomic physics so that we have confined ourselves to references and, in a few instances, to a schematic description of basic experiments.

(4) The acquaintance assumed with general courses in general and atomic physics has allowed us to rely on a certain (very restricted) knowledge of quantum mechanics in our treatment of statistical physics.

(5) Classical mechanics usually forms a separate course so that this topic has been omitted although detailed reference has been made to handbooks of mechanics.

(6) The book similarly does not cover hydrodynamics, aerodynamics, the theory of heat transfer, or problems related to electrical- and radio-technology.

(7) Detailed reference is made to mathematical manuals. The mathematical apparatus utilized, except in the sections marked by an asterisk, is covered by the usual courses in analysis. In the case of quantum mechanics, however, the mathematical apparatus has been included, since it is of a specific character and is not taught in traditional mathematical courses.

(8) As the book is intended as a systematic course in theoretical physics no attempt has been made to achieve the same level of accessibility in all sections. It is a well-known fact that a student's comprehension and assimilation of difficult material increases as a course progresses, and that this is also true for the associated mathematical apparatus. Moreover, experi-

mental physicists will constantly encounter new problems in quantum mechanics which can only be handled using advanced methods of treatment. The section on quantum mechanics (Part V) therefore deals with some topics having a more advanced character than those in other sections. The analysis of applications of the kinetic equations is similarly treated rather extensively.

The uniqueness of the book's objectives has affected the content of individual sections, so that some topics in modern physics have been included at the expense of more traditional material.

Part I contains the foundations of the theory of the electromagnetic field in a vacuum, based on the system of Maxwell-Lorentz equations. A basic knowledge of electromagnetism is assumed. The focus of attention is the theory of radiation and the motion of charged particles in external fields.

In Part II, devoted to the theory of relativity, a four-dimensional form of representation is adopted which not only corresponds to the spirit of the theory but also predominates in contemporary literature. The problems of dynamics in the theory of relativity are treated in some detail. A number of the most recent applications of the theory of relativity, particularly those related to nuclear physics, are covered here for the first time in a textbook.

Part III is a revised version of Levich's 'Introduction to Statistical Physics' and treats statistical physics and the fundamentals of statistical thermodynamics. Classical thermodynamics would require too much space, and did not seem indispensable.

Part IV contains the theory of electromagnetic processes in matter. Relatively little attention is paid to problems in theoretical electrical- and radio-technology. The phenomenological theory of electric and magnetic properties of matter is analyzed in some detail, and the notion of the physics of the plasma state of matter is given.

In Part V the basic ideas of present-day relativistic quantum mechanics are included as well as the traditional problems of non-relativistic quantum mechanics. Applications to solid-state theory are considered at length.

Part VI contains the essential concepts of physical kinetics, which are not usually presented in a general course on theoretical physics.

The experience of teaching theoretical physics shows that the greatest difficulties are often encountered not in understanding new physical ideas but in the actual mathematical treatments. All mathematical operations have therefore been performed in sufficient detail.

For convenience we have presented a brief derivation of those formulae of

vector analysis which are encountered throughout, as well as the necessary data on Fourier integrals and δ -function theory.

The numbering of formulae and sections starts afresh in each Part and references to appendices have been given Roman numerals.

The author hopes that the readers, after making themselves familiar with the foundations of theoretical physics expounded in this book, will be able to proceed to a more profound study using the many-volume treatise of Landau and Lifshitz. The scientific and educational ideas of their work were of great influence on the author, who is a disciple of Landau.

Parts I–IV and Part VI were written by B.G. Levich. Part V was written by Y.A. Vdovin and V.A. Myamlin under the general scientific guidance of B.G. Levich. Chapter XV * of Part V was written by A.I. Naumov.

The author expresses his gratitude to the colleagues who read the book and the manuscripts, and made a number of valuable remarks: B.M. Grafov, R.R. Dogonadze, V.A. Kiryanov, V.S. Krylov, V.S. Markin, V.P. Smilga, Y.A. Chizmadzhev and Y.I. Yalamov.

The creation of a textbook on theoretical physics sufficiently comprehensive in content and clear in presentation is a very complex task. The author is therefore conscious of the fact that shortcomings and errors will be discovered and would be grateful to receive an account of them which can be taken into consideration in the next edition of the book.

1962

* Chapter 13 of the English edition.

Theoretical Physics: Outline of Vols. 1—4

Volume 1

Part I Theory of the Electromagnetic Field

- Chapter 1 General theory of the electromagnetic field
- 2 The electrostatic field
 - 3 The quasistationary magnetic field
 - 4 The electromagnetic field of arbitrarily moving charges
 - 5 Radiation theory
 - 6 Electromagnetic field in a vacuum and electromagnetic wave scattering
 - 7 The motion of particles in electromagnetic fields

Part II Theory of Relativity

- Chapter 1 General principles of the theory of relativity
- 2 Relativistic mechanics
 - 3 Relativistic electrodynamics

Appendix I, II and III

Subject index

Volume 2 (for details see p. xv)

Part III Statistical Physics

- Chapter 1 The basic concepts of the theory of probability
- 2 The kinetic theory of gases

- 3 Statistical distribution
- 4 Statistical and phenomenological thermodynamics
- 5 Ideal gases
- 6 Systems of interacting particles
- 7 Crystals
- 8 The theory of fluctuations
- 9 Systems with a variable number of particles
- 10 Statistical distributions in quantum statistics and some of their applications

Part IV Electromagnetic Processes in Matter

- Chapter 1 Electromagnetic fields in matter
- 2 Electrostatics
 - 3 Direct electric current and the magnetic properties of matter
 - 4 Quasistationary electromagnetic fields
 - 5 High-frequency fields
 - 6 Matter in the plasma state

Appendix IV

Subject index

Volume 3

Part V Quantum Mechanics

- Chapter 1 The basic concepts of quantum mechanics
- 2 The Schrödinger equation
 - 3 The mathematical apparatus of quantum mechanics
 - 4 Motion in a centrally symmetric field
 - 5 The quasi-classical approximation
 - 6 The matrix form of quantum mechanics
 - 7 Perturbation theory
 - 8 Spin and identity of particles
 - 9 Applications of quantum mechanics to the consideration of the properties of atomic and nuclear systems
 - 10 The theory of diatomic molecules
 - 11 Scattering theory

- 12 The method of second-quantization and radiation theory
- 13 Relativistic quantum mechanics
- 14 Some problems of quantum electrodynamics
- 15 Fundamentals of the theory of elementary particles

Subject index

Volume 4

Part VI Quantum Statistics and Physical Kinetics

- Chapter 1 Quantum statistics
- 2 Physical kinetics
- 3 Kinetic theory of gases and gas-like systems
- 4 Time correlation function method and Onsager's theory
- 5 Solid-state theory

Subject index

Contents of Volume 2

Part III Statistical physics

Chapter 1 The basic concepts of the theory of probability

§ 1 Problems of statistical physics. Necessary results from classical and quantum mechanics	1
2 Basic ideas of the theory of probability	19
3 Mean values and fluctuations	25
4 Normal distribution and moments	31
5 The correlation function	35

Chapter 2 The kinetic theory of gases

6 The simplest statistical system — an ideal gas	39
7 The Maxwell distribution	43
8 Collisions of molecules with the wall of the container. Pressure. The connection of the parameter α with the absolute temperature	47
9 Properties of the Maxwell distribution	51
10 The calculation of characteristic quantities	55
11 Collisions of molecules with each other	59
12 The mean free path	62

Chapter 3 Statistical distribution

13 Quasi-independent systems	66
14 Statistical distribution	68

PART III

STATISTICAL PHYSICS

The Basic Concepts of the Theory of Probability

§1. Problems of statistical physics. Necessary results from classical and quantum mechanics

In this part we shall acquaint ourselves with the fundamentals of the atomic theory of macroscopic bodies. By macroscopic bodies we shall understand systems made up of a very large number of particles. It is usual to divide the atomic theory of macroscopic bodies into two parts — statistical physics and physical kinetics.

In statistical physics one restricts oneself to the treatment of the properties of macroscopic systems whose states do not change in time. The states in which a macroscopic system can remain for an indefinitely long time are called equilibrium states. Hence it can be said that the problem of statistical physics (sometimes called statistical mechanics or physical statistics) is the investigation of the properties and behaviour of macroscopic systems in a state of equilibrium on the basis of the known properties of the particles constituting them.

Macroscopic bodies can be made up of elementary particles — electrons, protons, neutrons and so on, or their combinations — nuclei, atoms and molecules. For brevity we shall call all the particles, i.e. molecules, atoms, electrons, protons etc., microparticles. The major constituents of bodies in

ordinary physical conditions are the atoms or molecules representing their structural units. Only in a high-temperature plasma (see Part IV) does one need to take into account the possibility of the dissociation of atoms into electrons and nuclei.

In statistical physics the properties and the laws of motion of the elementary particles, atoms and molecules, are considered known. The problem consists of finding the behaviour of systems containing very large numbers of particles with known properties.

The investigation of the properties of such macroscopic systems by the methods of statistical physics allows one to show an essential feature of such systems. This is that the behaviour of macroscopic systems is determined by laws of a special type, statistical laws.

It turns out that the general equilibrium properties of systems depend relatively little on the actual properties of the particles constituting the bodies and their laws of interaction. Hence in statistical physics one succeeds in establishing the general laws of behaviour of all macroscopic bodies in a state of equilibrium. In particular, statistical physics allows one to find the universal laws of thermal behaviour of macroscopic bodies (the laws of thermodynamics). However, the application of a number of general relations of statistical physics to concrete systems requires a certain amount of information, albeit very restricted, about the laws determining the behaviour of atomic systems.

We have stressed more than once that classical physics turns out to be inapplicable in the realm of atomic phenomena. Hence the application of the laws of statistical physics to real systems is, in practice, impossible if one tries to restrict oneself to the classical concepts of the motion of atomic particles. Therefore we shall be obliged to present a certain amount of data from quantum mechanics.

In addition to establishing the equilibrium properties of macroscopic bodies it is also of great interest in physics to find the behaviour of bodies whose states change in time. The study of the non-equilibrium properties of macroscopic systems is the problem of physical kinetics. It is clear that the laws of change of state of macroscopic systems — the laws of physical kinetics — are substantially more complex than the laws determining the behaviour of equilibrium systems. In physical kinetics it has not been possible to obtain rigorous laws for the change of state of systems in time which have universal validity. Hence at present there exist only laws for the behaviour of non-equilibrium systems of the simplest character.

We now turn to the presentation of the results required from classical and quantum mechanics. For a clear description of the behaviour of mechanical

systems, the motion of which is described by Hamilton's equations

$$\dot{p}_i = -\frac{\partial H}{\partial q_i}, \quad \dot{q}_i = \frac{\partial H}{\partial p_i} \quad (i=1, 2, \dots, f) \quad (1.1)$$

(where p_i and q_i are respectively the generalized momenta and generalized coordinates, f is the number of degrees of freedom equal to $3N$, N is the number of material points in the system, and H is the Hamiltonian), use is often made of graphical methods. One of these methods is the motion of a state of a mechanical system in phase space.

This is the space in which the generalized coordinates and momenta are chosen as the coordinate axes.

Consider first the case of a system with one degree of freedom. Let the dependence of the coordinate q and momentum p on time be known. Then graphs of $q(t)$ and $p(t)$, showing the change of these quantities in time, can be plotted. It is more convenient, however, to have a graph representing a sequence of the states of a system, than to have individual graphs presenting the change of the position and momentum of the system. In order to obtain the graph of a sequence of states it is necessary to match the two graphs $q(t)$ and $p(t)$, eliminating the time from them. We choose the generalized coordinate q as the x -axis, and the generalized momentum p as the y -axis. The curve in fig. III.1 shows the change of states of the system. Thus, for example, at point 1 the system had a coordinate q_1 and a momentum p_1 , at point 2 it had a coordinate q_2 and a momentum p_2 and so on. As the time increases the coordinate q of the system and its momentum vary according to the law shown by the graph. The space of fig. III.1 is called phase space. It should be strongly emphasized that phase space has nothing in common with real space and is a purely imaginary concept.

To each point of phase space there corresponds a definite state of the system. A point whose position in phase space characterizes a state of the system is called the representative point. As the state of the system changes,

Fig. III.1

i.e. as the position and momentum of the system vary in real space, the position of the representative point in phase space changes and the point describes a certain phase trajectory. The form of this trajectory is not at all like that of the real trajectory. However, they are connected, as well as with the law of change of the momentum, by a one-to-one correspondence.

In order to picture the above more clearly, we shall consider the motion of a linear harmonic oscillator moving under the action of a quasi-elastic force $F = -\kappa q$ about the origin $q = 0$. The equation of motion has the form

$$m\ddot{q} = -\kappa q. \quad (1.2)$$

It is easily integrated. We have

$$q = A \sin(\omega t + \alpha). \quad (1.3)$$

In this case the momentum of the oscillator is equal to

$$p = m\omega A \cos(\omega t + \alpha). \quad (1.4)$$

where A is the amplitude and α is the phase, determined by the initial conditions; the frequency is

$$\omega = 2\pi\nu = \sqrt{\kappa/m}.$$

Formula (1.3) represents the equation of the real motion. In order to find the trajectory of the representative point in phase space it is necessary to find the relation between p and q . Squaring and adding up eqs. (1.3) and (1.4), we find

$$\left(\frac{p}{m\omega A}\right)^2 + \left(\frac{q}{A}\right)^2 = 1.$$

This is the equation of an ellipse. Thus, for oscillations about the point $q = 0$ with an amplitude A the representative point in phase space describes an ellipse with semi-axes $a = A$ and $b = m\omega A$ (fig. III.1). Its area S is equal to $S = \oint p dq = \pi ab = \pi m\omega A^2$. Also, calculating the energy of the oscillator ϵ , we have

$$\epsilon = \frac{p^2}{2m} + \frac{1}{2}\kappa q^2 = \frac{1}{2}\kappa A^2, \quad (1.5)$$

from which we find the important relation

$$\epsilon = \frac{S_K}{2\pi m\omega} = \nu \oint p \, dq . \quad (1.5')$$

The notion of phase space can also be introduced for a system with more than one degree of freedom. In this case the number of dimensions of the phase space is obviously equal to twice the number of degrees of freedom, since for each degree of freedom the coordinate is taken as one axis, and the momentum is taken as another axis. In the case of systems with a large number of degrees of freedom the phase space has very many dimensions and cannot be shown graphically. Nevertheless, in this case the concept of phase space also proves to be of great use. In what follows we shall need the expression for a volume element in phase space. Generalizing the usual definition of a volume element $dV = dx dy dz$ to the case of many dimensions, one can write the following expression for an element of phase space

$$d\Gamma = dq_1 dq_2 \dots dq_{3N} dp_1 dp_2 \dots dp_{3N} , \quad (1.6)$$

where dq_i is the differential of the i th coordinate, and dp_i is the differential of the i th momentum corresponding to this coordinate ($i = 1, 2, \dots, 3N$). The product on the right-hand side of the expression (1.6) involves the differentials of $3N$ generalized coordinates and $3N$ momenta as factors.

In addition to the idea of phase space, use is often made of the ideas of configuration space and momentum space.

The representative space of $3N$ dimensions, in which generalized coordinates are chosen as the axes, is called the configuration space. The set of all positions of the particles of a system is characterized by the position of a representative point in the configuration space. An element of the configuration space is

$$dV_{\text{conf}} = dq_1 \dots dq_{3N} . \quad (1.7)$$

In momentum space the $3N$ components p_1, p_2, \dots, p_{3N} of the momenta of the particles serve as the coordinate axes. A representative point characterizes the value of all the momenta of the particles. An element of the momentum space is equal to

$$dV_{\text{mom}} = dp_1 \dots dp_{3N} , \quad (1.8)$$

so that

$$d\Gamma = dV_{\text{conf}} dV_{\text{mom}}. \quad (1.9)$$

The notion of phase space, as well as those of configuration and momentum space, are very useful for a clear representation of the laws of statistical physics.

The motions of mechanical systems are determined by the so-called dynamical laws. A characteristic feature of a dynamical law is that, if the initial state of the system and the action of surrounding bodies on the system are known, the state of the system at any subsequent instant of time can be determined unambiguously. In other words, for given forces acting on the system the initial state of the system unambiguously determines its subsequent overall motion.

General features characteristic of a dynamical law show up not only in mechanics but also in a wide range of other physical phenomena, in particular in electrodynamics. However, it would in principle be incorrect to state, as was done by a number of investigators, beginning with Laplace, that dynamical laws exhaust all forms of causality and mutual conditionality of phenomena in nature.

As we shall see below, the behaviour of macroscopic bodies is not given by dynamical laws but is determined by laws of another type — statistical laws.

In the following we shall assume that atoms, molecules and other particles forming macroscopic systems move according to the laws of quantum mechanics. The latter are presented in Part V of this book. Here we shall give, without proof, the most necessary data and relations.

A distinctive feature of all microsystems (atoms, molecules, etc.) is the fact that in certain conditions they can be in discrete, or quantum, states. Experimental and theoretical (see Part V) investigation of the states of atoms and molecules has shown that their energy can assume a discrete series of values $\epsilon_1, \epsilon_2, \epsilon_3, \dots$. The transition between these states, for example, between ϵ_1 and ϵ_2 , takes place without passing through states with intermediate energies between ϵ_1 and ϵ_2 . States with intermediate energies do not exist. Thus, atoms can absorb or emit energy only in definite amounts or quanta.

Not only the energy but also a number of other quantities characterizing the states of atomic systems have a discrete, quantum, character (for example, the angular momentum, which in the atom can assume a discrete series of values and can vary only in jumps). The energy and similar quantities are called quantized quantities, and the set of their possible values is called the spectrum. The quantized values of energy are also often called energy levels.

The existence of quantized states radically contradicts the laws of classical mechanics, in which the states of a system can always change continuously.

At the beginning of the development of atomic theory some formal rules were obtained, by means of which it was possible to choose from all states allowed according to classical mechanics, those which can actually be realized in an atom. These rules were called Bohr's quantum conditions.

Subsequent development of atomic physics showed that the concepts of classical physics needed an even more profound alteration.

At present the laws of motion of microparticles are adequately described by quantum mechanics. Postponing our detailed acquaintance with them till Part V, we shall, in the meantime, make use of some of them.

1.1. *Quantized motion of a particle in a box*

The simplest quantum-mechanical system – a microparticle with mass m confined in a one-dimensional box with impenetrable walls – will be considered in §8 of Part V. The motion of such a particle is restricted by the size of the box to the region $0 \leq x \leq a$, where the potential energy is equal to zero. At the limits of the region, at $x = 0$ and $x = a$, the potential energy of repulsion is infinitely large and the particle cannot go out of the box.

From the general propositions of quantum mechanics it follows that the energy and momentum of such a particle should have a discrete series of values. The allowed values of the energy and momentum are given by the formulae

$$p_n = \frac{nh}{2a}, \quad (1.10)$$

$$\epsilon_n = \frac{p_n^2}{2m} = \frac{h^2 n^2}{8ma^2}. \quad (1.11)$$

Here h is a quantity called the universal quantum constant or Planck constant. It is equal to $h = 6.62 \times 10^{-27}$ erg sec. n is a quantity running through the integer values ($n=1, 2, 3, \dots$), and called the quantum number.

Formula (1.11) shows that the energy levels of the particle form a discrete series or spectrum. The separation between neighbouring energy levels is equal to

$$\Delta\epsilon_n = \epsilon_{n+1} - \epsilon_n = \frac{h^2}{8ma^2} (2n+1). \quad (1.12)$$

We see that these separations are smaller the larger the mass of the particle and the dimension a of the region of motion.

In the case of the motion of a particle in a region of sufficiently large dimensions the separation between energy levels is so small that for practical purposes they form a continuous spectrum. Similarly any particle with a large, macroscopic mass has a continuous energy spectrum.

The relative separation between energy levels is obviously equal to

$$\frac{\epsilon_{n+1} - \epsilon_n}{\epsilon_n} = \frac{2n+1}{n^2}. \quad (1.13)$$

For $n \gg 1$ the relative separation between energy levels or the magnitude of the "steps" of the energy spectrum is equal to

$$\frac{\epsilon_{n+1} - \epsilon_n}{\epsilon_n} \approx \frac{2}{n}. \quad (1.14)$$

For large quantum numbers the relative separation between energy levels decreases rapidly with increasing n , so that the discrete character of the spectrum is smoothed away.

Thus we see that the discreteness of the energy levels of a quantum particle becomes apparent: 1) for small mass, 2) for motion of the particle in a small region, and 3) for small quantum numbers. On the contrary, for large masses, for motion in a large region, and for large quantum numbers the quantization shows up relatively weakly.

In order to have a feeling for the orders of magnitude, let us put in some numbers. For example, let a proton with mass $m_p = 1.7 \times 10^{-24}$ g move in a box which has atomic dimensions ($a = 10^{-8}$ cm). Expressing the energy in electron-volts we find

$$\epsilon_n = 0.02n^2 \text{ eV}$$

and

$$\Delta\epsilon_n = 0.02(2n+1) \text{ eV}.$$

For small n 's the separations between energy levels turn out to be of the same order of magnitude as the energies themselves (for example, for $n = 3$, $\epsilon_3 \approx 0.2$ eV, $\Delta\epsilon_3 \approx 0.1$ eV).

However, the situation is different when a proton moves in a region of macroscopic dimensions (for example, $a = 1$ cm). Then

$$\epsilon_n = 2 \times 10^{-18} n^2 \text{ eV} \quad (1.15)$$

and the separation between neighbouring levels is

$$\Delta\epsilon_n = 2 \times 10^{-18} (2n+1) \text{ eV} . \quad (1.16)$$

Let the proton have an energy of 2×10^{-2} eV (as will be seen in what follows such an energy is possessed by atoms in thermal motion at normal temperature). Then from (1.15) we find $n \approx 10^8$. For such values of n the relative separation between energy levels is negligibly small. Thus, when the proton moves in a region of sufficiently large dimensions the discrete, quantum character of its states is manifested very weakly. The same holds, to an even higher degree, for a macroscopic ball with a mass of, say, 1 g. The motion of such a ball is described with a high degree of accuracy by the laws of classical mechanics.

The regularities appearing in the special case which we have considered, of a particle moving in a box, are of general character.

In Part V it will be shown that classical mechanics represents the limiting case of quantum mechanics into which the latter goes over when effects proportional to the Planck constant can be disregarded. This is possible for phenomena which take place on a relatively large scale, when the masses of the particles, the dimensions of the region of motion and so on are sufficiently large.

It turns out that the transition from quantum mechanics to classical mechanics can be made in two ways. Simply, by assuming $\hbar = 0$, we disregard all quantum effects — the existence of the wave properties of microparticles, the quantization of energy and other quantities, and so on. However, it can also be assumed that \hbar is small but nevertheless different from zero. It turns out that in this approximation the wave properties of particles are shown very weakly. Particles can be assumed to be moving on definite trajectories, as in classical mechanics. However, the quantization of states still arises in the fact that only some of the classical trajectories are possible. Such an approximation is called quasi-classical (as distinct from the classical approximation, in which the quantum properties of particles are not taken into account at all). In order to see what the character of the restrictions imposed upon the classical trajectories consists of, we again turn to the example of a particle in a one-dimensional box. We assume that use can be made of the concepts of classical

Fig. III.2

mechanics and that the particle can be considered as a material point moving between reflecting walls. The phase diagram in fig. III.2 shows the sequence of its states. We now take into account the quantization of states and out of all possible states we choose those which satisfy the quantization condition (1.10). Not all states $p = \text{const}$ are possible, only those with a separation determined by the relation (1.10). Fig. III.2 shows the n th state (the solid line) and the $(n-1)$ th state (the dotted line). The number of possible quantum states with a momentum lying between $p_n = hn/2a$ and $p = h/2a$ is equal to n .

We now calculate the area S_n in the phase plane, corresponding to these n states. Obviously,

$$S_n = \oint p \, dx = 2p_n a = hn.$$

The integral $\oint p \, dx$ denotes the integral of p taken over the total cycle of motion, i.e. over the area bounded by the solid straight lines in fig. III.2. This integral is equal to

$$\oint p \, dx = \int_0^a p \, dx - \int_a^0 p \, dx = 2 \int_0^a p \, dx.$$

If the lines corresponding to other possible states are drawn, then the entire surface will be divided into cells. It is easily seen that the area of all the cells is the same and equal to h . Indeed, the distance between possible states along the p -axis is equal to

$$\frac{hn}{2a} - \frac{h(n-1)}{2a} = \frac{h}{2a}.$$

The area of a cell (hatched in the drawing) is equal to $2(h/2a)a = h$.

Thus, in the quasi-classical approximation to each possible state there corresponds in phase space a cell having an area h . The stationary, possible states of a system are those for which the condition

$$\oint p \, dx = nh \quad (1.17)$$

is fulfilled. This equality is called the Bohr condition of the old quantum theory.

The example considered is typical, and the condition (1.17) is of a general character. In order to convince ourselves of this we shall consider another example — a linear oscillator. A diatomic molecule is an example of an oscillator performing small vibrations about the equilibrium position, as we shall see below. In quantum mechanics (see § 10 of Part V) it turns out that the state of an oscillator is characterized by a quantum number k which can take on a number of half-integer values

$$k = \frac{1}{2}, \frac{3}{2}, \frac{5}{2}, \dots, \quad k = n + \frac{1}{2}$$

(n is an integer). The energy of an oscillator takes on a number of values (see (10.13) of Part V)

$$\epsilon_n = h\nu \left(n + \frac{1}{2}\right). \quad (1.18)$$

When an oscillator passes from a given quantum state to a neighbouring, lower, one it emits radiation with a frequency

$$\nu_{mn} = \frac{\epsilon_m - \epsilon_n}{h} = \nu,$$

equal to the natural frequency of oscillation of the classical oscillator*.

Comparing (1.18) with formula (1.5') we see that the quantum condition (1.18) selects as possible those states of an oscillator for which the relation

* In quantum mechanics it turns out that for an oscillator only the transitions between neighbouring states are possible, so that $m = n + 1$. See Part V.

$$\oint p \, dq = h(n + \frac{1}{2}) . \quad (1.19)$$

holds.

All possible paths of the representative point of the oscillator, corresponding to quantum states n_1, n_2, \dots , are represented by ellipses. The area of the ellipse corresponding to a state n differs from that of the ellipse corresponding to a state $n-1$ by an amount

$$\oint_n p \, dx - \oint_{n-1} p \, dx = h ,$$

where the subscript denotes the number of the state. In fig. III.2 this area is hatched.

We arrive at the conclusion that a cell in phase space the area of which is equal to h corresponds to each quantum state of an oscillator.

Thus, in the quasi-classical approximation (for large quantum numbers or dimensions of the region of motion, and for large particle masses) the condition of quantization of states consists of the fact that to each quantum state of an arbitrary system there corresponds a cell in phase space having an area h . It can be shown that the form of the cell is arbitrary.

Up to now we have confined ourselves to the consideration of systems having one degree of freedom. However, it turns out that the results obtained are of general character and can be applied to a system with an arbitrary number f of degrees of freedom. The state of such a system is characterized by the definition of f quantum numbers (for examples see below). The phase space of a system with f degrees of freedom has $2f$ dimensions.

Again as an illustrative example we shall consider the motion of a free particle in a box with ideally reflecting walls, but now having three dimensions. For simplicity we assume the box to have the form of a cube with edge a . Since the motion in any of the three directions is independent and all the directions are in principle equivalent, we can write for each of the components of the momentum

$$|p_x| = \frac{hn_1}{2a} , \quad |p_y| = \frac{hn_2}{2a} , \quad |p_z| = \frac{hn_3}{2a} . \quad (1.20)$$

The motion of a particle in the three dimensions is characterized by three quantum numbers n_1, n_2, n_3 which can take on a number of integer values. The energy of the particle is equal to

$$\epsilon = \frac{p_x^2 + p_y^2 + p_z^2}{2m} = \frac{h^2}{8ma^2} (n_1^2 + n_2^2 + n_3^2). \quad (1.21)$$

It is characterized by a number $n = \sqrt{n_1^2 + n_2^2 + n_3^2}$, but for given n does not depend on the value of the separate contributions to this n of each of the quantum numbers n_1, n_2, n_3 . Because of this, several different quantum states can correspond to one and the same value of the energy. For example let $n_1 = 1, n_2 = 2, n_3 = 2$ and $n_1 = 2, n_2 = 1, n_3 = 2$. In both cases $n = 3$, so that both states have the same energy. If one and the same energy corresponds to several different states, then such states are called degenerate.

The number of states having the same energy is called the degeneracy or statistical weight.

The phase space of a particle in a box has six dimensions, so that it is impossible to present it graphically. However, it can be said that it is split into three subspaces of two dimensions, each corresponding to the motion in the corresponding direction. A simple calculation leads us then to the conclusion that to each state (the triplet of numbers n_1, n_2, n_3) of the particle there corresponds a volume h^3 .

In the most general case of an arbitrary system having f degrees of freedom it can be shown that in the transition to the quasi-classical approximation, the motion of the system can be considered in the same way as in classical mechanics, but with a restriction imposed on the possible states: to each quantum state of a system with f degrees of freedom in the quasi-classical approximation there corresponds a cell in its phase space having a volume h^f . The proof of this statement will be given in §41 of Part V.

In the exposition of statistical physics we shall need, in most cases, to consider the motion of relatively heavy particles (for example, molecules) moving in macroscopic volumes, as well as the behaviour of macroscopic bodies containing an enormous number of molecules.

For such systems quantum effects play a relatively minor role. Nevertheless, as will be seen later, they cannot be completely disregarded. Hence we shall take them into account in the quasi-classical approximation, based on the quantization rule quoted above. In other respects, if not specified otherwise, the motion of the systems will be considered classically. Of course, in certain cases when the mass of the system is sufficiently large, one can pass over from the quasi-classical treatment to the purely classical one and completely disregard quantum effects. This will be done in Chapter 3. However, in general discussions and conclusions we shall assume the states of the system to be discrete.

1.2. Number of quantum states

The notion of the number of quantum states corresponding to the energy of a system lying in a given interval between ϵ and $\epsilon + \Delta\epsilon$, will play an important role in our overall further development. We shall denote it by $\Omega(\epsilon)\Delta\epsilon$.

We shall first calculate this number for a particle moving freely in a box. According to the above, there corresponds to each state a volume h^3 of the phase space. Hence the number of states sought for will be found by calculating the volume of the phase space corresponding to the energy of the particle lying between ϵ and $\epsilon + \Delta\epsilon$, and dividing it by h^3 .

In calculating the phase volume we shall make use of the fact that in the quasi-classical approximation quantum jumps are small, and we shall assume the momentum to vary almost continuously. Then an element of the phase space can be written in the form (1.6). The volume of the phase space corresponding to an energy of the particle smaller than a given value is obtained by integrating the expression (1.6) with respect to all coordinates and all momenta satisfying the relation $0 \leq p \leq \sqrt{2m\epsilon}$. Passing over to spherical coordinates, we can write

$$\begin{aligned} \Gamma &= \int dx dy dz \int dp_x dp_y dp_z \\ &= 4\pi V \int_0^{\sqrt{2m\epsilon}} p^2 dp = \frac{4\pi p^3 V}{3} \Big|_0^{\sqrt{2m\epsilon}} = \frac{4\pi(2m)^{\frac{3}{2}} \epsilon^{\frac{3}{2}} V}{3}. \end{aligned} \quad (1.22)$$

The volume of phase space corresponding to energies in the range between ϵ and $\epsilon + \Delta\epsilon$ is

$$\Delta\Gamma = \frac{\partial\Gamma}{\partial\epsilon} \Delta\epsilon = 4\pi m V \sqrt{2m\epsilon} \Delta\epsilon. \quad (1.23)$$

The number of states of the particle with energies which lie between ϵ and $\epsilon + \Delta\epsilon$ is equal to

$$d\Omega = \Omega(\epsilon) \Delta\epsilon = \frac{1}{h^3} \frac{\partial\Gamma}{\partial\epsilon} \Delta\epsilon = \frac{4\pi m V \sqrt{2m\epsilon}}{h^3} \Delta\epsilon. \quad (1.24)$$

Since all quantities in the quasi-classical approximation vary almost continuously, we shall often write $\delta\epsilon$ instead of $\Delta\epsilon$ in formula (1.24), assuming $\delta\epsilon$ to be infinitely small.

It should be borne in mind that for large values (large quantum numbers)

the number of states corresponding to even a very small interval $\Delta\epsilon$ turns out to be enormous. Thus, for example, in the case of hydrogen atoms for $\Delta\epsilon = 0.005$ eV, $\epsilon = 0.025$ eV and $V = 1$ cm³ the value of $\Omega \Delta\epsilon$ turns out to be about 4×10^{28} . This value in practice differs very little from its classical limit i.e. infinite (as $\hbar \rightarrow 0$). Nevertheless, the finiteness of the number of quantum states, as we shall see later, plays an important role.

For an arbitrary system having f degrees of freedom

$$\Delta\Gamma = \frac{\partial\Gamma}{\partial\epsilon} \Delta\epsilon, \quad (1.25)$$

where $\Delta\Gamma$ is determined by formula (1.6). Correspondingly, for the number of states we have

$$\delta\Omega = \Omega(\epsilon)\delta\epsilon = \frac{1}{h^f} \frac{\partial\Gamma}{\partial\epsilon} \delta\epsilon, \quad (1.26)$$

or

$$\Omega = \int d\Omega = \Delta\Gamma/h^f. \quad (1.26')$$

The quantity $\Omega(\epsilon)$ can be called the number density of states per unit energy range. In what follows we shall, for brevity, simply call $\Omega(\epsilon)$ the number of states with given energy. This should not lead to misunderstanding.

For what follows we shall need one more sufficiently obvious property of Ω . That is, if there is a system consisting of two independent parts, and the number of states of each of the parts is equal to Ω_1 and Ω_2 respectively, then the number of states of the combined system is equal to $\Omega = \Omega_1 \Omega_2$. Indeed, the phase volume of a combined system is by definition equal to $d\Gamma = d\Gamma_1 d\Gamma_2$, from which the above mentioned property follows immediately.

In the general case

$$\Omega = \prod_i \Omega_i, \quad (1.27)$$

where the product \prod_i is taken with respect to all parts of the system.

We shall make use of this property of Ω in order to estimate the number of states of a system consisting, for example, of 100 independent particles moving in a volume $V = 1$ cm³ with an energy within the interval $\Delta\epsilon = 0.005$

eV, for $\epsilon = 0.025$ eV and a mass equal to that of the proton. We find

$$\Omega = \Omega_1 \Omega_2 \dots = (4 \times 10^{28})^{100} \approx 10^{2860}.$$

1.3. Spin

Up to now, in considering an individual microscopic particle (for example, an electron or proton), we have assumed that its state is completely characterized by the definition of three quantum numbers corresponding to three degrees of freedom. However, it turns out that for a complete characterization of the state of an elementary particle one more quantum number must be specified.

A large number of particles possess, besides an orbital angular momentum, an additional, intrinsic angular momentum which is not associated with a spatial displacement. It is called the spin. The smallest angular momentum which can be possessed by an elementary particle is its spin. Most elementary particles (electrons, neutrons, protons) possess a spin s equal to $\frac{1}{2}\hbar/2\pi$. This means that the spin projection s_z onto an arbitrary z -axis in space can have two values: $\frac{1}{2}\hbar/2\pi$ and $-\frac{1}{2}\hbar/2\pi$. It is said that the spin coordinate takes on two values: $\frac{1}{2}$ and $-\frac{1}{2}$. The spin of complex particles can be integer as well as half-integer, depending on the elementary particles constituting them.

1.4. The principle of identity of elementary particles

It turns out that the idea of the discrete character of the states of a system and, in particular, discrete energy levels, allows one to treat a wide range of problems which were unsolved in classical physics. However, in addition it will be necessary also to take into account some other features of quantum systems which basically affect the behaviour of real macroscopic systems. In the following we shall often have to deal with systems consisting of numbers of identical particles (for example, electrons or atoms of given type). The laws of the behaviour of such systems in quantum mechanics differ sharply from classical laws. In classical physics, however similar physical bodies may be in their properties, in principle one can always follow their individual motion and distinguish them from one another.

In quantum mechanics the situation is radically different. The reason for this lies in the fact that in quantum mechanics the principle of identity of like particles holds. According to this principle all particles of a given kind (for example electrons) entering into a given quantum-mechanical system are completely identical. In a system consisting of particles of a given kind the states do not change when particles are interchanged.

For example, let the system consist of two electrons. The first electron is in a state characterized by a set of quantum numbers n_1 , and the second electron is in a state with quantum numbers n_2 . If the states of these electrons are exchanged, then we obtain a state of the system with the same energy. At first sight the impression that the states of the system are two-fold degenerate may arise. However, from arguments based on the general propositions of quantum mechanics as well as from statistical considerations it is possible to state that this is not so (see §37 and §64 of Part V).

The identity of particles of a given kind is so complete that, for example, the exchange of an electron in a given state by another is not a physical event. Hence it makes no sense to say that electron No. 1 is in a state 1 and electron No. 2 is in a state 2. It should be noted that a system of two electrons is in a definite state. From this statement, which follows directly from a number of experimental facts, very important consequences for statistical physics are obtained. We shall acquaint ourselves with these in Chapter 5, and, in particular, in Chapter 10.

The properties of systems of particles with integer spin differ so fundamentally from those of systems of particles with half-integer spin that, reasoning strictly, it is necessary to speak of two different aspects of quantum mechanics: one for particles with integer spin and the other for those with half-integer spin. This is apparent from the following. For particles with half-integer spin the so-called Pauli exclusion principle holds: "only one particle with half-integer spin can be in each quantum state".

The exclusion principle is often formulated in a somewhat different way: "no more than two electrons with an opposite spin orientation can be in each quantum state". The equivalence of the two formulations is obvious.

For particles with integer spin there is no restriction upon the number of identical particles occupying a given quantum state. Below it will be shown that this fact radically affects the statistical behaviour of systems consisting of particles with integer spin in comparison with those of half-integer spin.

1.5. *Energy levels of a system consisting of a large number of particles*

Consider a system consisting of N identical atoms or molecules, assuming N to be a large number. From general considerations it is clear that, since the system is macroscopic, the internal energy of the system must vary continuously and quantum effects should not be of essential importance. We shall see now how a continuous energy level distribution arises when atoms with discrete energy levels are combined.

For simplicity we shall consider two hydrogen atoms each in the same non-degenerate state with energy ϵ_0 a large distance apart (in comparison with

their dimensions). At an infinitely large distance the atoms do not interact with each other and the energy of the entire system ϵ is equal to the sum of the energies of the two atoms, i.e.

$$\epsilon = 2\epsilon_0.$$

The state of the system will be two-fold degenerate: the state of the system when one electron is near the first nucleus and the second electron is near the second nucleus will possess the same energy as when the electrons are exchanged, in view of the identity of electrons.

Now draw the atoms nearer to a distance such that they may interact with each other. Calculation shows that when the interaction arises the energy level of the system splits into two levels lying close to each other. It is said that the interaction has removed the degeneracy. This will be treated in detail in §54 of Part V.

If one continues to bring the atoms nearer forming a molecule, the splitting of the levels will increase (fig. III.3, the lower level). Very often the energy levels of each of the atoms are in themselves degenerate. Then there arise from one energy level not two but a larger number of levels of the system of interacting particles (fig. III.3, two upper levels). We see that the number of energy levels in a system of interacting particles turns out to be larger than in a system of separated particles. The degeneracy of the levels is removed by the interaction. This result is not unique to a system of two atoms, but is of general character. If the system is one of atoms, characterized by quantum numbers, then in forming a system of strongly interacting particles, for example a crystal, all the energy levels of individual atoms split into individual energy levels of the system as a whole. The latter, in general, are not degenerate.

If the number of atoms in the system (or, more precisely, the number f) is large, then the total number of energy levels in the system turns out to be enormous. They approach each other rapidly with increasing energy (as is seen in fig. III.3; compare the first, second and third level), and for large f and large excitation energies they merge almost completely, forming continuous bands of allowed energy levels.

From this it is clear that the statement about the continuous variation of the energy of a macroscopic body is not completely true. The lowest energy levels are discrete. As the energy increases energy levels approach each other rapidly and the energy of the system becomes continuous. We shall see later that the discreteness of the lowest energy levels in macroscopic systems fundamentally affects their behaviour at very low temperature, close to absolute zero.

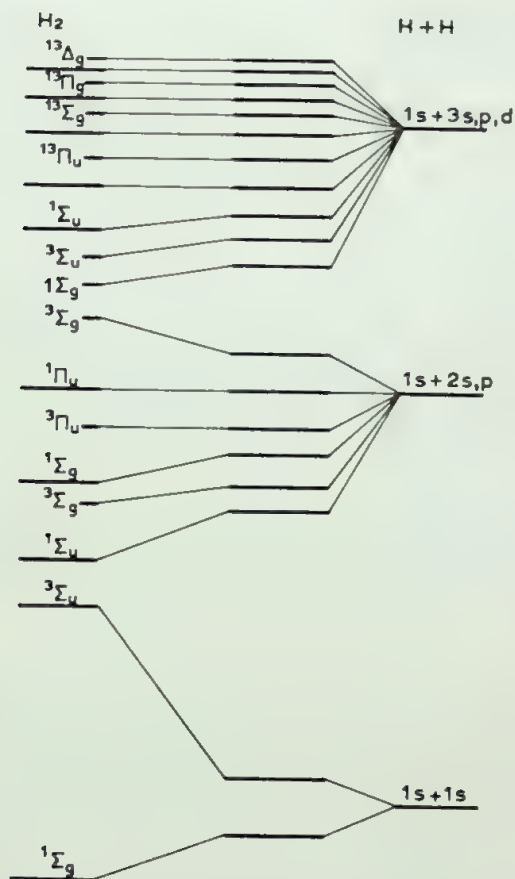

Fig. III.3

§2. Basic ideas of the theory of probability

Our next problem is the study of statistical laws in systems consisting of a very large number of particles.

This study will be based on the mathematical apparatus of the theory of probability.

We shall not discuss the theory of probability in the form in which it is done in mathematical courses. We shall introduce from the very beginning a

special definition of probability, which is completely equivalent to that adopted in the mathematical theory of probability but is more obvious and convenient in considering probability processes in statistical physics. This definition is closely associated with the concept of the relation between the probability and the frequency of occurrence of an event, used in every-day practice.

Consider a completely arbitrary physical system which can be in different physical states. We assume at first that these states form a discrete series, and number them by the integers 1, 2, 3, We denote by L any quantity depending on the state of the system. The quantity L can represent, for example, the energy, volume, compressibility or any other quantity which is a function of the state and changes with a change of the state of the system. We consider L to be a single-valued function of the state of the system, so that to each state 1, 2, 3, ... there corresponds a well-defined value of the quantity L : L_1, L_2, L_3, \dots . Conversely, if the quantity L has a value L_i , then this means that the system must be in the i th state.

Assume that in the course of a very long time T by virtue of diverse processes taking place in the system its states change in such a way that it passes through a sequence of different states 1, 2, 3, ..., i , For clarity we assume that in the course of the entire time T the value of the quantity L is measured regularly every Δt seconds.

The system will exist in certain states for a long time and will be in them often, whereas other states will be occupied by it for only a negligible time. As a result of the measurements we shall obtain some value of L more often than others. Let the system spend a time t_i , constituting a part of the total observation time T , in a certain state i . As a result of $N_i = t_i/\Delta t$ measurements it will be found that the quantity L has the value L_i . The total number of measurements will obviously be equal to $N = T/\Delta t$. The limit of the ratio of the number of measurements giving a value of L equal to L_i to the total number of measurements, as the latter increases indefinitely, i.e.

$$w_i = \lim_{N \rightarrow \infty} \frac{N_i}{N}, \quad (2.1)$$

will be called the probability of the i th state w_i or the probability of the value L_i . In other words, the probability of the i th state w_i is defined as the limit of the ratio of the time t_i during which the system is in this state to the total observation time T as the latter increases indefinitely:

$$w_i = \lim_{T \rightarrow \infty} \frac{t_i}{T}. \quad (2.2)$$

It is necessary to see clearly that the probability of a given state i and the probability for the quantity L to have the value L_i corresponding to the state i are the same. Hence instead of (2.2) we can write

$$w_{L_i} = \lim_{T \rightarrow \infty} \frac{t_i}{T}. \quad (2.3)$$

where w_{L_i} is the probability for the quantity L to have the value L_i .

The definition (2.2) implies the assumption that the limit of the ratio t_i/T exists. The existence of this limit is ensured in the case where during the course of the entire observation time the system is in unchanged external conditions. If this is not so and the external conditions may vary continuously during the course of the measurements, the ratio t_i/T may not tend to any limit. Thus, for example, if we considered a gas expanding indefinitely, then the system would not be in any state for a finite time interval. Its states would vary continuously during the course of the entire observation time. Hence the limit of the ratio t_i/T would not even exist.

In practice one often encounters systems whose states do not vary in a discrete way but continuously. In other words, the quantities characterizing the state of the system often run through a continuous series of values. In this case the probability definition (2.3) does not have a direct meaning. The system will spend an infinitely short time in a state in which the quantity L has a value exactly equal to L_i . Hence, as in other cases where one has to deal with continuously changing quantities, it is necessary to speak not of the value L_i but of a certain interval of the value of this quantity. We therefore have to speak of the probability for the quantity L to have a value lying in the interval between L and $L + dL$. We shall denote this probability by dw_L . By definition,

$$dw_L = \lim_{T \rightarrow \infty} \frac{\Delta t_L}{T},$$

where Δt_L is the time during the course of which the system is in the states corresponding to the values of L lying between L and $L + dL$. It is obvious that the time Δt_L and, consequently, also the probability dw_L , are proportional to the value of the interval dL , other things being equal. Hence it is convenient to write dw_L in the form

$$dw_L = \rho(L) dL, \quad (2.4)$$

where $\rho(L)$ is the probability for the value of L to lie in a certain "unit" interval. The function $\rho(L)$ is called the probability density. It replaces the probability itself in those cases when the value of L can change continuously.

In addition to the definition (2.2), use is also made in statistical physics of another definition of probability.

Instead of considering the changes of state of a system in time, one can imagine a set of systems which are identical with the given system but which are at a certain instant of time distributed randomly over all possible states. Such a system is called a statistical ensemble. We shall determine the number of systems in an ensemble which are in different possible states. Out of the total number N of systems in the ensemble let N_i systems be in the i th state. Then the probability that a system will be detected in this state in a random measurement is equal to

$$w_i = \lim_{N \rightarrow \infty} \frac{N_i}{N}. \quad (2.5)$$

The probability defined by formula (2.5) is called the probability with respect to the ensemble.

Now let there be a complex mechanical system moving on a certain trajectory in phase space. The complexity of the trajectory rules out the possibility of observing it directly and the phase points are distributed randomly in phase space. The probability of detecting the system in a given region of phase space is, according to (2.1), determined by the time of stay of the system in this region. Instead of observing the process of displacement of the representative point in phase space in time, one can consider an ensemble of systems differing in their initial conditions. If the initial conditions are distributed randomly, then the probability for the system to be found in the i th region of phase space is determined by the number of representative points in this region corresponding to different systems of the ensemble. It is natural to assume that the number of such points for an ensemble is proportional to the time of stay of an individual system in this region. The ratios figuring in the definitions (2.1) and (2.5) lead to the same value of the probability. This assumption in statistical physics is called the ergodic hypothesis. We shall return to a discussion of it in §15.

We shall make use of the two definitions of probability, considering them to be equivalent.

We now consider the definition of certain propositions of the theory of probability.

2.1. *The law of addition of probabilities*

Consider a physical system which can be in different states. If the system is in the state i , then it obviously cannot simultaneously be in any state k . The simultaneous occupation of the states i and k by one and the same system are two events which rule each other out. Assume that the probabilities of the states i and k are known. For many purposes it is very important to find the probability for a system to be found in one or other of these states — no matter in which one. In other words, we want to find the probability for a system to be either in the state i or in the state k . To find this probability we note that the total time of stay of the system in one or other of the states is equal to the sum of the times of stay in the i th and k th state. Hence the probability w_{i+k} sought for is

$$w_{i+k} = \lim_{T \rightarrow \infty} \frac{t_i + t_k}{T} = \lim_{T \rightarrow \infty} \frac{t_i}{T} + \lim_{T \rightarrow \infty} \frac{t_k}{T} = w_i + w_k. \quad (2.6)$$

Formula (2.6) expresses the law (theorem) of addition of probabilities: The probability for a system to be in one or other of two states which are mutually exclusive, is equal to the sum of the probabilities for the system to be in each of the states separately.

The theorem of addition of probabilities can easily be applied to the case of three states or a larger number of states. In the general case the probability for a system to be in one or other of the mutually exclusive states i, k, l, \dots is equal to

$$w_{i+k+l+\dots} = \sum w_j, \quad (2.7)$$

where the summation is carried out over all states i, k, l, \dots of the system.

From the theorem of addition of probabilities there follows an important consequence which we shall often use in what follows.

Assume that the state of a system is characterized by two quantities L and M which are independent of each other. For example, L can represent the velocity of motion of the system in one direction, while M can represent the velocity of motion of the system in another direction, or L and M can be respectively the energy and volume of an ideal gas, and so on. Let L have the possible values $L_1, L_2, \dots, L_i, \dots$, and M the values $M_1, M_2, \dots, M_k, \dots$. We assume that the probability for the system to be in a state in which L is equal to L_i and M is equal to M_k is known. Let this probability be equal to $w_{L_i M_k}$.

We now find the probability w_{L_i} for the system to have the value L_i for any value of the quantity M . According to the theorem of addition of probabilities we can write

$$w_{L_i} = w_{L_i M_1} + w_{L_i M_2} + \dots + w_{L_i M_k} + \dots = \sum w_{L_i M_j}, \quad (2.8)$$

where the summation is carried out over all values of the quantity M . In the case when the quantities L and M vary continuously the summation in formula (2.8) should be replaced by integration.

2.2. Statistical independence and the law of multiplication of probabilities

The second important proposition of the theory of probability is called the theorem or law of multiplication of probabilities.

Consider two physical systems and assume that they are completely independent of each other. We denote by w_{L_i} the probability for the first system to be in the state characterized by the value L_i , and denote by w_{M_k} the probability for the second system to be in the state characterized by the value M_k . The probabilities w_{L_i} and w_{M_k} are independent if the probability for the first system to be in the state i does not depend on whether or not the second system is in the state k .

The law of multiplication of probabilities for statistically independent systems reads: "the probability of the simultaneous occupations of the i th state in which $L = L_i$, by the first system, and the k th state in which $M = M_k$, by the second system, is equal to the product of the probabilities w_{L_i} and w_{M_k} ", i.e.

$$w_{L_i M_k} = w_{L_i} w_{M_k}. \quad (2.9)$$

The law of multiplication represents a strict definition of the statistical independence of two systems.

The above reasoning can be applied to two arbitrary independent physical systems. Let the first of them spend a time Tw_{L_i} in the state with $L = L_i$. If this time is sufficiently long, then it can be used as the time of observation of the states of the second system. Out of the entire time of observation of the second system (Tw_{L_i}) it spends a part equal to $(Tw_{L_i})w_{M_k}$ in the state with $M = M_k$. The probability that the first system is in the state with $L = L_i$ and that the second system is simultaneously in the state with $M = M_k$ is equal to

$$\lim_{T \rightarrow \infty} \frac{Tw_{L_i}w_{M_k}}{T} = w_{L_i}w_{M_k},$$

which accounts for the law of multiplication.

An important consequence of the law of addition of probabilities is the very obvious statement that the probability for a system to be in some allowed state is equal to unity. This means that we shall surely find our system in one of the states. The validity of the statement is seen from the fact that

$$\sum w_i = \sum \lim_{T \rightarrow \infty} \frac{t_i}{T} = \lim_{T \rightarrow \infty} \frac{\sum t_i}{T} = 1. \quad (2.10)$$

since, by definition, $T = \sum t_i$.

If the quantities characterizing the states of the system vary continuously, then instead of (2.10) we can write

$$\int dw = \int \rho(L) dL = 1. \quad (2.11)$$

In what follows we shall always assume probabilities to be normalized in such a way that the sum of all the probabilities is equal to unity. In this case we shall speak of the probability normalized to unity. In those cases when the initial probability distribution is not normalized, we shall always normalize it to unity.

§3. Mean values and fluctuations

It is now necessary to give a definition of the concept of the statistical mean value of a quantity which depends on the state of the system. The idea of the statistical mean will play a basic role in the subsequent discussion. The statistical mean is a natural generalization of the concept of the arithmetical mean which we are used to.

Suppose that we have a number of values of a certain quantity, for example the velocity of an arbitrary body. We understand the arithmetical mean to be the ratio of the sum of all these values to their total number, i.e. a sum of the form

$$\frac{\sum L_i N_i}{N},$$

where L_i is a value of L , N_i is the number of measurements leading to this value, and N is the total number of measurements.

By the statistical mean of a quantity L , which we shall denote by \bar{L} , we mean the limit of the ratio

$$\bar{L} = \lim_{N \rightarrow \infty} \frac{\sum L_i N_i}{N}.$$

Since $N_i = t_i/\Delta t$ and $N = T/\Delta t$, we can write

$$\bar{L} = \lim_{T \rightarrow \infty} \frac{\sum L_i t_i}{T} = \sum L_i w_{L_i}, \quad (3.1)$$

where t_i is the time during which the system is in the i th state, in which the quantity L has the value L_i , T is the total time of observation, and w_{L_i} is the probability that the quantity L has the value L_i . The summation is carried out over all states of the system. Formula (3.1) is the definition of the statistical mean. In what follows we shall for brevity omit the term "statistical" and say simply "mean value".

In the case of systems whose states vary continuously, so that instead of the probability w_i we must write dw , formula (3.1) should be rewritten in the form

$$\bar{L} = \int L dw = \int L \rho(L) dL, \quad (3.2)$$

where the integration is carried out over all possible states of the system.

In calculating mean values we shall make use of the following simple theorem: if there are two quantities L and M which are functions of the state, then the mean value of their sum $(\overline{L+M})$ is equal to the sum of the means $\bar{L} + \bar{M}$. For the proof we note that, by definition,

$$(\overline{L+M}) = \sum (L_i + M_i) w_i = \sum L_i w_i + \sum M_i w_i = \bar{L} + \bar{M}.$$

Assume that we know the distribution of the probabilities $w_{L,i}$ for a quantity L to take the values L_i . Then by means of formula (3.1) we can find the mean value of this quantity \bar{L} .

Thus, for example, knowing the probability distribution for different values of the energy of a system, one can calculate the mean value of the energy of this system. The question naturally arises: to what degree does the definition of the mean value characterize the real value of this quantity. In the example presented it can be asked to what degree the indication of the mean energy can characterize the actual energy of the system. It is clear that, if the deviations of the quantity from its mean value are sufficiently small, then the true value of the quantity can always, without much error, be replaced by its mean value.

In order to give a precise answer it is necessary to introduce a quantity which can characterize the deviation of the true value of a quantity L from its mean value \bar{L} .

At first sight it might seem that the difference $L - \bar{L}$ could be chosen as such a criterion. However, that is not so. The deviation of a quantity from its mean value can be large, but will nevertheless play a negligible role if it occurs relatively seldom. If, for example, considerable deviations of an energy from its mean value occur so seldom that the time interval between two successive deviations is very large in comparison with the observation time, then such deviations will not be noticed at all in the course of the time of observation. However, if deviations from the mean are not very large but occur often, then in this case the indication of merely the mean value \bar{L} does not characterize sufficiently the true value of the quantity L . One could try to choose as the criterion the mean value of the difference $L - \bar{L}$, i.e. $\overline{L - \bar{L}}$. However, this quantity is exactly equal to zero:

$$\overline{\Delta L} = \overline{L - \bar{L}} = \bar{L} - \bar{L} = 0.$$

(It should be noted that it is not necessary to carry out the secondary averaging of \bar{L} , since the mean \bar{L} is a constant quantity. But the mean value of a constant quantity is obviously equal to the quantity itself.)

The fact that the quantity $\overline{L - \bar{L}}$ is equal to zero expresses the fact that the deviations of L from \bar{L} in two directions, the direction of larger values and the direction of smaller values, occur equally frequently. In order that deviations from \bar{L} in the two directions may not cancel but be added, it is necessary to choose as the criterion not the mean difference $\overline{\Delta L} = \bar{L} - \bar{L}$, but the mean square of the difference $(\Delta L)^2$. The values of $(\Delta L)^2$ will be larger the larger the deviations of L from \bar{L} , independently of the signs of the devia-

tions, and the more often these deviations occur. The quantity $\overline{(\Delta L)^2} = \overline{(L - \bar{L})^2}$ is called the mean square deviation. The mean square deviation is an essentially positive quantity. It takes on its lowest possible value, zero, only in the case when L is always exactly equal to its mean value \bar{L} . Every deviation from the mean gives a contribution to the value of $\overline{(\Delta L)^2}$.

From the definition of $\overline{(\Delta L)^2}$ we have

$$\begin{aligned}\overline{(\Delta L)^2} &= \overline{(L - \bar{L})^2} = \overline{L^2 - 2L\bar{L} + (\bar{L})^2} \\ &= \bar{L}^2 - 2\bar{L}\bar{L} + (\bar{L})^2 = \bar{L}^2 - (\bar{L})^2.\end{aligned}\quad (3.3)$$

It is clear that for the absolute deviation to be small it is necessary that large departures of L from \bar{L} should have small probability, i.e. that they should occur relatively seldom. Thus, the quantity $\overline{(\Delta L)^2}$ can characterize the deviation of L from its mean value. If $\overline{(\Delta L)^2}$ is small, then the value of L is always close to its mean value. In this case the mean value \bar{L} can with sufficient accuracy characterize the value of L . The relative error which we shall incur by replacing L by its mean value \bar{L} can be estimated from the value of the quantity $\delta_L = \sqrt{\overline{(\Delta L)^2}}/\bar{L}$ called the relative fluctuation.

If $\delta_L \ll 1$, then this means that the value of L is on the average so close to \bar{L} that replacing of L by \bar{L} does not introduce any considerable error. We shall now prove a theorem of basic importance for subsequent developments. This theorem reads:

If there is a system consisting of N independent parts, then the relative fluctuation of any additive function* of the state, L , is inversely proportional to the square root of the number of parts N , i.e.

$$\delta_L = \frac{1}{\sqrt{N}}. \quad (3.4)$$

In order to prove this theorem we shall calculate the value of δ_L . By the definition of an additive quantity, $L = \sum_{k=1}^N L^{(k)}$, where $L^{(k)}$ is the value of the quantity L for the k th independent part of the system (in order to avoid misunderstandings, we write the index characterizing the number of the system as a superscript), and the summation is carried out over all independent parts constituting the system.

* By an additive function is meant a function possessing the property that the value of this function for a complex system is equal to the sum of its values for all independent parts.

From the law of addition of probabilities it follows that

$$\bar{L} = \sum_{k=1}^N \overline{L^{(k)}}. \quad (3.5)$$

We now calculate the mean square deviation of L , i.e. the quantity

$$\overline{(\Delta L)^2} = \overline{\left[\Delta \sum_{k=1}^N L^{(k)} \right]^2}.$$

For simplicity we assume at first that the system consists of only two independent parts. Then we have

$$\overline{[\Delta(L_1 + L_2)]^2} = \overline{(\Delta L_1)^2} + \overline{2\Delta L_1 \cdot \Delta L_2} + \overline{(\Delta L_2)^2}.$$

Now, since L_1 and L_2 are independent quantities, the mean of the product $(\Delta L_1)(\Delta L_2)$ is equal to the product of the means

$$\overline{(\Delta L_1)(\Delta L_2)} = \overline{(\Delta L_1)} \cdot \overline{(\Delta L_2)}.$$

But $\overline{(\Delta L_1)} = \overline{(\Delta L_2)} = 0$, so that

$$\overline{[\Delta(L_1 + L_2)]^2} = \overline{(\Delta L_1)^2} + \overline{(\Delta L_2)^2},$$

i.e. the mean square deviation of a system of two independent quantities is equal to the sum of the mean square deviations of these quantities. Generalizing this to the case of N independent parts constituting a system we can write

$$\overline{\left[\Delta \left(\sum_{k=1}^N L^{(k)} \right) \right]^2} = \sum (\Delta L^{(k)})^2. \quad (3.6)$$

The number of terms in the sum (3.6) is equal to the number of independent parts in the system, i.e. to N . We assume that the fluctuations in different independent parts of the system are of the same order of magnitude (since all the parts of the system are equivalent). Then the value of the sum on the right-hand side of formula (3.6) is proportional to the number of terms, i.e. to the value of N , so that

$$\left[\Delta \left(\sum_{k=1}^N L^{(k)} \right) \right]^2 \sim N. \quad (3.7)$$

The mean value \bar{L} is also proportional to the number of terms in the sum of formula (3.6), i.e. to N . Hence the relative fluctuation of the quantity L is equal to

$$\delta_L = \frac{\sqrt{(\Delta L)^2}}{\bar{L}} = \frac{\sqrt{\left[\Delta \left(\sum L^{(k)} \right) \right]^2}}{\sum \bar{L}^{(k)}} \sim \frac{\sqrt{N}}{N} \sim \frac{1}{\sqrt{N}}. \quad (3.8)$$

Thus, the theorem is proved.

As has already been pointed out in the introduction, the problem of statistical physics is the study of the properties of macroscopic systems consisting of an enormous number of particles — atoms or molecules. We shall see later that the methods of investigating the properties of such systems are based on the application of statistical laws. The application of these laws allows one to find the mean values of different quantities characterizing the state of a system. From the theorem presented above it follows that the relative fluctuations of all physical quantities whose value for the entire system is equal to the sum of their values for all the particles are inversely proportional to the square root of the number of particles. Since the number of particles in a macroscopic system is expressed as a rule by enormous numbers (of the order of 6×10^{23}), the relative fluctuation of any additive quantity turns out to be practically equal to zero. This means that all additive quantities have values very close to the means. Therefore the replacement of actual quantities by their mean values can be carried out with a high degree of accuracy. The mean values of different quantities, calculated on the basis of the laws of statistical physics, agree to a very high degree of accuracy with their true values. This means that predictions based on probability in practice assume a completely reliable character.

Imagine, for example, that we want to find the pressure exerted by a mole of a gas on the walls of the container in which it is confined. By means of the propositions of statistical physics it turns out that it is possible to calculate the mean pressure \bar{p} of the gas. The true pressure p exerted on the wall is not equal to the mean pressure. Depending on the complex laws of motion of molecules in a gas, it will take on different values varying rapidly in time (fig. III.4), which can be both larger and smaller than the mean pressure.

Fig. III.4

Nevertheless, the theorem on fluctuations shows that the relative error which we shall incur by replacing the true pressure varying in time by its mean value (shown in fig. III.4 by the horizontal line) will be of the order of $\delta_p \approx (6 \times 10^{23})^{-\frac{1}{2}}$, i.e. the error will amount to $\approx 10^{-10}\%$.

It is obvious that such an error lies far beyond the limits of accuracy of measurements by the best manometers, and is of no practical importance. Hence we can make use of the mean value of pressure, without being concerned that any error will be committed. The same holds also for other functions of the state of the system. Examples of these functions will be given later.

§4. Normal distribution and moments

Returning to the discussion of the properties of the additive quantity $L = \sum_{k=1}^N L^{(k)}$ it should be noted that in the theory of probability the following very important theorem, called the central limit theorem, has been proved: "as the number of terms in the sum increases (as $N \rightarrow \infty$) the statistical probability distribution for the quantity L tends to the normal (Gaussian) distribution having the form:

$$\rho(L)dL = \frac{1}{\sqrt{2\pi(\Delta L)^2}} \exp \left[-\frac{(L-\bar{L})^2}{2(\Delta L)^2} \right] dL. \quad (4.1)$$

Applied to physical systems this means that the normal distribution for additive quantities, for example energy, will be established in any physical system containing a sufficiently large number of independent particles. We shall not present the proof of the central limit theorem, but shall confine ourselves to the consideration of a characteristic example.

Consider a system of N identical statistically independent particles. Let the probability for one of the particles to get into the p th state be equal to p . We shall find the probability that n particles be found in this state. For this we write the probability that n particles be found in the state p and that the remaining $(N-n)$ particles be found in other states in the form $p^n(1-p)^{N-n}$ (on the basis of (2.9), since the particles are independent).

The number of ways in which n arbitrary particles can be chosen out of the total number of particles N is equal to the number of combinations of N elements taken n at a time. The latter is equal to

$$\binom{N}{n} = \frac{N!}{n!(N-n)!}.$$

Hence the total probability that n arbitrarily chosen particles be found simultaneously in the p th state is equal to

$$w_N(n) = \frac{N!}{n!(N-n)!} p^n (1-p)^{N-n}. \quad (4.2)$$

The expression obtained is called the binomial law. We shall now assume that the system contains a very large number of particles, so that $N \gg n$. Then omitting n in the exponent of the last factor, we can write

$$\begin{aligned} w_N(n) &\cong \frac{N!}{n!(N-n)!} p^n (1-p)^N \\ &= \frac{N(N-1) \dots (N-n+1)}{n!} p^n (1-p)^N = \frac{(\bar{n})^n}{n!} \left(1 - \frac{\bar{n}}{N}\right)^N, \end{aligned}$$

where $\bar{n} = pN$. It is obvious that \bar{n} represents the mean number of particles in the p th state. In the limit $N \rightarrow \infty$ we obtain

$$w(n) = \lim_{N \rightarrow \infty} w_N(n) = \frac{(\bar{n})^n e^{-\bar{n}}}{n!}. \quad (4.3)$$

This formula is called the Poisson formula. Finally, we shall find the asymptotic expression of the Poisson formula for the case when not only is N very large but also the number of particles n in a given state is large. This means that n and \bar{n} can be considered to be large numbers (in comparison with unity), and the difference $n - \bar{n} \ll \bar{n}$.

Taking the logarithm of the Poisson formula, we have

$$\ln w(n) = n \ln \bar{n} - \bar{n} - \ln n! .$$

Making use of Stirling's formula (Appendix IV), we can write

$$\ln n! \cong n \ln n - n ,$$

so that

$$\begin{aligned} \ln w(n) &= n \ln (\bar{n}/n) + (n - \bar{n}) \\ &= -n \left\{ \ln \left(\frac{n}{\bar{n}} \right) + \frac{n - \bar{n}}{n} \right\} . \end{aligned}$$

Using $\ln(1+x) = x - \frac{1}{2}x^2 \dots$ and $\bar{n} \sim n$, we obtain

$$w(n) = \text{const} \exp \left[-\frac{(n - \bar{n})^2}{2\bar{n}} \right] .$$

The constant is found from the normalization condition. For large values of n the summation can be replaced by integration. We then obtain

$$dw(n) = w(n)dn = \frac{1}{\sqrt{2\pi\bar{n}}} \exp \left[-\frac{(n - \bar{n})^2}{2\bar{n}} \right] dn , \quad (4.4)$$

i.e. the normal (Gaussian) probability distribution. The mean square deviation of the number of particles in the state considered is equal to

$$\overline{(\Delta n)^2} = \overline{(n - \bar{n})^2} = \frac{1}{\sqrt{2\pi\bar{n}}} \int (n - \bar{n})^2 dw(n) = \bar{n} . \quad (4.5)$$

In the case given formula (3.7) turns out to be exact, not approximate. Hence the Gaussian distribution can be written in the form

$$dw(n) = \rho(n)dn = \frac{1}{\sqrt{2\pi(\Delta n)^2}} \exp \left[-\frac{(n - \bar{n})^2}{2(\Delta n)^2} \right] dn , \quad (4.6)$$

which is the same as (4.1). We see, in this particular example, that for large values of the numbers N and n the normal probability distribution is established, since the deviation of the numbers n from their mean values are on the average sufficiently small.

The mean square deviation characterizes the effective width of the normal distribution. The smaller $(\Delta n)^2$, or in the general case $(\Delta L)^2$, the smaller the width of the Gaussian distribution. In the limit $(\Delta L)^2 \rightarrow 0$ the Gaussian distribution goes over into the δ -function. In this case the probability of finding a value $L \neq \bar{L}$ tends to zero, while the probability of the value $L = \bar{L}$ tends to unity. The normal distribution has a symmetric character, so that $w(L) = w(-L)$, i.e. the probability of a deviation from the mean is the same in both directions. If a distribution is not Gaussian, then, generally speaking, it is not symmetric with respect to the sign of L . The degree of asymmetry of the distribution is characterized by a quantity called the skewness and equal to

$$(\overline{\Delta L})^3 = \bar{L}^3 - 3\bar{L}(\overline{\Delta L})^2 = \bar{L}^3 - 3\bar{L}[\bar{L}^2 - (\bar{L})^2]. \quad (4.7)$$

The mean square deviation and the skewness are expressed in terms of quantities \bar{L} and \bar{L}^n ($n=2,3$). The latter, defined in general form by the formula

$$\bar{L}^n = \int L^n \rho(L) dL, \quad (4.8)$$

are called the moments of n th order. It turns out that, if $\rho(L)$ is an analytical function having derivatives of all orders, then the set of moments of all orders $(\bar{L}, \bar{L}^2, \bar{L}^3, \dots)$ completely determines the form of the function $\rho(L)$. Indeed, carrying out the Fourier transformation on $\rho(L)$, we have

$$\psi(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \rho(L) e^{i\omega L} dL. \quad (4.9)$$

The function $\psi(\omega)$ is called the characteristic function of the probability distribution.

Differentiating (4.9) with respect to ω and setting $\omega = 0$, we find

$$\begin{aligned} \left(\frac{d\psi}{d\omega} \right)_{\omega=0} &= \frac{i}{2\pi} \int_{-\infty}^{\infty} L \rho(L) dL = \left(\frac{i}{2\pi} \right) \bar{L}, \\ \left(\frac{d^2\psi}{d\omega^2} \right)_{\omega=0} &= \frac{i^2}{2\pi} \int_{-\infty}^{\infty} L^2 \rho(L) dL = \left(\frac{i^2}{2\pi} \right) \bar{L}^2, \end{aligned}$$

$$\dots\dots\dots,$$

$$\left(\frac{d^n \psi}{d\omega^n}\right)_{\omega=0} = \frac{i^n}{2\pi} \int_{-\infty}^{\infty} L^n \rho(L) dL = \left(\frac{i^n}{2\pi}\right) \overline{L^n}.$$

Hence, if all moments are known, then the coefficients in the expression

$$\psi(\omega) = \psi(0) + \psi'_0 \frac{\omega}{1!} + \psi''_0 \frac{\omega^2}{2!} + \dots \quad (4.10)$$

are known and, consequently, the function $\psi(\omega)$ itself is known. Then the probability distribution is obtained directly from the transformation

$$\rho(L) = \int_{-\infty}^{\infty} \psi(\omega) e^{-i\omega L} d\omega. \quad (4.11)$$

Sometimes the moments $\overline{L^n}$ or, in any case, the first few moments are known, but the probability distribution itself is not known. Then, by finding exactly the characteristic function $\psi(\omega)$ (or approximately), one can find exactly (or approximately) the probability distribution $\rho(L)$.

§5. The correlation function

In what follows we shall often have to consider random functions. A random function is a function $f(x)$ the values of which do not depend in an unambiguous way on the variable x . For a fixed value of x , the function $f(x)$ can take on randomly all possible values. In this case one can only speak of the probability that, for a given x , the function $f(x)$ has a value lying between $f(x)$ and $f(x) + df(x)$. For concreteness we shall assume in what follows that the random quantity depends on time, i.e. we shall consider a random function of time $f(t)$. A process described by a random function of time is called a stochastic process. Physical examples of stochastic processes and random functions depending on time will be given below.

The most important quantitative characteristic of random processes is their correlation function (or, more precisely, autocorrelation). By the correlation function $K(\tau)$ is meant the mean value (with respect to time or with respect to the ensemble) of the product of a random function describing a stochastic process in a certain system, taken at time t , and the same function taken at time $t + \tau$:

$$K(\tau) = \lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T f(t) f(t+\tau) dt, \quad (5.1)$$

where τ can be positive as well as negative. For brevity we shall write

$$K(\tau) = \overline{f(t) f(t+\tau)}. \quad (5.2)$$

The bar denotes averaging over time.

In addition to averaging over time, averaging with respect to an ensemble of identical physical systems in which a random physical process takes place, can be carried out. By virtue of what was said in §2, the two averages are equivalent. Hence we can write

$$K(\tau) = \langle f(t) f(t+\tau) \rangle. \quad (5.3)$$

The brackets $\langle \rangle$ denote the average with respect to the ensemble.

The correlation function $K(\tau)$ is a quantitative measure of the connection between the values of a random function at successive instants of time. In other words, $K(\tau)$ is a measure of the rate of change in time of a function $f(t)$ describing a stochastic process.

The values of the correlation function depend only on τ , and not on the choice of the value of t . Indeed, because of the uniformity of time, a change of the origin cannot affect mean values, so that

$$K(\tau) = \overline{f(t) f(t+\tau)} = \overline{f(t') f(t'+\tau)}. \quad (5.4)$$

If the values of a random function $f(t)$ vary so rapidly that its value at an instant $t + \tau$ does not depend at all on the value at the instant t , then

$$K(\tau) = \overline{f(t)} \overline{f(t+\tau)} = 0. \quad (5.5)$$

When $\tau \rightarrow \infty$ we have the obvious equality

$$K(\tau \rightarrow \infty) \rightarrow 0, \quad (5.6)$$

called the property of attenuation of correlation at infinity.

In the other limiting case $\tau = 0$ the equality

$$K(0) = [f(t)]^2 = \langle f^2(t) \rangle \quad (5.7)$$

shows that $K(0)$ is the same as the mean-square value (the second moment) of the random function $f(t)$. Finally, the symmetry of the stochastic process in time allows one to write the condition

$$K(\tau) = K(-\tau) . \quad (5.8)$$

The actual form of a correlation function depends, of course, on the nature of the random process. However, there exists a theorem relating two important characteristics of a random process – the correlation function and the so-called spectral density. The random function $f(t)$ can be expanded in a Fourier integral:

$$f(t) = \int_{-\infty}^{\infty} e^{i\omega t} f(\omega) d\omega . \quad (5.9)$$

The frequencies ω form a continuous spectrum.

We write the mean-square value $\langle f^2 \rangle$ in the form

$$\langle f^2(t) \rangle = \int_{-\infty}^{\infty} I(\omega) d\omega = 2 \int_0^{\infty} I(\omega) d\omega , \quad (5.10)$$

where the function $I(\omega)$ is called the spectral density. By definition $I(\omega)$ is an essentially positive function, $I(\omega)$ being equal to $I(-\omega)$.

Substituting (5.9) into the definition (5.7) of $\langle f^2 \rangle$, we find

$$\langle f^2(t) \rangle = \iint d\omega d\omega' e^{i(\omega+\omega')t} \langle f(\omega) f(\omega') \rangle . \quad (5.11)$$

We write the expression for $\langle f(\omega) f(\omega') \rangle$, making use of the inversion formula:

$$f(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} f(t) e^{-i\omega t} dt . \quad (5.12)$$

We then obtain

$$\langle f(\omega) f(\omega') \rangle = \frac{1}{4\pi^2} \iint \langle f(t) f(t') \rangle e^{i(\omega t + \omega' t')} dt dt' .$$

Assuming $t' = t + \tau$, we have

$$\begin{aligned}\langle f(\omega) f(\omega') \rangle &= \frac{1}{4\pi^2} \iint e^{i(\omega+\omega')t} e^{i\omega'\tau} \langle f(t) f(t+\tau) \rangle dt d\tau \\ &= \frac{1}{4\pi^2} \iint e^{i(\omega+\omega')t} e^{i\omega'\tau} K(\tau) dt d\tau.\end{aligned}\quad (5.13)$$

According to (5.4) the correlation function $K(\tau)$ does not depend on t , and in the last expression one can take $K(\tau)$ out of the integral with respect to t :

$$\begin{aligned}\langle f(\omega) f(\omega') \rangle &= \frac{1}{4\pi^2} \int e^{i\omega'\tau} K(\tau) d\tau \int_{-\infty}^{\infty} e^{i(\omega+\omega')t} dt \\ &= \frac{1}{2\pi} \int e^{i\omega'\tau} K(\tau) d\tau \delta(\omega+\omega').\end{aligned}\quad (5.14)$$

Substituting (5.14) into (5.11), we have

$$\begin{aligned}\langle f^2(t) \rangle &= \frac{1}{2\pi} \int d\tau d\omega d\omega' e^{i\omega'\tau} K(\tau) \delta(\omega+\omega') \\ &= \frac{1}{2\pi} \int_{-\infty}^{\infty} \int K(\tau) e^{-i\omega\tau} d\omega d\tau.\end{aligned}\quad (5.15)$$

Comparing (5.15) and (5.10), we finally obtain

$$I(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{-i\omega\tau} K(\tau) d\tau.\quad (5.16)$$

Inverting the last integral, we can also write

$$K(\tau) = \int_{-\infty}^{\infty} e^{i\omega\tau} I(\omega) d\omega.\quad (5.17)$$

Formulae (5.17) and (5.16) represent the content of the Wiener-Khintchine theorem. They relate the correlation function and the spectral density. The latter turns out to be the Fourier transform of the correlation function.

In studying stochastic processes in physical systems we shall encounter applications of the Wiener-Khintchine theorem.

The Kinetic Theory of Gases

§6. The simplest statistical system — an ideal gas

It is natural to begin the study of systems containing a very large number of particles with the simplest case — an ideal gas.

The density of matter in the gaseous state is small, so that the mean distance between particles is very large in comparison with the geometrical dimensions of the particles, the atoms or molecules. Because of this each of the particles is relatively distant from the other gas particles for most of the time of motion.

The forces of intermolecular interaction decrease rapidly with increasing distance and become negligibly small when molecules are at a distance considerably exceeding their geometrical size. Thus, a characteristic feature of the motion of molecules in a gas is the smallness of the intermolecular interaction during most of the time. Because of the absence of interaction the gas molecules move rectilinearly and uniformly until a collision takes place between a given molecule and any other molecule or the wall of the container. In collisions of gas molecules with each other or with the molecules of the wall of the container the molecules can be considered to be undeformable. This means that the collisions between molecules obey the same laws as the collisions between ordinary hard balls. In the process of a collision an exchange

of kinetic energy and momentum takes place between molecules. Analogously, when a gas molecule collides with the wall of the container or, more precisely, with a molecule of the substance of this wall, it can be assumed that the gas molecule is reflected elastically from the wall.

An ideal gas is a statistical system the particles of which interact with one another only through collisions, while during the remaining time they move as free particles.

The motion of every gas molecule is determined strictly by the laws of mechanics (in the first approximation those of classical mechanics). Hence, by integrating the equations of motion of all the molecules constituting a gas, one could in principle find the trajectory of every one of the molecules. However, such a calculation would, in practice, present great difficulties. Even the integration of the equations of motion of three interacting material points (the three-body problem) is a very complicated problem, the general case being still unsolved. The general solution of the four-body problem is so complicated that ways of solving it are not even known. And in a gas the number of interacting particles is expressed by numbers of the order of 10^{20} . From the macroscopic point of view, innumerable collisions between the molecules and with the wall of the container take place in an extremely short time interval. Hence, in order to find the trajectories of all the molecules of a gas it would be necessary to write down and solve 3×10^{20} inter-related equations of motion taking into account the corresponding initial conditions. From this it is clear that such a problem is difficult not only in practice but also in principle.

At first sight it may seem that the above statement deprives us of any possibility of studying physical laws in systems consisting of a very large number of particles. In reality, however, this is not so. Although every one of the particles constituting a system is in itself a "mechanical system" and obeys the laws of mechanics, the set of an enormous number of molecules is a system differing qualitatively from a system consisting of a small number of particles. Laws of a special type, which are not at all inherent in simple mechanical systems, and which are called statistical laws, are shown by it.

Consider a gas consisting of an enormous number of molecules confined in a closed container. Such a gas represents a mechanical system with an enormous number of degrees of freedom. Knowing the initial conditions, it would, in principle, be possible to integrate the equations of motion of all the gas molecules and to find their trajectories. Putting aside the question as to the practical feasibility of such a calculation, it should be noted that such a solution would be of no interest. We know from experience that the properties of a gas do not depend at all on the initial conditions, i.e., the initial

positions and velocities of the molecules. Thus, for example, the properties of a gas in a closed container in no way depend on the method of filling the container: independently of whether the gas flowed into the container through one opening and slowly, or through two openings and rapidly, after the lapse of a certain time interval from the admission, the gas will come into a definite state in which it will henceforth be found.

It is said that the gas comes into an equilibrium state. The properties of a gas in an equilibrium state do not depend on its previous history and do not change in time.

It is well known from experience that a gas always tends to occupy the entire volume available completely and uniformly. Hence a form of motion of a gas in which the density is equal in different parts of the container is ruled out or, more precisely, is extremely improbable. No obvious contradiction with the laws of mechanics would appear in this case. If the state of a system depended on the initial conditions, then the latter could in principle be chosen in such a way that the density of the gas in different parts of the container would be different. The fact that the state of a gas does not depend on the initial conditions of the positions and velocities of its molecules makes of no use the knowledge of the trajectories of individual molecules. Assume that we succeeded in overcoming all mathematical difficulties and found the trajectory of an individual molecule. Suppose it turned out that the trajectory of the given molecule lay almost entirely in one of the corners of a cube. It is clear that we could not draw from this any conclusion about the behaviour of the entire gas.

A gas as a whole, containing an enormous number of particles, appears to be a system differing qualitatively from an individual molecule, and its behaviour obeys different, statistical, laws. In this connection one of the founders of statistical physics, Smoluchowski, wrote that even if we were able to find the trajectories of the gas molecules we would still make use of laws of probability theory in describing the properties of the gas.

In finding statistical laws we shall look for the mean value of the quantities characterizing the state of a gas as a whole. Because the number of particles in a gas is very large, it follows from the results of §5 that the mean values found will agree to a high degree of accuracy with the true values of these quantities.

Earlier reasoning allows us to bring forward the most important feature of "mass" processes, i.e. processes which are characterized by the presence of a large number of more or less equivalent events. This feature is the fact that in such processes peculiar statistical laws are shown which are not inherent in individual systems or processes.

Consider a closed container filled by a gas. Assume that an equilibrium state is established in the gas. We shall try to find the statistical laws determining the behaviour of the gas. In correspondence with direct experimental data we shall assume that the molecules of the gas are distributed over the whole volume of the closed container with a uniform density (i.e. that the number of molecules per unit volume is constant everywhere in container). We shall also assume that the molecules of the gas have velocities which are uniformly distributed over all directions in space. This means that the number of molecules moving in any direction must be the same. If this were not so and if there existed a preferential direction of motion of molecules, then a flow of gas would arise in this direction. It follows from experiment that in a gas confined in a closed container and not subjected to any action from without no stationary gas flow can arise. The assumption of a uniform distribution of molecules in space and a uniform velocity distribution over all directions is called the assumption of molecular disorder.

The question naturally arises as to how the uniform distribution of the velocities of molecules in all directions is established. It is clear that, if molecules did not interact with one another at all, then there would be no way of changing the initial direction of motion of a molecule. Hence the presence or absence of a directed flow would entirely be determined by the initial conditions. The establishment of molecular disorder is due to the existence of interaction between the molecules. Because of collisions between molecules their directions of motion change continually, and a random motion with a uniform velocity distribution over directions in space is established in the gas.

The role of molecular collisions does not only give rise to the establishment of a uniform velocity distribution over directions. In molecular collisions a change in the absolute value of the velocities of the molecules takes place in addition to a change of the direction of flight. If initially all molecules had the same velocity, then random collisions between them would lead to the fact that some of the molecules would randomly get an excess of kinetic energy at the expense of other molecules which would correspondingly lose a part of their energy. Owing to this the equality of the velocities of gas molecules would be violated, and a certain number of molecules having larger and smaller velocities would appear in the gas. In other words, a certain distribution of molecules over velocities will arise in the gas. A number of molecules having large velocities, and a number of molecules with medium and small velocities will appear.

Our problem is to find the velocity distribution of the molecules of an ideal gas. This distribution will be characterized by the mean number of molecules having a given value of the velocity.

From the assumption of the random character of molecular motion it follows that the appearance of molecules with a variety of velocities is possible, so that the distribution of molecules can be characterized by a certain continuous function. Since the velocities of motion of molecules vary continually, one has, of course, to speak not of the number of molecules having a given exact velocity but of the number of molecules having a velocity close to the given one.

§ 7. The Maxwell distribution

Let us denote by dn_v the mean number of molecules in unit volume of a gas having velocity components lying within the interval between v_x and $v_x + dv_x$, v_y and $v_y + dv_y$, v_z and $v_z + dv_z$.

We shall assume that the gas is in a stationary state, so that the state of molecular disorder, which does not change in time, is established. The number of particles with given velocity components does not depend on time.

It is clear that the mean number of molecules dn_v can be written in the following form

$$dn_v = n(v_x, v_y, v_z) dv = n(\mathbf{v}) dv_x dv_y dv_z, \quad (7.1)$$

where $n(v_x, v_y, v_z) = n(\mathbf{v})$ is the mean number of molecules with velocity components v_x, v_y, v_z , in unit interval. The function $n(\mathbf{v})$ is called the velocity distribution function of the molecules.

Since all directions of motion of molecules in space are equivalent, the velocity distribution must be isotropic and the distribution function $n(\mathbf{v})$ cannot depend on the direction of the velocity. This means that $n(v_x, v_y, v_z)$ cannot be an arbitrary function of the velocity components v_x, v_y, v_z but must be a function of the argument $v = |\mathbf{v}| = (v_x^2 + v_y^2 + v_z^2)^{1/2}$ i.e. of the absolute value of the velocity, and

$$dn_v = dn_v. \quad (7.2)$$

Changing from velocity components to the absolute value of the velocity and its direction characterized by the polar angles ϑ and ψ , we can, by virtue of (1.67) write that

$$dn_v = n(v) v^2 dv \sin \vartheta d\vartheta d\psi. \quad (7.3)$$

The total number of particles in unit volume $n = N/V$ determines the normalization condition

$$n = \int n(v) v^2 dv \sin \vartheta d\vartheta d\psi = 4\pi \int n(v) v^2 dv. \quad (7.4)$$

The range of integration with respect to the velocity components v_x, v_y, v_z or with respect to the absolute value of the velocity v will be considered later.

Our problem is to find the explicit form of the distribution function $n(v)$. Here we shall confine ourselves to the simplest, although not completely rigorous, derivation of a form of the distribution function called the Maxwell distribution function or, briefly, the Maxwell distribution. In this derivation the role of molecular collisions and the proposition of molecular disorder, in the establishment of the equilibrium velocity distribution of molecules, is particularly clear.

Let us consider the process of collision between two particles moving with velocities \mathbf{v}_1 and \mathbf{v}_2 . Since the forces of intermolecular interaction decrease rapidly with increasing distance and are, in fact, different from zero only at the moment of direct contact of the particles, we can replace the real process of collision by an idealized scheme of the elastic collision between two material points. Here the concrete form of the interaction forces does not play any role. As a result of the collision, let the velocities of the molecules be changed. After the collision the first particle moves with a velocity \mathbf{v}_3 , and the second one with a velocity \mathbf{v}_4 . The number of such collisions per unit time in unit volume of the gas must be proportional to the number of molecules with velocity \mathbf{v}_1 and the number with velocity \mathbf{v}_2 , i.e. to the product $n(v_1) n(v_2)$. Consider further the reverse process of collision. Then the velocities of the molecules change from the values \mathbf{v}_3 and \mathbf{v}_4 to the values \mathbf{v}_1 and \mathbf{v}_2 . The number of such collisions per unit time in unit volume is proportional to the number of molecules with velocity \mathbf{v}_3 and the number with velocity \mathbf{v}_4 , i.e. to $n(v_3) n(v_4)$.

Because of our assumption that the number of molecules with given values of velocity does not change by the processes of molecular collision in a gas in a stationary state, we can consider that the number of molecules for which the velocities are changing from the values $\mathbf{v}_1, \mathbf{v}_2$ to the values $\mathbf{v}_3, \mathbf{v}_4$ is equal to the number of molecules for which the velocities are changing from $\mathbf{v}_3, \mathbf{v}_4$ to $\mathbf{v}_1, \mathbf{v}_2$, i.e. it can be assumed that

$$n(v_1) n(v_2) = n(v_3) n(v_4). \quad (7.5)$$

The equality (7.5) expresses the balance of particles acquiring and losing corresponding velocities.

Since in the process of collision the energy of the molecules is conserved, for the direct and reverse process we can write

$$v_1^2 + v_2^2 = v_3^2 + v_4^2. \quad (7.6)$$

The equality (7.6) expresses the energy conservation law for the collision. The common factor $\frac{1}{2}m$, figuring in both sides, has here been dropped.

The equalities (7.4), (7.5) and (7.6) represent the whole set of conditions which must be satisfied by the distribution function sought.

From formula (7.6), into which only the squares of the velocities enter, it is seen that the functional eq. (7.5) will look much simpler if the square of the velocity is chosen instead of its absolute value as the argument of the distribution function writing the required function in the form $n(v^2)$. This does not change the essence of the problem, but allows one to rewrite (7.5) in a form which is simpler from the mathematical point of view

$$n(v_1^2) n(v_2^2) = n(v_3^2) n(v_4^2). \quad (7.7)$$

The functional eq. (7.7) is easy to transform into a simple differential equation. For this we express v_4 in terms of v_1, v_2 and v_3 by means of (7.6) and rewrite (7.7) in the form

$$n(v_1^2) n(v_2^2) = n(v_3^2) n(v_1^2 + v_2^2 - v_3^2).$$

Taking the logarithm of this equality, we have

$$\ln n(v_1^2) + \ln n(v_2^2) = \ln n(v_3^2) + \ln n(v_1^2 + v_2^2 - v_3^2). \quad (7.8)$$

We differentiate the above equality with respect to the argument v_1^2 . Here we have to keep in mind that eq. (7.8) is valid for completely arbitrary and independent values of v_1, v_2 and v_3 [the value of v_4 is determined by formula (7.6)]. We have

$$\frac{1}{n(v_1^2)} \frac{dn(v_1^2)}{dv_1^2} = \frac{1}{n(v_1^2 + v_2^2 - v_3^2)} \frac{dn(v_1^2 + v_2^2 - v_3^2)}{d(v_1^2 + v_2^2 - v_3^2)}.$$

Analogously,

$$\frac{1}{n(v_2^2)} \frac{dn(v_2^2)}{dv_2^2} = \frac{1}{n(v_1^2 + v_2^2 - v_3^2)} \frac{dn(v_1^2 + v_2^2 - v_3^2)}{d(v_1^2 + v_2^2 - v_3^2)}.$$

Comparing the two equations, we obtain

$$\frac{1}{n(v_1^2)} \frac{dn(v_1^2)}{dv_1^2} = \frac{1}{n(v_2^2)} \frac{dn(v_2^2)}{dv_2^2}. \quad (7.9)$$

Since v_1 and v_2 are independent variables, and the equality (7.9) must hold for completely arbitrary values of the independent quantities v_1 and v_2 , it is clear that it can be fulfilled only when the right and left hand sides of (7.9) are each equal to a constant.

We denote this constant by $-\alpha$. Then instead of (7.9) we can write

$$\frac{1}{n(v^2)} \frac{dn(v^2)}{dv^2} = -\alpha. \quad (7.10)$$

In the above equation we have dropped the subscript on the velocity, since from the preceding considerations it is clear that the equation must be valid for any value of the velocity.

Integrating (7.10) we find

$$n(v^2) = A e^{-\alpha v^2}, \quad (7.11)$$

where A is the integration constant. The integration constant A can be determined from the normalization condition (7.4). By virtue of (7.11) and (7.4) we have

$$4\pi A \int e^{-\alpha v^2} v^2 dv = n. \quad (7.12)$$

Now let us consider the integration range in the normalization condition (7.12). The lower limit of integration in (7.12) corresponds to the lowest possible value of the velocity v which is, obviously, equal to zero. As to the upper limit, we cannot, of course, indicate the value of the highest velocity which can be possessed by a molecule of the gas. However, the form of the distribution entering into (7.12) shows that, in essence, there is no need to know this value. The integrand decreases so rapidly with increasing argument that we shall not make any error by substituting infinity for the upper limit in (7.12). Hence the normalization condition (7.12) can be written in the form

$$4\pi A \int_0^{\infty} e^{-\alpha v^2} v^2 dv = n. \quad (7.13)$$

From (7.13) it follows directly that $\alpha > 0$. Otherwise the integral does not exist. The integration gives

$$A = n(\alpha/\pi)^{\frac{3}{2}}. \quad (7.14)$$

Finally, the distribution function can be written in the form

$$n(v) = n(\alpha/\pi)^{\frac{3}{2}} e^{-\alpha v^2}. \quad (7.15)$$

The number of molecules per unit volume with velocities between v and $v+dv$ is, thus, equal to

$$dn_v = 4\pi n(\alpha/\pi)^{\frac{3}{2}} e^{-\alpha v^2} v^2 dv. \quad (7.16)$$

Formula (7.16) is called the Maxwell distribution.

In addition to the velocity distribution one can also write the distribution over the components of velocities

$$dn_v = n(\alpha/\pi)^{\frac{3}{2}} \exp[-\alpha(v_x^2 + v_y^2 + v_z^2)] dv_x dv_y dv_z. \quad (7.17)$$

The transition from (7.16) to (7.17) corresponds to the ordinary transformation of polar coordinates into Cartesian coordinates.

In formula (7.17) it can be assumed that the components of the velocity vary from $-\infty$ to $+\infty$.

It should be noted that the velocity component distribution function can be written in the form of the product of three velocity component distribution functions

$$\begin{aligned} dn_v &= dn_{v_x} dn_{v_y} dn_{v_z} = \\ &= n(\sqrt{\alpha/\pi} e^{-\alpha v_x^2} dv_x) (\sqrt{\alpha/\pi} e^{-\alpha v_y^2} dv_y) (\sqrt{\alpha/\pi} e^{-\alpha v_z^2} dv_z). \end{aligned} \quad (7.18)$$

Before proceeding to a discussion of the results following from the distributions (7.16) and (7.17) it is necessary to explain the meaning of the parameter α appearing in them.

§8. Collisions of molecules with the wall of the container. Pressure. The connection of the parameter α with the absolute temperature

During their motion the molecules of a gas confined in a container undergo

Fig. III.5

collisions with its walls. The walls of the container have molecular structure and do not form geometrically sharp boundaries. A gas molecule approaching the wall undergoes a very strong repulsion by the wall molecules, and is reflected back into the container. Fig. III.5 shows schematically the form of the potential energy of a molecule near the walls of the container. The latter can be considered as an infinitely high impenetrable potential barrier for molecules. It can be assumed that the reflection of a molecule from the wall of the container is completely elastic. This means that, in the reflection, the velocity component perpendicular to the surface of the wall changes to its exact opposite.

Consider a certain wall area dS , perpendicular to the x -axis. Then a molecule having velocity components v_x, v_y, v_z acquires, when reflected, velocity components $-v_x, v_y, v_z$. In the reflection of the molecule from the area the momentum component along the x -axis changes from the value mv_x to $-mv_x$, i.e. by the amount $2mv_x$. This momentum is transferred to the reflecting wall.

Thus, collisions of molecules with the wall lead to the appearance of a force acting on the surface of the container. We identify the force acting on unit surface of the wall by all molecules of the gas with the macroscopic pressure. This statement which, in essence, is the basis of the kinetic theory of gases, seemed at one time to be very radical. However, at present it appears to be natural and completely obvious.

In order to find the pressure exerted on the wall it is necessary to calculate the total change in the momentum of gas molecules undergoing reflection from unit surface area of the container in unit time. It is obviously equal to the change in the momentum in one collision with the wall multiplied by the total number of collisions per cm^2 of the surface per sec. The change in the momentum is equal to $2mv_x$. Multiplying this expression by the number of

impacts per cm^2 per sec by molecules having a given velocity component v_x , and summing or, more exactly, integrating this product over all values of v_x , we find the pressure sought. In unit time the surface of the wall will be reached by all molecules which are a distance from it smaller than or equal to v_x (since v_x is the path traversed in unit time by a molecule moving in the positive direction of the x -axis). All molecules contained in a parallelepiped of a height v_x and a base of 1 cm^2 will impinge on 1 cm^2 of the wall surface per second (fig. III.6). The volume of this parallelepiped is, obviously, equal to $v_x \text{ cm}^3$. It contains $dn v_x$ molecules whose velocity components lie between v_x and $v_x + dv_x$, v_y and $v_y + dv_y$, v_z and $v_z + dv_z$. The wall surface will be reached by all molecules contained in this parallelepiped, independently of the values of the velocity components v_y and v_z parallel to this surface.

The number of particles with given velocity component v_x (for arbitrary values of the two other components v_y and v_z) per unit volume is equal to

$$\begin{aligned} dn_{v_x} &= n(\alpha/\pi)^{\frac{3}{2}} e^{-\alpha v_x^2} dv_x \int_{-\infty}^{\infty} \int e^{-\alpha(v_y^2 + v_z^2)} dv_y dv_z = \\ &= n(\alpha/\pi)^{\frac{1}{2}} e^{-\alpha v_x^2} dv_x . \end{aligned}$$

Fig. III.6

The number of particles contained in the parallelepiped of volume v_x is correspondingly equal to

$$dv = v_x \, dn_{v_x} = n(\alpha/\pi)^{\frac{1}{2}} e^{-\alpha v_x^2} v_x \, dv_x. \quad (8.1)$$

This expression gives the number of molecules having the given value of the velocity component v_x and reaching 1 cm² of the wall surface per second.

Each of dv molecules impinging on the wall transfers to it a momentum $2mv_x$, so that molecules with a given value of v_x transfer to the wall each second a momentum equal to $2mv_x dv$. Integrating this expression over all possible values of the velocity component v_x , we find the momentum transferred to 1 cm² of the wall surface per second by all the gas molecules striking it. This rate of transfer of momentum is, obviously, equal to the force acting on 1 cm² of the surface, i.e. to the gas pressure p

$$p = n(\alpha/\pi)^{\frac{1}{2}} \int_0^{\infty} 2mv_x e^{-\alpha v_x^2} v_x \, dv_x. \quad (8.2)$$

The integration in (8.2) is carried out only with respect to positive values of v_x , since molecules with negative values of the velocity component along the x -axis are moving away from the wall considered, not toward it*. It gives

$$p = \frac{m}{2\alpha} n, \quad (8.3)$$

or

$$p = \frac{m}{2\alpha} \frac{N}{V}. \quad (8.4)$$

To determine the numerical value of α it is necessary to compare eq. (8.4) with the experimental value of the pressure of a sufficiently rarefied gas. The latter is given by the equation of state

$$pV = NkT.$$

Comparing this expression with (8.4) we see that the parameter α is connected with the absolute temperature T by the relation

* In expression (8.2) collisions between molecules are not taken into account. However, molecules which do not reach the wall transfer their momentum to those reaching it.

$$\alpha = \frac{m}{2kT}. \quad (8.5)$$

The equality (8.5) confirms that the parameter α , which we introduced formally, is essentially a positive quantity. In determining the connection between α and the temperature T we had to resort to experimental data. In what follows we shall encounter a parameter analogous to α . The problem of the determination of the meaning and value of the parameter will then be discussed in more detail. We shall see that the meaning of α can be explained without directly involving experimental data.

Let us find the number ν of the impacts of molecules per cm^2 of the wall per second. Formula (8.1) gives the number of molecules reaching the wall per second and having a velocity between v_x and $v_x + dv_x$. The total number of molecules striking 1 cm^2 of the wall per second is obtained by integration of (8.1) over all values of v_x from zero to infinity. This gives

$$\nu = n(\alpha/\pi)^{\frac{1}{2}} \int_0^{\infty} e^{-\alpha v_x^2} v_x dv_x = n(kT/2\pi m)^{\frac{1}{2}}. \quad (8.6)$$

§9. Properties of the Maxwell distribution

Now we rewrite the Maxwell distributions (7.17) and (7.16), expressing the parameter α in terms of the absolute temperature of the gas

$$dn_v = n \left(\frac{m}{2\pi kT} \right)^{\frac{3}{2}} \exp \left[-\frac{m(v_x^2 + v_y^2 + v_z^2)}{2kT} \right] dv_x dv_y dv_z, \quad (9.1)$$

$$dn_v = 4\pi n \left(\frac{m}{2\pi kT} \right)^{\frac{3}{2}} \exp \left[-\frac{mv^2}{2kT} \right] v^2 dv. \quad (9.2)$$

Instead of making use of the state distribution function of gas particles, we can introduce the equivalent distribution, of the probabilities for a particle to be in a given state.

If the mean number of molecules having given velocity is equal to dn per cm^3 of the gas, while the total number of molecules is equal to n , then, obviously, the probability for an arbitrarily chosen molecule to be in a state with given velocity is equal to

$$dw = \frac{dn}{n}.$$

Hence the Maxwell distribution function can be treated as the function of distribution of the probabilities for a molecule to be in a given state. The latter is characterized by the values of the velocity components v_x , v_y and v_z .

Figs. III.7 and III.8 show, respectively, the functions of distribution of the probability density $n^{-1}(dn_{v_x}/dv_x)$ over the velocity components and $n^{-1}(dn_v/dv)$ over the absolute value of the velocity. Since it is impossible to show graphically a function of three variables, the quantity $n^{-1}(dn_{v_x}/dv_x)$ is plotted on the vertical axis, and the quantity $(m/2kT)^{1/2}v_x$ is plotted on the horizontal axis in fig. III.7.

Fig. III.7

Fig. III.8

In fig. III.8 the function $n^{-1}(dn_v/dv)$ is plotted on the vertical axis, and the quantity $(m/2kT)^{1/2}v$ is plotted on the horizontal axis.

The numbers of molecules in a gas with very low and very high velocities turn out to be relatively small. Nevertheless, it is always possible to find a certain number of very fast and very slow molecules. At first sight it may seem strange that the velocity distribution function has a maximum. Indeed, the factor $\exp(-mv^2/2kT)$ decreases exponentially with the square of the velocity of the molecule. Hence the number of molecules with given velocity must be lower the higher the velocity. However, the second factor v^2 varies in the opposite direction and increases with increasing velocity. This factor characterizes the number of states of a molecule having a velocity lower than the given one. The competition of the two factors leads to the appearance of a maximum in the distribution function.

With increasing temperature the distribution becomes more and more gently sloping. This means that the relative number of molecules with a large value of the velocity increases progressively. Fig. III.9 shows the variation of the Maxwell distribution with increasing temperature (for oxygen molecules).

In addition to the velocity distribution one often has to make use of the momentum distribution and energy distribution of molecules.

Introducing into the distribution (7.17) the new variables

$$p_x = mv_x, \quad p_y = mv_y, \quad p_z = mv_z,$$

we find for the number of molecules with given momentum

Fig. III.9

$$dn_p = n \left(\frac{1}{2\pi mkT} \right)^{\frac{3}{2}} \exp \left[-\frac{p_x^2 + p_y^2 + p_z^2}{2mkT} \right] dp_x dp_y dp_z. \quad (9.3)$$

Analogously, the number of molecules with absolute value of the momentum lying between p and $p+dp$ is equal to

$$dn_p = 4\pi n \left(\frac{1}{2\pi mkT} \right)^{\frac{3}{2}} \exp \left[-\frac{p^2}{2mkT} \right] p^2 dp. \quad (9.4)$$

Expressing the momentum in terms of the energy of the molecule $p = (2m\epsilon)^{\frac{1}{2}}$ we obtain for the number of particles with given energy

$$dn_\epsilon = n \frac{2}{[\pi(kT)^3]^{\frac{1}{2}}} e^{-\epsilon/\theta} \epsilon^{\frac{1}{2}} d\epsilon. \quad (9.5)$$

Experimental verification of the Maxwell distribution was one of the most important problems of molecular physics. Hence several methods of measuring the velocity distribution were devised. The most obvious of these is an experiment similar to the well-known Fizeau experiment on the determination of the velocity of light.

Molecules evaporating from the surface of a hot filament are let through a collimating system of slits, forming a narrow molecular beam travelling in vacuum in the direction of a cold trap. Two rotating discs with radial slits, through which the beam must pass, are placed in the path of the beam. In order that molecules having a velocity v_x may pass through both slits for a given angular velocity ω of the rotation of the discs and distance l between them, the slits must be displaced by an angle φ equal to

$$\varphi = \omega t = \omega \frac{l}{v_x}.$$

Thus, to each velocity v_x at given angular velocity ω there corresponds a definite displacement of the slits by an angle φ .

The number of particles in the beam having given velocity was determined directly from photometric measurement of the thickness of the deposit on the trap cooled by liquid air.

After evaluating the velocity distribution in the molecular beam corresponding to the velocity distribution in isotropic conditions, one obtains the histogram shown in fig. III.10. The curve in the drawing represents the Maxwell distribution (for mercury vapour).

Fig. III.10

Another very accurate method of measuring the velocity distribution in the molecular beam of the vapour of lithium, sodium or similar gases is based on the investigation of the behaviour of the beam in a magnetic field perpendicular to the direction of motion of the beam. It represents a reproduction of the well-known Stern–Gerlach experiment for the determination of magnetic moments, but it cannot be described here in detail (see Part V).

§ 10. The calculation of characteristic quantities

Knowing the distributions (9.1) and (9.5), one can find the mean values of any quantities characterizing the properties of gas molecules. Let us find, first of all, the mean value of any velocity component, for example \bar{v}_x . By definition of the mean value

$$\bar{v}_x = \int v_x dw = \int v_x \frac{dn_v}{n} = \left[\frac{m}{2\pi kT} \right]^{\frac{3}{2}} \int_{-\infty}^{\infty} v_x \exp\left(-\frac{mv_x^2}{2kT}\right) dv_x \times \iint_{-\infty}^{\infty} \exp\left[-\frac{m(v_y^2 + v_z^2)}{2kT}\right] dv_y dv_z.$$

The integral with respect to dv_x , which is an odd function, is equal to zero. Hence the mean value of v_x is equal to zero:

$$\bar{v}_x = 0.$$

This result is quite obvious. It shows that both directions of motion along the x -axis are equally probable.

We would obtain a similar result in calculating any other velocity component.

We now find the mean value of the absolute value of the velocity. We have

$$\begin{aligned}\bar{v} &= \int v \frac{dn_v}{n} = 4\pi \left(\frac{m}{2\pi kT} \right)^{\frac{3}{2}} \int_0^{\infty} \exp \left[-\frac{mv^2}{2kT} \right] v^3 dv = \\ &= \frac{2}{\sqrt{\pi}} \left(\frac{2kT}{m} \right)^{\frac{1}{2}} = 1.13 \left(\frac{2kT}{m} \right)^{\frac{1}{2}}.\end{aligned}\quad (10.1)$$

In accordance with the foregoing the mean velocity of a molecule increases with increasing temperature. This increase is proportional to the square root of the absolute temperature of the gas. We see also that the mean velocity of a molecule is inversely proportional to the square root of the mass of the molecule.

Of great interest is the mean value $\bar{\epsilon}$ of the kinetic energy of a gas molecule. From (9.5) it is equal to

$$\bar{\epsilon} = \int \epsilon \frac{dn_{\epsilon}}{n} = \frac{2}{\sqrt{\pi}(kT)^{\frac{3}{2}}} \int_0^{\infty} \exp [-\epsilon/kT] \epsilon^{\frac{3}{2}} d\epsilon.$$

In calculating the above integral it is necessary to introduce a new variable $x = \epsilon^{\frac{1}{2}}$. A simple calculation leads to the formula for the mean value of the kinetic energy of the translational motion of a molecule.

$$\bar{\epsilon} = \frac{3}{2} kT. \quad (10.2)$$

It is seen that the mean energy of a molecule does not depend on its nature and is proportional to the gas temperature T . The mean energy E of all gas molecules in a container is equal to the sum of the energies of the translational motion of all the molecules, since there is no interaction between them:

$$E = N\bar{\epsilon} = \frac{3}{2} NkT. \quad (10.3)$$

where N is the total number of molecules in the gas.

The energy of a given portion of an ideal gas does not depend on the volume of the container and is determined only by the absolute temperature *.

We shall identify this mean energy of the mechanical motion of gas molecules with the macroscopic thermal energy. In this connection we must treat the absolute temperature, from the kinetic point of view, as a quantity characterizing the mean energy of the motion of molecules. At present such a treatment is the only possible one. In the following chapter we shall discuss these statements in detail.

The expressions obtained for the mean energy of a molecule and for the gas as a whole can be interpreted in the following way. Every molecule has three translational degrees of freedom, and its motion can be resolved into the motion in three mutually perpendicular directions. By virtue of the equivalence of all directions in space, the mean energy of motion in each direction must be the same. Thus, formula (10.2) means that there corresponds to each degree of freedom of the motion, on the average, an energy equal to $\frac{1}{2}kT$. This statement is a particular case of the general law of equipartition of energy over degrees of freedom. In §39 we shall discuss this law in detail and point out the limits of its applicability.

It is of interest to establish the connection between the energy ϵ of the gas and its pressure p .

Writing the expression (8.2) in the form

* It may seem that the independence of the mean energy of a gas molecule on the size of the container contradicts the quantum formula (1.11) for the energy, according to which $\epsilon_n \sim 1/a^2$, where a is the linear dimension of the container. However, it should be borne in mind that the mean energy is determined by the integral of the product of the energy and the number of quantum states. The latter is, according (1.24), proportional to $\Omega(\epsilon)\Delta\epsilon \sim V\sqrt{\epsilon}\Delta\epsilon \sim a^3(\Delta\epsilon/a) \sim a^2\Delta\epsilon$. This leads to the independence of the energy on the volume.

$$\begin{aligned}
 p &= 2n \left(\frac{m}{2\pi kT} \right)^{\frac{1}{2}} \int_0^{\infty} \exp \left[-\frac{mv_x^2}{2kT} \right] (mv_x^2) dv_x = \\
 &\quad \frac{4n}{3} \left[\left(\frac{m}{2\pi kT} \right)^{\frac{3}{2}} \int_0^{\infty} \frac{mv_x^2}{2} \exp \left[-\frac{mv_x^2}{2kT} \right] dv_x \int_{-\infty}^{\infty} \exp \left[-\frac{m(v_y^2+v_z^2)}{2kT} \right] dv_y dv_z \right. \\
 &\quad + \left(\frac{m}{2\pi kT} \right)^{\frac{3}{2}} \int_0^{\infty} \frac{mv_y^2}{2} \exp \left[-\frac{mv_y^2}{2kT} \right] dv_y \int_{-\infty}^{\infty} \exp \left[-\frac{m(v_x^2+v_z^2)}{2kT} \right] dv_x dv_z \\
 &\quad \left. + \left(\frac{m}{2\pi kT} \right)^{\frac{3}{2}} \int_0^{\infty} \frac{mv_z^2}{2} \exp \left[-\frac{mv_z^2}{2kT} \right] dv_z \int_{-\infty}^{\infty} \exp \left[-\frac{m(v_x^2+v_y^2)}{2kT} \right] dv_x dv_y \right] = \\
 &= \frac{2n}{3} \left(\frac{m}{2\pi kT} \right)^{\frac{3}{2}} \int_{-\infty}^{\infty} \frac{mv^2}{2} \exp \left[-\frac{mv^2}{2kT} \right] dv_x dv_y dv_z = \\
 &= \frac{2}{3} \frac{N}{V} \left(\frac{mv^2}{2} \right) = \frac{2}{3} \frac{N\bar{\epsilon}}{V} = \frac{2}{3} \frac{E}{V}, \tag{10.4}
 \end{aligned}$$

we see that the pressure of an ideal gas turns out to be numerically equal to $\frac{2}{3}$ of the kinetic energy of the translational motion of gas molecules contained in unit volume.

Finally, the velocity of gas molecules at which the Maxwell distribution has a maximum, i.e. the most probable velocity $v_{m.p.}$, is determined from the condition

$$\frac{d}{dv} \left(\exp \left[-\frac{mv^2}{2kT} \right] v^2 \right) = 0.$$

We easily find

$$v_{m.p.} = \left(\frac{2kT}{m} \right)^{\frac{1}{2}}. \tag{10.5}$$

Comparing (10.5) with (10.1) we see that the mean velocity of the molecules is 13% higher than the most probable velocity.

The notion of the root-mean-square velocity $(\overline{v^2})^{\frac{1}{2}}$, which characterizes the energy of gas molecules, is also often introduced. By virtue of (10.2) this quantity is equal to

$$(\overline{v^2})^{\frac{1}{2}} = \left(\frac{3}{2}\right)^{\frac{1}{2}} \left(\frac{2kT}{m}\right)^{\frac{1}{2}} = 1.22 \left(\frac{2kT}{m}\right)^{\frac{1}{2}}. \quad (10.6)$$

The root-mean-square velocity is 22% higher than the most probable velocity. This is quite natural, since the contribution of fast molecules to the energy must be larger than that of slow molecules.

§11. Collisions of molecules with each other

Consider two molecules moving in an ideal gas with the velocities \mathbf{v}_1 and \mathbf{v}_2 . It is obvious that for the collision of these molecules with each other the absolute values and directions of the velocities do not in themselves play any role. The relative motion of one molecule with respect to the other only is of importance. If, for example, both molecules are moving on a straight line one following the other, then a collision will take place in unit time if the second molecule manages to "reach" the first molecule in 1 second. The velocities of motion of the two molecules in space with respect to the walls of the container are not relevant.

Thus, in solving the problem of collisions it is necessary to consider their relative motion. In §42 of Part I it has been shown that the motion of two particles can always be resolved into the motion in space of the common centre of mass and their relative motion.

We write the probability that the first molecule has a velocity \mathbf{v}_1 and the second \mathbf{v}_2 in the form

$$\begin{aligned} dw_{12} &= dw_1 dw_2 = \\ &= \left(\frac{m_1}{2\pi kT}\right)^{\frac{3}{2}} \exp\left[-\frac{m_1 v_1^2}{2kT}\right] d\mathbf{v}_1 \left(\frac{m_2}{2\pi kT}\right)^{\frac{3}{2}} \exp\left[-\frac{m_2 v_2^2}{2kT}\right] d\mathbf{v}_2. \end{aligned}$$

We pass over from the variables \mathbf{v}_1 and \mathbf{v}_2 to new variables \mathbf{R} , \mathbf{v}_{rel} , making use of formulae (42.4) of Part I. Then we have

$$m_1 v_1^2 + m_2 v_2^2 = M \dot{R}^2 + \mu v_{\text{rel}}^2, \quad d\mathbf{v}_1 d\mathbf{v}_2 = |I| d\dot{\mathbf{R}} dv_{\text{rel}},$$

where $\mu = m_1 m_2 / (m_1 + m_2)$ is the reduced mass, $M = m_1 + m_2$, and $|I|$ stands for the determinant of the Jacobian of the transformation from $\mathbf{v}_1, \mathbf{v}_2$ to $\dot{\mathbf{R}}, \mathbf{v}_{\text{rel}}$

$$|I| = \begin{vmatrix} \frac{\partial \mathbf{v}_1}{\partial \mathbf{v}_{\text{rel}}} & \frac{\partial \mathbf{v}_1}{\partial \dot{\mathbf{R}}} \\ \frac{\partial \mathbf{v}_2}{\partial \mathbf{v}_{\text{rel}}} & \frac{\partial \mathbf{v}_2}{\partial \dot{\mathbf{R}}} \end{vmatrix} = \begin{vmatrix} \frac{m_2}{m_1 + m_2} & 1 \\ -\frac{m_1}{m_1 + m_2} & 1 \end{vmatrix} = 1.$$

Thus,

$$\begin{aligned} dw_{12} &= \left(\frac{m_1 m_2}{2\pi(m_1 + m_2)kT} \right)^{\frac{3}{2}} \exp \left[-\frac{\mu v_{\text{rel}}^2}{2kT} \right] d\mathbf{v}_{\text{rel}} \left(\frac{m_1 + m_2}{2\pi kT} \right)^{\frac{3}{2}} \exp \left[-\frac{M \dot{R}^2}{2kT} \right] d\dot{\mathbf{R}} = \\ &= dw_{\text{rel}} dw_{\text{c.m.}} \end{aligned}$$

We see that the probability of a given state of motion of two particles is equal to the product of the probabilities of two independent events: the probability for the particles to have a given relative velocity,

$$dw_{\text{rel}} = \left(\frac{\mu}{2\pi kT} \right)^{\frac{3}{2}} \exp \left[-\frac{\mu v_{\text{rel}}^2}{2kT} \right] dv_{\text{rel}}, \quad (11.1)$$

and the probability for the centre of mass of the system of the two particles to move in space with a given velocity

$$dw_{\text{c.m.}} = \left(\frac{M}{2\pi kT} \right)^{\frac{3}{2}} \exp \left[-\frac{M \dot{R}^2}{2kT} \right] d\dot{\mathbf{R}}.$$

In the problem of collisions, only the first probability is of interest. In the case of particles with the same mass $\mu = \frac{1}{2}m$, so that

$$dw_{\text{rel}} = \left(\frac{m}{4\pi kT} \right)^{\frac{3}{2}} \exp \left[-\frac{mv_{\text{rel}}^2}{4kT} \right] dv_{\text{rel}}. \quad (11.2)$$

By means of the probability distribution (11.2) the mean value \bar{v}_{rel} of the velocity of relative motion can be found

$$\bar{v}_{\text{rel}} = 4\pi \left(\frac{m}{4\pi kT} \right)^{\frac{3}{2}} \int_0^{\infty} \exp \left[-\frac{mv_{\text{rel}}^2}{4kT} \right] v_{\text{rel}}^3 dv_{\text{rel}} = \sqrt{2} \bar{v}. \quad (11.3)$$

Thus, the mean velocity of relative motion is almost one and a half times the mean velocity of the thermal motion.

Let us now find the number of collisions undergone per unit time by a molecule of a gas having a number density n . We assume that the gas is so rarefied that the molecules only collide in pairs, that is, collisions in which three or more molecules come simultaneously into direct contact can be disregarded. The process of collision of molecules can be characterized by their cross section σ .

In considering collisions between gas molecules we shall assume that all the gas molecules except one are at rest. The molecule singled out moves relative to those at rest with a velocity v_{rel} . In unit time it traverses a path v_{rel} and collides with all particles lying in a cylinder of volume σv_{rel} . The number of such collisions is, obviously, equal to $\sigma v_{\text{rel}} dn_{v_{\text{rel}}}$, where $dn_{v_{\text{rel}}} = n dw_{\text{rel}}$ and dw_{rel} is given by formula (11.2).

The total number of collisions undergone by the molecule per unit time is obtained by integrating this expression over all possible values of v_{rel} :

$$\begin{aligned} \nu &= \int \sigma v_{\text{rel}} dn_{v_{\text{rel}}} = \\ &= 4\pi \left(\frac{m}{4\pi kT} \right)^{\frac{3}{2}} n \int_0^{\infty} \sigma(v_{\text{rel}}) \exp \left[-\frac{mv_{\text{rel}}^2}{4kT} \right] v_{\text{rel}}^3 dv_{\text{rel}}. \end{aligned} \quad (11.4)$$

If the cross section for the collision can be assumed to be independent of the velocity, then instead of (11.4) we obtain

$$\begin{aligned}
 \nu &= 4\pi \left(\frac{m}{4\pi kT} \right)^{\frac{3}{2}} n\sigma \int_0^{\infty} \exp \left[-\frac{mv_{\text{rel}}^2}{4kT} \right] v_{\text{rel}}^3 dv_{\text{rel}} = \\
 &= n\sigma \bar{v}_{\text{rel}} = n\sigma \sqrt{2} \bar{v} = 4n\sigma \left(\frac{kT}{\pi m} \right)^{\frac{1}{2}}.
 \end{aligned} \tag{11.5}$$

This is just the number of collisions undergone by the molecule per second.

§ 12. The mean free path

Let us now find the mean path traversed by a molecule between two successive collisions, which is called the mean free path.

In one second a molecule traverses in space a path equal, on the average, to \bar{v} , and undergoes ν collisions. The mean path between collisions is equal to

$$\lambda = \frac{\bar{v}}{\nu} = \frac{\bar{v}}{n\sigma \bar{v}_{\text{rel}}} = \frac{1}{n\sigma \sqrt{2}}. \tag{12.1}$$

The path λ is on the average proportional to the ratio of the mean path traversed per unit time by the molecule to the number of collisions undergone by it. Hence the quantity λ is called the mean free path. The mean free path λ turns out to be inversely proportional to the gas density n and the cross section σ .

Formula (12.1) gives the mean free path. However, it is often important to know the probability for a molecule to traverse an arbitrary path x without undergoing any collision. In other words, what is of interest here is the law of the probability distribution of free paths for the molecules. We denote by $w(x)$ the probability for a molecule to traverse a distance x without undergoing any collision.

Correspondingly, $w(x+dx)$ represents the probability for a molecule to traverse a path $x+dx$ without undergoing any collision.

The traversal of the path $x+dx$ is a complex event, consisting of two independent stages: the traversal of the path x without collisions and the subsequent traversal of the path dx also without collisions.

Since these events are independent, we can write that

$$w(x+dx) = w(x) w(dx). \tag{12.2}$$

It is convenient to rewrite the above probability in another form. It is obvious that the probability $w'(dx)$ for a molecule to undergo a collision on the infinitesimally small path dx is proportional to the length dx and can be written in the form adx , where a is a certain coefficient of proportionality. The probability that a molecule will traverse the path dx without collisions is equal to

$$w(dx) = 1 - w'(dx) = 1 - adx .$$

Substituting this into (12.2) we find

$$w(x+dx) = w(x) (1 - adx) . \quad (12.3)$$

Expanding $w(x+dx)$ in a series in powers of dx and confining ourselves to infinitely small quantities of the first order of smallness, we have

$$w(x+dx) = w(x) + \frac{dw}{dx} dx ,$$

whence, substituting into (12.3), we obtain

$$dw = -aw(x) dx .$$

Integrating, we find

$$w(x) = Ae^{-ax} .$$

In order to determine the arbitrary constant A , we note that the probability for a molecule to traverse an arbitrarily small path without collisions is equal to unity:

$$w(x \rightarrow 0) = 1 .$$

Whence it follows that $A = 1$ and, finally,

$$w(x) = e^{-ax} . \quad (12.4)$$

In order to determine the meaning of the constant a we shall find the mean free path λ , making use of formula (12.4).

By definition the mean free path λ is equal to

$$\lambda = \int_0^{\infty} x dP, \quad (12.5)$$

where dP is the probability that a molecule, after traversing a path x , without collisions, will undergo a collision on the segment $x, x+dx$. According to the foregoing, we can write

$$dP = w(x) w'(dx) = w(x) a dx = a e^{-ax} dx. \quad (12.6)$$

Substituting the value of dP into (12.5) we find

$$\lambda = a \int_0^{\infty} x e^{-ax} dx = a^{-1}. \quad (12.7)$$

Thus, the constant a turns out to be a quantity inversely proportional to the mean free path.

Formula (12.4) for the probability that a molecule will traverse a path x without undergoing any collision can be rewritten in the form

$$w(x) = e^{-x/\lambda}. \quad (12.8)$$

This probability turns out to be an exponentially decreasing function of the distance. It should be stressed that $w(x)$ gives the probability for a molecule to traverse a path x without collisions irrespective of the position where it underwent the last collision. This means that the distance x is measured from an arbitrary point and not from the position of the last collision.

The probability for a molecule to traverse a path without collisions and then to collide in the segment $x, x+dx$ is, according to (12.6) and (12.7), equal to

$$dP = \lambda^{-1} e^{-x/\lambda} dx. \quad (12.9)$$

Formula (12.8) is important for the experimental determination of the mean free path of gas molecules. Imagine a narrow collimated molecular beam entering a container, evacuated to a relatively low pressure, containing a cooled plate placed in the path of the beam, first at a distance x_1 and then at a distance x_2 from the inlet. Molecules which traverse the paths x_1 and x_2

without collisions will reach the plate, forming a deposit on it. The ratio of the number of particles deposited on the plate in the two positions is, according to (12.8), equal to

$$\frac{N(x_1)}{N(x_2)} = \frac{e^{-x_1/\lambda}}{e^{-x_2/\lambda}}. \quad (12.10)$$

By measuring the numbers $N(x_1)$ and $N(x_2)$ and assuming that λ is the same for all molecules of the beam, λ can be determined by means of (12.10).

In accordance with the requirements of the theory, λ turns out to be inversely proportional to the density or, what is the same, to the pressure of the gas. The order of magnitude of λ amounts to about 10 cm at $p \approx 10^{-3}$ mm of mercury and about 10^{-5} cm at atmospheric pressure.

Statistical Distribution

§ 13. Quasi-independent systems

Consider a macroscopic system consisting of a very large number of particles. We assume that the motion of all the particles is determined by the laws of quantum mechanics; the state of each particle is characterized by certain quantum numbers. We divide the whole system into a large number of parts in such a way that the interaction between these parts is very weak and can be neglected in the first approximation. We shall call the whole system under investigation the ensemble of its almost independent parts.

These weakly interacting parts of the system are, in the first approximation, moving independently of one another. However, the interaction existing between them leads to the fact that, in reality, the motion of one of the parts affects the motion of another, and that they are not completely independent. In the following we shall call the weakly interacting parts of a large system the quasi-independent subsystems, or simply subsystems.

We first of all dwell on the problem for which the subsystems forming a large system can be considered as independent.

It is obvious that the subsystems are quasi-independent if the energy of their interaction is, on the average, small in comparison with the energy of each of the subsystems. This means that in some cases the interaction between

the subsystems can be relatively large, but the duration of the interaction must be so small that they spend an overwhelmingly large part of the time without interacting with each other.

As an example of such subsystems one can mention the molecules of an ideal gas, which interact strongly with one another only seldom and then for a very short time interval.

In other cases a continuous, but weak, interaction can exist between subsystems. Imagine, for example, that each of the subsystems of the system contains a very large number of particles (atoms or molecules) and, thus, represents a macroscopic system. Then the total energy of a subsystem, made up of the energies of motion of the individual particles, is proportional to the total number of particles of the subsystem. The number of particles is in its turn proportional to the volume of that subsystem. The interaction between various subsystems is mainly due to the forces of molecular interaction between the molecules which are at the surface of each of the interacting subsystems *. These forces decrease so rapidly with distance that the contribution to the energy of interaction of molecules which are deep inside the subsystems is small in comparison with that of the surface molecules. Hence the energy of interaction between the subsystems is proportional to the number of molecules at their surface, i.e. to the size of the surface.

Thus, the energy $\bar{\epsilon}$ of a subsystem is proportional to R^3 , where R is the characteristic linear dimension of the system, and the interaction energy is $\bar{\epsilon}_{\text{int}} \sim R^2$. Their ratio

$$\frac{\bar{\epsilon}_{\text{int}}}{\bar{\epsilon}} \sim \frac{R^2}{R^3} \sim \frac{1}{R} \sim N^{-\frac{1}{3}}$$

becomes negligibly small for a sufficiently large N .

The energy of the entire ensemble of quasi-independent systems can then be assumed to be equal to the sum of the energies of the individual parts, i.e.

$$E \approx \sum \epsilon_i, \quad (13.1)$$

* We shall nowhere take into account the gravitational interaction between the molecules, because it is very weak and does not play any part in molecular processes. However, it should be noted that, in studying the macroscopic properties of matter in astrophysical problems, the gravitational field is in a number of cases of essential importance and must be taken into account.

where the sign \approx underlines the fact that in writing (13.1) we have disregarded the energy of interaction between the subsystems forming the ensemble. The summation in (13.1) is carried out over all parts of the system (the subsystems).

§ 14. Statistical distribution

From the whole system we single out mentally an arbitrarily chosen subsystem. This subsystem consists of a certain number of molecules (as we have just explained, it can be either small or large, depending on the actual nature of the subsystems constituting the system) moving according to the laws of quantum mechanics. The energy of our subsystem is not strictly constant, but, on the contrary, varies continuously within the range of the value ϵ_{int} , where ϵ_{int} is the energy of the interaction of the system with its surroundings. Although ϵ_{int} is very small and can be disregarded in the energy balance, it nevertheless plays an essential part in the behaviour of the system. The interaction of the subsystem with bodies surrounding it is the cause of its transitions from one quantum state into others. This interaction is of an extremely complicated character. Even in the simplest case, when individual molecules were taken as subsystems, we saw that an attempt to determine the motion of each molecule, i.e. the sequence of change of states, presented great difficulties. In a gas consisting of a very large number of particles new laws are introduced which we have briefly formulated in the proposition of molecular disorder. The situation is completely analogous also in the general case of the macroscopic system consisting of a large number of quasi-independent subsystems. The interaction between the subsystems is so complex that an accurate determination of the state of each of the subsystems becomes a problem even more difficult than finding the motion of individual gas molecules. At the same time, such a determination loses any physical meaning. Indeed, even if we succeeded in the determination of the state in which a certain subsystem is at a given instant, it would, as a result of the interaction with other subsystems, pass over into another state in a very short time. Hence the particular known state of a subsystem entering into a large ensemble of systems, at a certain instant, does not characterize the overall ensemble, just as the velocity of an individual gas molecule does not characterize the properties of the gas as a whole. In this connection we renounce beforehand any attempt to describe the behaviour of an individual subsystem, and instead look for the statistical laws characterizing the behaviour of the overall ensemble of the subsystems as a whole. This means that we shall not try to

trace in detail the successive changes of state of an individual subsystem in the course of time, but shall seek to find the probability w_i for an arbitrarily chosen subsystem of the ensemble to get into a certain i th state. If we find this distribution, we shall then be able:

(1) *to find the mean number of subsystems* in a given state, if an ensemble consisting of N identical subsystems is given (for example, the number of molecules in a given state, if the subsystems correspond to individual gas molecules);

(2) *to find the mean value of any quantity characterizing the state of an individual system*, for example its energy, from the general rules set out in §4;

(3) *to find the deviations of quantities from their mean values*, characterized by the mean square deviation.

In this case we can apply the general statistical considerations of §5 to a macroscopic quasi-independent subsystem consisting in its turn of a very large number of particles. These considerations show that in such a system all quantities have values differing very little from their mean values. Hence if we know the latter, then we can assume, with a high degree of accuracy, that we know the true values of all the quantities characterizing a state of a subsystem.

Thus we see that the statement of the problem in statistical physics differs in no way in principle from that in the kinetic theory of gases. We shall investigate the statistical laws shown in systems consisting of a very large number of particles. Knowing these laws, we can calculate the mean values of all sorts of quantities. Since, however, the objects in which we are interested are macroscopic bodies consisting of a very large number of particles, the predictions obtained from statistical laws have a completely reliable character. The mean values of all the quantities are the same as the true values to a high degree of accuracy.

However, besides this similarity between the general statement of the problem in statistical physics and in the kinetic theory of gases there is also a fundamental difference between them. In the kinetic theory of gases an individual quasi-independent system was always a molecule of a rarefied gas. The molecule was assumed to be monatomic, since only its translational motion was considered. The gas as a whole corresponded to our ensemble of systems. In statistical physics the problem is stated much more broadly. An individual subsystem can be any quasi-independent system. It can be a monatomic molecule in a rarefied gas as well as a polyatomic molecule performing not only a translational motion but also a rotational and vibratory motion. The system can also be a gas as a whole, confined to a certain con-

tainer. The walls of this container and the bodies surrounding it play the role of other systems with which the gas in the container (a quasi-closed system) interacts weakly and exchanges energy. The gas, the walls of the container and the bodies surrounding it form an ensemble of subsystems. A subsystem can, for example, be a solid body containing a sufficiently large number of particles. The bodies surrounding it play the role of other parts of the ensemble.

Thus, an ideal gas, considered in the kinetic theory of gases, is a particular and the simplest case of a general statistical system.

In the preceding chapter we have, for the particular case of an ideal gas, partly fulfilled the programme which we outlined at the beginning of this section. We saw that the stationary probability density distribution of different states of a molecule in the gas is established because of the interaction between gas molecules in collisions.

In the same way, in the general case of an ensemble of arbitrary quasi-stationary systems, a certain distribution of the probabilities for a subsystem to get into a definite energy state ϵ_i will be established. In the following sections the derivation of the statistical probability distribution for an arbitrary subsystem will be developed.

§ 15. The probability of a state of a system

Let us observe mentally the changes of state of a subsystem which we have singled out arbitrarily. We shall, for brevity, call all other parts of the system, constituting the surroundings of this subsystem, the reservoir. The meaning of this term will be clear from what follows. We shall call the subsystem itself, if not specified otherwise, simply the system. Each state of the system is characterized by a set of quantum numbers. If the system has f degrees of freedom, then its state is characterized by a set of f quantum numbers.

To each set of quantum numbers there corresponds a certain quite definite energy of the system*. If the system consists of a large number of particles and has many degrees of freedom, different energy levels corresponding to different, but mutually similar sets of quantum numbers, lie very close to one another. In the limiting case where the number of particles is very large,

* In what follows we shall dwell in more detail on this problem and take into account the case where different sets of values of the quantum numbers correspond to one and the same energy, i.e. the case of degenerate systems.

so that the system is macroscopic, we pass over from a quantum system to a classical system *. In this case all the energy levels merge into a continuous spectrum, and instead of discrete levels use can be made of the continuous energy range of the classical theory.

As we have already stressed, because of the interaction with the surroundings the energy of the system is not constant. Hence it is senseless to speak about a well defined energy of the system, and it should be said only that its energy lies within ϵ and $\epsilon + \delta\epsilon$. To energy values of the system lying within the range ϵ and $\epsilon + \delta\epsilon$ there corresponds a certain number $\Omega(\epsilon)\delta\epsilon$ of quantum states. We shall often call $\Omega(\epsilon)$ the number of quantum states corresponding to the energy ϵ of the system, or the degeneracy of a given state. This should not lead to misunderstanding. In fact, we shall assume the above definition. It is obvious that to different energy values ϵ there corresponds a different number $\Omega(\epsilon)$ of quantum states. It is different also for different physical systems.

In the case where the system is an individual atom or molecule, the number of quantum states corresponding to a given energy is small for small excitation energies, but increases rapidly with increasing energy. If the system is a macroscopic body, there is always a practically continuous energy spectrum.

In what follows we shall make use of the actual value of $\Omega(\epsilon)$ for the simplest systems, as derived in ch. 1.

As a result of complex and random interactions between the system and its surroundings (the reservoir) the states of the system will change and it will go over from one quantum state into others. The system will perform transitions between different states corresponding to a given energy value ϵ (more precisely, corresponding to an energy lying within the range ϵ , $\epsilon + \delta\epsilon$) as well as between states with different energies ϵ_1 , ϵ_2 ,

For example, in the case where the subsystem is an individual molecule, collisions with other molecules and the wall of the container, forming the thermostat, lead to transitions into other states with the same energy (changes in the direction of motion only) or into states with a different energy (inelastic collisions or elastic collisions with a relatively large momentum transfer).

If one observes the change of the system during a relatively long time interval, then it will pass through all possible states. The state of the system at a given instant will depend neither on its initial state nor on the initial state of the reservoir. The effect of initial conditions will be completely concealed

* The problem of the transition to classical systems will be considered more precisely in Part V.

by complicated transitions, interactions, and so on. Hence we can say that the state of the system at any instant will be determined by the complex pattern of random interaction between the system and its surroundings.

If attention is first drawn to transitions between different states belonging to a given energy value (between ϵ and $\epsilon + \delta\epsilon$), then it is physically obvious that all these states are mutually equivalent and that no one can have any advantages over others. The equivalence of the states of the system belonging to a given energy is a generalization of the proposition of molecular disorder in an ideal gas. In fact, the latter means that all states with the same energy but with different directions of motion in space and different positions in the container are equally probable in an ideal gas.

If the system is observed during a sufficiently long time interval, then, since all states with a given energy are equivalent, it will appear in all these states, irrespective of the state which it was in initially. Moreover, since the transition of the system from one state into another occurs as a result of accidental perturbations and the action of its surroundings and all quantum states belonging to a given energy are completely equivalent, it can be said that the system will have an equal chance to get into each of them. Hence the time during which the system is in each of the quantum states belonging to a given energy is the same for all these states. To characterize a state, one usually gives not the time interval during which the system is in it, but the ratio of this time to the overall observation time, i.e. the probability of realization of a given state. Then the preceding statement can be formulated briefly as the following principle: in a quasi-closed system all quantum states belonging to a given energy (lying between ϵ and $\epsilon + \delta\epsilon$) are equivalent. This statement is called the law of equal probability of elementary quantum states.

The question as to whether, in fact, a macroscopic system can be in all states with a given energy, without exceptions, has been the object of discussion of physicists and mathematicians over the course of a number of years.

Systems which can enter any state of a given energy during a sufficiently long time interval are called ergodic systems. If at the initial instant the ergodic system is in a certain state, then sooner or later it will get into any other state previously chosen out of a given group of states (ergodic hypothesis). Although this proposition seems to be very likely, there is no proof for it. Difficulties arising in connection with this hypothesis are overcome in quantum statistics by considering idealized systems in which transitions into some of the states are forbidden by selection rules. These rules are understood to be certain restrictions of the possibility of transitions due to various

causes, which we cannot go now into *. Then all the microscopic states can be divided into two groups — those between which transitions are possible, and those into which systems of the first group cannot get. If the second group of states is indeed completely forbidden, then, in considering the properties of the system, the states of this group can be assumed to be non-existent. On the contrary, the system sooner or later gets into all states of the first group.

In reality, there are no such idealized systems in nature. Also, more or less probable transitions between any states of the system are possible. The probabilities of these transitions can be considerably different from each other. Imagine, for example, a system consisting of atoms which can be in different states and which can interact with one another. Various processes can take place in the system as a result of this interaction, provided they do not contradict the basic laws of motion. For example, a fraction of the atoms can obtain energy from other atoms and pass over into an ionized state. However, such processes occur with such a low probability and, hence, proceed so slowly that in considering the behaviour of the system during any practically feasible time interval in terrestrial conditions, we can completely disregard the possibility of their occurrence.

The same thought can be expressed as follows: the transition of the system into a state corresponding to bare nuclei and free electrons is forbidden, and only the states of the system consisting of atoms should be considered. Since our purpose is the calculation of mean values, and the contribution of highly improbable states to them is very small, we shall not commit any significant error by ignoring completely transitions into forbidden states which are possible, but improbable. If it is assumed that transitions are possible between other (allowed) states and that the system spends a sufficiently long time in all these states (in this restricted form the ergodic hypothesis is physically sufficiently convincing), then the principle of equal probability of all microscopic states can be illustrated by the following considerations.

Assume that there is a system of particles which can be in states 1, 2, ..., i , ... with one and the same energy. Let us denote by N_i the number of particles in the i th state and by N_k the number of particles in the k th state. Further, let w_{ik} be the probability of transition of a particle from the i th state into the k th state. This probability can be calculated by means of the laws of quantum mechanics. Finally, let w_{ki} be the probability of transition from the k th state into the i th state.

In quantum mechanics it turns out that all processes taking place with

* See Part V, § 106.

individual microscopic particles are strictly reversible, so that the probabilities of a direct transition w_{ik} and a reverse transition w_{ki} are always equal to each other*. This is the so-called principle of microscopic reversibility. The number of particles passing over from the i th state into the k th state per unit time is, obviously, equal to the number N_i of particles in the i th state multiplied by the probability w_{ik} of the transition. The number of reverse transitions is correspondingly equal to $N_k w_{ki}$. In the stationary state the number of direct and reverse transitions must be the same, since the system must remain on the average in a steady state.

$$N_i w_{ik} = N_k w_{ki}, \quad (15.1)$$

but, by virtue of the principle of microscopic reversibility $w_{ik} = w_{ki}$, whence it follows that $N_i = N_k$.

This reasoning can be extended to all other states between which there are transitions (i.e. $w_{ik} \neq 0$). It turns out that the numbers of particles in all states must be equal to one another and, consequently, all quantum states must be equally probable.

If we now pass over to transitions between states of the system with different energy (more precisely, with an energy differing by an amount much larger than the interaction energy ϵ_{int}), then it can be stated that, because of the open character of the system, it can also make such transitions.

In transitions into states with a higher energy the energy difference will be drawn by the system from its surroundings. In transitions into states with a lower energy the energy excess will be transferred to its surroundings. The probability of such transitions is ensured by the existence of an interaction. It is just the interaction that is the cause of transitions of the system from one state into others. These considerations are a generalization of the principle of molecular disorder, which we have used in the kinetic theory of gases. However, it should be stressed that the reasoning given is more physically likely than strictly substantiated. Hence the ergodic hypothesis should be assumed as a postulate the validity of which is proved by comparison of theory with experiment. In any case, for statistics it is sufficient that this hypothesis be fulfilled approximately in most cases.

* See Part V, §56.

§ 16. The Gibbs distribution

We now ask the question: what is the probability w_i of finding our system in states with an energy lying between ϵ_i and $\epsilon_i + \delta\epsilon_i$ (where $\delta\epsilon_i \ll \epsilon_i$, and the subscript i runs through the values 1, 2, 3, ...)? To each value of the energy ϵ_i there corresponds a certain group $\Omega(\epsilon_i)$ of quantum states.

Consider at first a closed system which does not interact with the bodies surrounding it. In reality, no perfectly closed systems can exist in nature. Whatever the physical nature of the system may be, it always interacts, if only very weakly, with the bodies surrounding it. In quantum mechanics it turns out that a system can have a strictly constant energy only when it is in the ground state (for a macroscopic system this corresponds to the state at absolute zero; see § 34 of Part V).

Hence we shall understand a closed system to be a system whose energy during the entire time of observation remains within a given narrow range $\delta\epsilon_i$.

Since all states with a given energy are equally probable, the probability that a closed system be found in one of the states with given energy is simply proportional to the number of states with that energy:

$$w(\epsilon_i) \sim \Omega(\epsilon_i). \quad (16.1)$$

Formula (16.1) is called the Gibbs microcanonical distribution. The microcanonical distribution shows that the probability for a closed system to be in a state with given energy is proportional to its degeneracy.

The Gibbs microcanonical distribution is the basis of statistical physics. It shows that a closed system will be found with greater probability in a state with a higher degeneracy.

In phase space the states of a closed system lying in a narrow interval $\delta\epsilon$ form a very thin layer, which reduces to a constant-energy surface as $\delta\epsilon \rightarrow 0$. Each cell in the constant-energy layer (surface) corresponds to each possible quantum state.

As an example of the application of the microcanonical distribution we shall consider a system of N particles which do not interact with one another and which can be in two different states. Specifically, we shall speak of particles with a spin one half (in units of $\hbar/2\pi$). In this case the projection of the spin of every one of the particles onto an arbitrary axis can take on two values: $s_{\uparrow} = \frac{1}{2}$ and $s_{\downarrow} = -\frac{1}{2}$. We shall conditionally call these spins upward and downward directed respectively. In the absence of an external magnetic field the energy of the system depends neither on the orientation of the spins of

the particles nor on that of the total spin $S = \sum s$ of the system. Hence to a given value of the energy of the system ϵ there corresponds a large number of different states corresponding to different orientations of the spins of the individual particles.

According to what has been said, all states with a given distribution of spin orientation are equally probable.

We apply formula (16.1) for finding the probability for a system of N independent particles with a total spin S . The total spin S of the system is obviously equal to $s(N_1 - N_2) = sn$, where N_1 and N_2 are the number of particles with spin oriented upward and downward respectively, and $n = N_1 - N_2$. Since $N_1 + N_2 = N$, there correspond to a total spin S , $\frac{1}{2}(N+n)$ particles with a spin directed upward and $\frac{1}{2}(N-n)$ particles with a spin oriented downward. Let us find the number $\Omega(n)$ of independent distributions of $\frac{1}{2}(N+n)$ particles with one spin orientation and $\frac{1}{2}(N-n)$ particles with the other spin orientation for a given total number N of particles.

Each of these distributions leads to one of the equally probable states of the system, so that the probability of the state with spin S which interests us, is according to (16.1), equal to

$$w \sim \Omega(n).$$

N independent particles can be distributed in a given order in $N!$ ways. The mutual permutation of particles with one and the same spin orientation, i.e. $\frac{1}{2}(N+n)$ particles with a spin oriented upward and $\frac{1}{2}(N-n)$ particles with a spin oriented downward, does not change the total spin. The number of such permutations is equal to $[\frac{1}{2}(N+n)]!$ and $[\frac{1}{2}(N-n)]!$. Hence the number of states of the system with a spin S is equal to the number of such independent distributions of N particles between the two states in which $\frac{1}{2}(N+n)$ of the particles are in the first state (with the spin upward) and $\frac{1}{2}(N-n)$ are in the second state (with the spin downward). Correspondingly,

$$w \sim \Omega(n) = \frac{N!}{\left(\frac{N+n}{2}\right)! \left(\frac{N-n}{2}\right)!}.$$

To obtain a more obvious formula use can be made of Stirling's formula (see Appendix IV) and it can be assumed that $n \ll N$. Then, upon taking the logarithm, we have

$$\begin{aligned}\ln w &= \ln N! - \ln \left(\frac{N+n}{2} \right)! - \ln \left(\frac{N-n}{2} \right)! \approx \\ &\approx N \ln \frac{N}{e} - \frac{N+n}{2} \ln \frac{N+n}{2e} - \frac{N-n}{2} \ln \frac{N-n}{2e} \approx N \ln 2 - \frac{n^2}{2N},\end{aligned}$$

or

$$w(n) \sim e^{-n^2/2N}.$$

We have arrived at the probability of a state expressed by a Gaussian distribution. The factor of proportionality can be found from the normalization condition. It is obvious that the most probable state is the state with $n = 0$, i.e. the state in which the number of spins oriented upward is equal to that of spins oriented downward. This state is an analogue of the state of molecular disorder in a gas. The probability distribution has a sharper maximum at the point $n = 0$ the larger the total number of particles in the system.

As we have already stressed, the Gibbs microcanonical distribution, establishing the probability of a given state of a closed system, is of fundamental importance. However, in practice one has much more often to deal not with closed systems, but with subsystems in a reservoir. We shall therefore turn to the consideration of such subsystems.

A subsystem and a reservoir together form a closed system the energy of which (with the above reservation) can be considered to be constant:

$$E = \text{const.}$$

We are interested, however, not in the probability distribution for a complex system but in the probability distribution for the subsystem (for any probability distribution for the reservoir). In order to find this it is necessary to take into account the particular character of the interaction between the subsystem and the reservoir.

As has already been pointed out, this interaction is weak, so that the energy of interaction can be neglected in the total energy balance. Writing the latter in the form

$$E = E_k^{(0)} + \epsilon_i = \text{almost a constant}, \quad (16.2)$$

where $E_k^{(0)}$ is the energy of the reservoir in the k th state, ϵ_i is the energy of

the subsystem in the i th state, and the term "almost a constant" underlines the fact that terms expressing the interaction between the subsystem and the reservoir, as well as between the complex system and the bodies surrounding it, are omitted in the energy conservation law (16.2).

The neglect of the energy of interaction between the system and the reservoir means that we can consider the quasi-closed system and the reservoir to be independent systems for an overwhelmingly large part of the time.

The subsystem can be in any of $\Omega(\epsilon_i)$ states with an energy ϵ_i , while the reservoir can be in any of $\Omega_0(E_k^{(0)})$ states with an energy $E_k^{(0)}$.

If the transitions mentioned do not take the system out of the group of states with an energy ϵ_i and the reservoir correspondingly out of a state with an energy $E_k^{(0)}$, then a change in the state of the subsystem in no way affects the state of the reservoir and, conversely, a change in the state of the reservoir has no effect on the state of the subsystem. On the other hand, by virtue of the energy conservation law (16.2) the energy of the reservoir and that of the subsystem are unambiguously interrelated. If the subsystem has an energy ϵ_i , then the reservoir must have an energy $E_k^{(0)}$.

After these remarks we can now turn to finding the probability that the subsystem be in one of the states with an energy ϵ_i .

From the last remark this probability w_i is equal to the probability that the complex system (subsystem + reservoir) be in such a state that the subsystem has an energy ϵ_i and the reservoir an energy $E_k^{(0)}$. Since w_i is the probability of a given state of a closed system, it is expressed in terms of the number of states according to formula (16.1):

$$w_i \sim \Omega(E) = \Omega(E_k^{(0)} + \epsilon_i). \quad (16.3)$$

On the other hand, the number of states of a closed system consisting of two independent parts is equal to the product of the number of states of the two parts, i.e.

$$\Omega(E_k^{(0)} + \epsilon_i) = \Omega_0(E - \epsilon_i) \Omega(\epsilon_i). \quad (16.4)$$

Here, in the expression for the number of states of the reservoir Ω_0 we have written as the argument the expression $E - \epsilon_i$ on the basis of (16.2).

Substituting the expression (16.4) into (16.3), we find

$$w_i \sim \Omega_0(E - \epsilon_i) \Omega(\epsilon_i). \quad (16.5)$$

The very weak interaction between the system and the surroundings serves

as the cause of transitions of the system from one state into another. Since the dimensions of the reservoir are very large in comparison with those of the system, we can assume that the energy $E_k^{(0)}$ of the reservoir for all values of k is also very large in comparison with the energy of the system. Hence, whatever the changes of the energy of the system may be, the energy of the reservoir can be considered to be almost constant. All different states in which the reservoir is found when the system passes from one energy state into another can be assumed to have one and the same energy.

Because of this we can expand $\Omega_0(E-\epsilon_i)$ in a series in powers of the small quantity ϵ_i and confine ourselves to the first term of the expansion. However, it should be noted that the function $\Omega_0(E-\epsilon_i)$ cannot itself be expanded directly in a power series. Indeed, we know that the number of states is a multiplicative function, while the energy is an additive function. The number of states of a system consisting of independent parts is equal to the product of the number of states of these parts, while the energy is equal to the sum of the corresponding energies. If we expanded $\Omega_0(E-\epsilon_i)$ in a series in powers of the small quantity ϵ_i , then we would obtain the expression

$$\Omega_0(E-\epsilon_i) \approx \Omega_0(E) - \frac{\partial \Omega_0}{\partial E} \epsilon_i, \quad (16.6)$$

which does not possess the required properties. If, for example, we considered two systems with the numbers of states $\Omega_0^{(1)}$ and $\Omega_0^{(2)}$ and energies $[E^{(1)}-\epsilon_i^{(1)}]$ and $[E^{(2)}-\epsilon_i^{(2)}]$ respectively, then the number of states should be equal to $\Omega_0^{(1)}\Omega_0^{(2)}$ and the energy should be equal to $[E^{(1)}-\epsilon_i^{(1)}+E^{(2)}-\epsilon_i^{(2)}]$. However, in multiplying the left-hand sides of the expansion (16.6) the right-hand sides are not multiplied.

Hence before expanding the number of states $\Omega_0(E-\epsilon_i)$ in a series we write it in the form

$$\Omega_0(E-\epsilon_i) = e^{\sigma(E-\epsilon_i)}, \quad (16.7)$$

where $\sigma(E-\epsilon_i)$ is a new function of the argument $(E-\epsilon_i)$. Such a representation is always possible, since the number of states by its very nature is an essentially positive quantity, the values of which are obviously not less than unity.

Writing $\sigma(E-\epsilon_i)$ in the form

$$\sigma(E-\epsilon_i) = \ln \Omega_0(E-\epsilon_i), \quad (16.8)$$

Expanding $\sigma(E - \epsilon_i)$ in a series in powers of the small quantity ϵ_i and confining ourselves to the first term, we have

$$\sigma(E - \epsilon_i) \approx \sigma(E) - \frac{\partial \sigma}{\partial E} \epsilon_i = \sigma - \frac{\epsilon_i}{\theta},$$

where θ stands for the quantity

$$\theta = \left(\frac{\partial E}{\partial \sigma} \right)_{\sigma_i=0}. \quad (16.9)$$

Then for $\Omega_0(E - \epsilon_i)$ we find

$$\Omega_0(E - \epsilon_i) \approx e^{\sigma(E)} e^{-\epsilon_i/\theta}. \quad (16.10)$$

It is easily seen that (16.10) satisfies the requirement of the product of Ω with the addition of the energies of independent systems.

Substituting the expression (16.10) into (16.5), we have

$$w_i = \text{const } e^{-\epsilon_i/\theta} \Omega(\epsilon_i), \quad (16.11)$$

where const stands for the product of the factor of proportionality and the quantity $e^{\sigma(E)}$, which does not depend on the value of ϵ_i or the properties of the subsystem.

Formula (16.11) determines the probability that a certain system, representing a small weakly interacting part of a certain ensemble of arbitrary physical systems, be found in one of $\Omega(\epsilon_i)$ states with an energy lying between ϵ_i and $\epsilon_i + \delta\epsilon_i$, and that the reservoir be found in one of the states with an energy lying between $E - \epsilon_i$ and $E - (\epsilon_i + \delta\epsilon_i)$. Since the state of the reservoir is of no interest, we shall for brevity say that w_i is the probability for the subsystem to be in one of the states with energy ϵ_i .

From the definition of the probability it follows that the following normalization conditions must hold:

$$\sum w_i = 1, \quad (16.12)$$

where the summation is carried out over all possible quantum states of the system.

From the normalization condition and the form of w_i it follows imme-

diately that the coefficient θ , introduced formally, is an essentially positive quantity. Only if this is so does the probability of states of arbitrarily large energies tend to zero, as is to be expected from the very meaning of the notion of physical probability, and as follows formally from the normalization condition. The constant in (16.11) can be found from the normalization condition. Substituting (16.11) into (16.12), we find

$$\text{const} = \frac{1}{\sum e^{-\epsilon_i/\theta} \Omega(\epsilon_i)}.$$

Hence the probability distribution can be put in the final form

$$w_i = \frac{e^{-\epsilon_i/\theta} \Omega(\epsilon_i)}{\sum e^{-\epsilon_i/\theta} \Omega(\epsilon_i)}. \quad (16.13)$$

The distribution (16.13) is the distribution sought, and will serve as the basis of all further discussion. It was first found by Gibbs in 1901 for systems obeying the laws of classical mechanics. This distribution is called the Gibbs distribution or the canonical distribution. The transition from quantum states possessing a discrete set of energy levels to classical systems presents no difficulty and will be made in one of the following paragraphs. The quantity θ figuring in the Gibbs distribution is called the distribution modulus or statistical temperature.

The Gibbs distribution describes the probability distribution of different states of a subsystem representing a small quasi-independent part of an arbitrary system in a state of statistical equilibrium. It should be stressed that, if the system is not in an equilibrium state, then all the foregoing reasoning is invalid. The principle of equal probability of states with a given energy is inapplicable to a non-equilibrium system.

The sum $\sum \exp(-\epsilon_i/\theta) \Omega(\epsilon_i)$ figuring in the denominator of (16.13) will play an important role in what follows. We introduce for it the special notation

$$Z = \sum e^{-\epsilon_i/\theta} \Omega(\epsilon_i), \quad (16.14)$$

and call it the partition function, since all states of the system give a contribution to it. In the literature it is often called the sum over states, or the statistical sum. However, this terminology does not appear to us to be quite apt. By introducing the partition function the Gibbs distribution can be written in the form

$$w_i = Z^{-1} e^{-\epsilon_i/\theta} \Omega(\epsilon_i). \quad (16.15)$$

The Gibbs distribution for any concrete physical system can be considered to be known if the energy levels of the system, i.e. the possible values of the energy ϵ_i , and the degeneracy of the states of the system, i.e. the number of different states $\Omega(\epsilon_i)$ corresponding to a given value of the energy ϵ_i , are known. For a number of systems which will be considered below these physical characteristics can be found.

A remarkable feature of the Gibbs distribution is the fact that the mechanism of interaction of the subsystem with its surrounding in no way figures in it.

By means of the Gibbs distribution one can calculate the mean value of any quantity depending on the state of the system. If $L(\epsilon_i)$ is the value of a certain physical quantity for the states corresponding to an energy ϵ_i , then, according to the general laws for finding a mean value, we can write

$$\begin{aligned} \bar{L} &= \sum L(\epsilon_i) w_i = Z^{-1} \sum L(\epsilon_i) e^{-\epsilon_i/\theta} \Omega(\epsilon_i) = \\ &= \frac{\sum L(\epsilon_i) e^{-\epsilon_i/\theta} \Omega(\epsilon_i)}{\sum e^{-\epsilon_i/\theta} \Omega(\epsilon_i)}. \end{aligned} \quad (16.16)$$

§17. The statistical temperature

Let us first of all consider the properties of the distribution modulus θ which we have already introduced. From its definition it follows that it characterizes the properties of the entire ensemble of systems, i.e. the reservoir, and not the subsystem that we singled out. Indeed, in formula (16.9) there appear only quantities referring to the entire ensemble of subsystems: its energy E and the function σ , whose value $(\partial E/\partial \sigma)$ is taken for $\epsilon_i = 0$, so that $\sigma = \sigma(E)$. Hence the modulus θ always refers to a macroscopic system and is a function of the state of this system. When the state, and in particular the energy of the entire system changes, the distribution modulus θ changes. Since the function σ , determined from formula (16.8) and representing the logarithm of the number of states with a given energy, is a

single-valued function of the state (energy) of the system, θ is also a single-valued function of the energy of state of the system.

Further, the distribution modulus θ is an essentially positive quantity. Indeed, if the energy ϵ_i can assume any arbitrarily large value, then the probability of a state with given energy ϵ_i must decrease with increasing energy. If that were not so, the normalization condition (16.12) could not be fulfilled.

Thus, θ can refer only to a macroscopic system and is essentially a positive single-valued function of its state. We shall show that the distribution modulus θ is a characteristic of the equilibrium state in the system. For this we shall consider two subsystems belonging to different systems, having distribution moduli θ_1 and θ_2 . Each of the subsystems will be assumed to be in a state of statistical equilibrium, so that the probabilities of their states are determined by formula (16.11):

$$w_1 = A_1 e^{-\epsilon_1/\theta_1} \Omega_1, \quad w_2 = A_2 e^{-\epsilon_2/\theta_2} \Omega_2.$$

We assume that both systems come into a weak interaction, so that an energy exchange can take place between them. The two interacting subsystems can be considered as one unified subsystem. If the latter turns out to be in a state of statistical equilibrium, then the probability distribution of its states must also be described by a law of the form

$$w = A e^{-\epsilon/\theta} \Omega. \quad (17.1)$$

On the other hand, since the interaction is weak, the interaction energy can be disregarded and each of the subsystems can be assumed to be quasi-independent. Then to find the probability distribution of the complex system use can be made of the theorem of multiplication, and one can write

$$w = w_1 w_2 = A_1 A_2 e^{-\epsilon_1/\theta_1} e^{-\epsilon_2/\theta_2} \Omega_1 \Omega_2. \quad (17.2)$$

In order that the distribution (17.2) may be identical with (17.1), it is necessary that

$$\theta_1 = \theta_2 = \theta.$$

Thus, if two equilibrium subsystems with equal moduli $\theta_1 = \theta_2$ are brought into interaction, then a unified equilibrium system with the same modulus $\theta = \theta_1 = \theta_2$ will be obtained. If θ_1 were different from θ_2 , then in establish-

ing the interaction a system would arise with a probability distribution expressed by formula (17.2). This distribution is not the Gibbs distribution for a system with energy $\epsilon = \epsilon_1 + \epsilon_2$. Hence the system formed when $\theta_1 \neq \theta_2$ will not be in an equilibrium state. The equilibrium state is not violated when an interaction is established between subsystems, if their moduli θ_1 and θ_2 are equal to each other, and is violated if $\theta_1 \neq \theta_2$.

That is why the quantity θ is called the statistical temperature. In the case where the subsystem contains such a large number of particles that it can be considered as macroscopic, one can also speak of its proper statistical temperature. Its temperature is determined from the condition of equilibrium of the subsystem and the reservoir and, consequently, is equal to the temperature of the latter. Therefore, θ can, for brevity, be called the temperature of the system.

It goes without saying that, if a quasi-closed subsystem contains an insufficiently large number of particles, then the notion of its temperature becomes approximate and, in the case of a subsystem represented by an individual molecule of an ideal gas, it completely loses any meaning.

The value of the statistical temperature is determined by formula (16.9) and depends on the energy of the system. It is, in the general case, impossible to find the form of this dependence, since it is determined by the particular properties of the system. However, in practice one is interested not in the dependence of θ on E but in the reverse, the dependence of the energy on the temperature $E = E(\theta)$. In what follows we shall see that the energy is a monotonic function of temperature. We shall find the concrete form of the dependence of the energy on the temperature θ for certain simple systems (gas, ideal crystal and so on).

§18. The properties of the Gibbs distribution and statistical equilibrium

The Gibbs distribution characterizes the probability distribution of different states of a quasi-closed system. The conditions for the Gibbs distribution to be applicable are:

- (1) the presence of a certain macroscopic system constituting the surroundings (reservoir) of the system considered.
- (2) the presence of a weak interaction between the system and the reservoir.

Other properties of the system are completely arbitrary.

The Gibbs distribution, as well as the Maxwell energy distribution, has a maximum at a certain energy value. At first sight the existence of this maxi-

num is not obvious: the exponentially decreasing factor $\exp(-\epsilon_i/\theta)$ figures in the Gibbs distribution.

However, it should be recalled that the number of states with given energy $\Omega(\epsilon_i)$ increases rapidly with the energy of the system. The more particles the system contains, the more states $\Omega(\epsilon_i)$ correspond to a given energy interval $\epsilon_i, \epsilon_i + \delta\epsilon_i$. Hence the increase of $\Omega(\epsilon_i)$ with energy proceeds the more rapidly the more particles there are in the system. As will, for example, be shown in § 20, if the subsystem is a gas consisting of N independent monatomic molecules, confined in a container with a constant temperature (reservoir), then $\Omega(\epsilon) \sim e^{-\frac{3}{2}N}$.

The product of two functions — the one decreasing rapidly and the other increasing with energy — leads to the appearance of a sharp maximum in the Gibbs distribution. This maximum is sharper, the more rapidly $\Omega(\epsilon_i)$ increases, i.e. the more particles there are in the system. We shall see in the same example that if the system is macroscopic, so that it contains a very large number of particles, then the width of the maximum is negligible. It is so sharp that it is impossible to represent the Gibbs distribution graphically without distorting the scale. This means that the probability for the system to be in states with an energy differing appreciably from the energy $\epsilon_{m,p} = \epsilon_{\max}$, corresponding to the maximum of the Gibbs distribution, is negligibly small (fig. III.11). The system spends an overwhelmingly large part of the time of observation in states with an energy very close to the latter. The state corresponding to the maximum of the Gibbs distribution is the most probable. The most probable state will give the basic contribution to the mean value of the quantities characterizing the system (for example, the energy). This

Fig. III.11

follows from the very definition of the idea of mean value: each state gives to the mean value a contribution proportional to its probability.

Hence in the case of a macroscopic system the partition function Z can be written in the following form:

$$Z = \sum e^{-\epsilon_i/\theta} \Omega(\epsilon_i) \approx e^{-\epsilon_{m.p.}/\theta} \Omega(\epsilon_{m.p.}) \approx e^{-\bar{\epsilon}/\theta} \Omega(\bar{\epsilon}), \quad (18.1)$$

where only one term, the largest, referring to the most probable energy, is retained in the sum over states. Here we have made use of the approximate equality of the most probable energy and the mean energy in a macroscopic system.

Analogously, for the mean value of any quantity L we can write

$$\bar{L} = \sum L(\epsilon_i) w(\epsilon_i) \approx L(\epsilon_{m.p.}) \approx L(\bar{\epsilon}), \quad (18.2)$$

i.e. the state with $\epsilon = \epsilon_{m.p.}$ is realized with a probability $w(\epsilon_{m.p.}) \approx 1$, while probability of other states $\epsilon \neq \epsilon_{m.p.}$ is close to zero. The mean value of all quantities will be close to their most probable value. This refers, in particular, also to the energy $\bar{\epsilon} \approx \epsilon_{m.p.}$ of the system. This result is in a complete agreement with the general conclusions arrived at in §5 on the properties of systems containing a large number of particles. The true values of all quantities are close to their mean values, and the latter are close to the most probable values.

The presence of a sharp maximum in the Gibbs distribution is a concrete manifestation of the general properties of systems with a large number of particles considered in §5.

Systems which are in such a state that the true values of the quantities characterizing them are close to mean values are called systems in a state of statistical equilibrium.

Thus we see that every macroscopic quasi-closed system described by the Gibbs distribution is in a state of statistical equilibrium during most of the time of observation.

§19. Transition to classical statistics

In most cases we shall have to deal with systems the energy levels of which are so close to each other that they can be considered to be distributed con-

tinuously. Then the set of discrete values of the energy levels $\epsilon_1, \epsilon_2, \dots, \epsilon_i, \dots$ can be replaced by a continuous function ϵ . In other words, we shall pass over from the quantal description of the system to the quasi-classical one in the sense explained in § 1.

From the Gibbs distribution it follows that, in order to replace a discontinuous function $\exp(-\epsilon_i/\theta)$ by a smooth function $\exp(-\epsilon/\theta)$, it is necessary that the magnitude of the steps, i.e. of the spacing between the levels $\Delta\epsilon_i = \epsilon_{i+1} - \epsilon_i$, should be small in comparison with the value of θ . Thus, other things being equal, the transition to quasi-classical statistics should take place in the range of high temperature. We shall frequently return to this statement in what follows. The application of the classical approach is of great importance and is often encountered in practice, since, in ordinary conditions, the energy spectrum of every macroscopic system is almost continuous.

The statistical physics of systems obeying the laws of classical mechanics is called classical statistics.

In the classical approximation we have to replace a discrete set of probabilities for different states by a continuous distribution. In the quasi-classical approximation the state of a system of N particles having $3N$ degrees of freedom is determined by the value of the coordinates q_1, q_2, \dots, q_{3N} and p_1, p_2, \dots, p_{3N} . The energy of the system $\epsilon(p, q)$ is expressed as a continuous function of all the coordinates and momenta. Since energy in the classical approximation can be considered to be a continuous function, the probability distribution of different states of the system is also expressed by a continuous function. Namely, in the classical approximation one can give the probability $d\omega$ for a system to have an energy lying between $\epsilon(p, q)$ and $\epsilon(p, q) + d\epsilon(p, q)$. According to (1.26), there corresponds to an energy lying in this interval a number of states $d\Omega = h^{-3N}(\partial\Gamma/\partial\epsilon)d\epsilon$, where N is the number of particles in the subsystem.

In the classical approximation the Gibbs distribution can be written in the form

$$d\omega = \frac{e^{-\epsilon(p, q)/\theta}}{Z} \frac{\partial\Gamma}{\partial\epsilon} \frac{d\epsilon}{h^{3N}}. \quad (19.1)$$

Here according to (16.14), the partition function of the system can be written in the form

$$Z = \frac{1}{h^{3N}} \int e^{-\epsilon(p,q)/\theta} \frac{\partial \Gamma}{\partial \epsilon} d\epsilon. \quad (19.2)$$

The difference between (19.2) and (16.14) lies in the fact that in the classical formula for Z an integration is carried out instead of a summation. Z is often called the statistical integral. The integration in (19.2) is carried out over the entire phase space available for the system, i.e. over all allowed values of the coordinates and momenta. Which values of the coordinates and momenta are allowed depends on the particular properties of the system and on the conditions in which it is found.

Substituting (19.2) into (19.1), we have

$$dw = \frac{e^{-\epsilon(p,q)/\theta} (\partial \Gamma / \partial \epsilon) d\epsilon}{\int e^{-\epsilon(p,q)/\theta} (\partial \Gamma / \partial \epsilon) d\epsilon} = \frac{e^{-\epsilon(p,q)/\theta} d\Gamma}{\int e^{-\epsilon(p,q)/\theta} d\Gamma}. \quad (19.3)$$

From this it is clear that Planck's constant drops out of the Gibbs classical distribution dw , as was to be expected. The Gibbs classical distribution is often written in the form

$$dw = \rho(p, q) d\Gamma, \quad (19.4)$$

where $\rho(p, q)$ is the normalized probability density:

$$\rho(p, q) d\Gamma = \frac{e^{-\epsilon(p,q)/\theta} d\Gamma}{\int e^{-\epsilon(p,q)/\theta} d\Gamma}; \quad \int \rho(p, q) d\Gamma = 1. \quad (19.5)$$

Here dw represents the probability of a given state of the system, i.e. the probability for the representative point of the system to be in a given element of phase space.

In other words, dw represents the probability for the system to be in a state in which its momenta and coordinates lie in the intervals $p_1, p_1 + dp_1; \dots, p_{3N}, p_{3N} + dp_{3N}$ and $q_1, q_1 + dq_1; \dots, q_{3N}, q_{3N} + dq_{3N}$.

Consider, in particular, the case when the quasi-closed subsystem is an individual molecule in an ideal gas. Then the energy of the subsystem $\epsilon(p, q)$ represents the energy of this molecule. For $N = 1$ our subsystem will have three degrees of freedom. Correspondingly, its phase space will have six dimensions. An element $d\Gamma$ of the phase volume will have the form

$$d\Gamma = dp_x dp_y dp_z dx dy dz$$

or, in spherical coordinates for the momenta, replacing for conciseness $dx dy dz$ by a volume element dV ,

$$d\Gamma = p^2 dp \sin \theta d\theta d\varphi dV.$$

If there are no external fields of force the energy of the molecule reduces to its kinetic energy:

$$\epsilon(p, q) = p^2/2m,$$

and depends neither on the direction of its motion (angles θ and φ) nor on its position in the container. Hence there corresponds to an energy lying in the interval between ϵ and $\epsilon + d\epsilon$ a number of states equal to

$$d\Omega = \frac{p^2 dp}{d\epsilon h^3} \int dV \int \sin \theta d\theta d\varphi d\epsilon = \frac{4\pi V}{h^3} p^2 \frac{dp}{d\epsilon} d\epsilon.$$

The calculation of $dp/d\epsilon$ gives.

$$d\Omega = \frac{4\pi V m^{\frac{3}{2}} (2\epsilon)^{\frac{1}{2}}}{h^3} d\epsilon.$$

Thus, the Gibbs distribution for one molecule has the form

$$dw = \frac{4\pi V m^{\frac{3}{2}}}{zh^3} e^{-\epsilon/\theta} (2\epsilon)^{\frac{1}{2}} d\epsilon, \quad (19.6)$$

where z is the partition function of an individual molecule. Comparison of (19.6) with the Maxwell energy distribution (9.5) convinces us of their identity, provided the statistical temperature θ is identified with the quantity kT . It should be stressed that the absolute temperature, appearing in the Maxwell distribution, refers not to an individual molecule (the subsystem) but to the entire gas (the reservoir). In § 26 we shall show that this relationship between θ and T is of a general character. At first sight it may seem that the normalization constant in the Maxwell distribution differs from that in (19.3). In particular, it does not contain the Planck constant h . In reality, however, this is not so. In order to convince ourselves of this, we write the explicit expression for z :

$$\begin{aligned}
 z &= \int e^{-\epsilon/\theta} \frac{d\Gamma}{h^3} = \frac{4\pi V m^{\frac{3}{2}}}{h^3} \int_0^\infty e^{-\epsilon/\theta} (2\epsilon)^{\frac{1}{2}} d\epsilon = \\
 &= \frac{4\pi V m^{\frac{3}{2}}}{h^3} \left(\frac{\pi \theta^3}{2} \right)^{\frac{1}{2}} = \left(\frac{2\pi m \theta}{h^2} \right)^{\frac{3}{2}} V.
 \end{aligned} \tag{19.7}$$

Hence

$$dw = \frac{2}{(\pi \theta^3)^{\frac{1}{2}}} e^{-\epsilon/\theta} \epsilon^{\frac{1}{2}} d\epsilon. \tag{19.8}$$

Thus, the Planck constant vanishes from the distribution, and the constants in (19.8) and (9.5) are the same.

As we have stressed in the preceding paragraph, the Gibbs distribution has a very sharp maximum for a certain value of energy. At first sight this statement contradicts the broad maximum in the Maxwell distribution. However, it should be borne in mind that the sharp maximum in the Gibbs distribution arises as a result of the competition of the exponentially decreasing factor $\exp(-\epsilon/\theta)$ and the increasing factor $\Omega(\epsilon)$. The latter increases as $\epsilon^{\frac{3}{2}N}$, or as $\epsilon^{\frac{3}{2}}$ in the case when $N = 1$. Hence for $N \gg 1$ the quantity $dw/d\epsilon$ varies rapidly and a sharp maximum arises, while for $N = 1$ it increases relatively slowly and the maximum in the distribution turns out to be broad.

If the quasi-classical subsystem contains a very large number of particles, then the integral over states, figuring in formula (19.2), has a very sharp maximum for an energy value $\epsilon_{\max} \approx \epsilon$, i.e. in the region of states corresponding to statistical equilibrium of the system.

In this case, analogously to (18.1), we can write

$$Z \approx e^{-\epsilon_{m.p}/\theta} \frac{\Delta\Gamma}{h^{3N}} = e^{-\bar{\epsilon}/\theta} \frac{\Delta\Gamma}{h^{3N}}, \tag{19.9}$$

where $\Delta\Gamma$ is the volume of that region of the phase space which corresponds to a state of statistical equilibrium, i.e. to $\epsilon \approx \epsilon_{m.p.}$. It is obvious that the number of states corresponding to statistical equilibrium of the system is equal to

$$\Omega(\epsilon_{m.p.}) = \frac{\Delta\Gamma}{h^{3N}}. \tag{19.10}$$

§ 20. The monatomic gas as a whole

The properties of the Gibbs distribution, described in § 18 and 19, can be shown most clearly by a concrete example.

Let us consider as a unique quasi-closed system, a gas as a whole, confined in a container of volume V . If the walls of the container are impenetrable to but can exchange energy with the gas molecules, then the walls of the container and the bodies surrounding the container form a reservoir. The entire container with the gas can be characterized by a definite temperature θ , equal to the temperature of the surrounding bodies. It can be assumed that the size of the latter and their energy are very large in comparison with the energy of the gas.

We see that all the conditions for the applicability of the Gibbs distribution to a gas as a whole are present, and that this distribution can be written for the gas as a whole. We assume that the gas is monatomic, and that there are no external fields of force. Then the energy of the gas is equal to the sum of the kinetic energies of all the particles constituting it. This is given by the classical expression and is a continuous variable. Let the gas contain N molecules of mass m . The state of the system is completely characterized by giving the coordinates and momenta of all molecules $q_1, q_2, \dots, q_{3N}, p_1, p_2, \dots, p_{3N}$. The phase space of the system has $6N$ dimensions. An element $d\Gamma$ of the phase space is equal to the product of the differentials of all the momenta and coordinates:

$$d\Gamma = dp_1 \dots dp_{3N} dq_1 \dots dq_{3N} . \quad (20.1)$$

The energy of the system depends only on the momenta of the molecules and can be written in the form

$$\epsilon(p, q) = \frac{1}{2m} (p_1^2 + p_2^2 + \dots + p_{3N}^2) . \quad (20.2)$$

In order to write down the Gibbs distribution it is necessary to find an expression for the number of states corresponding to the energy of the system lying between ϵ and $\epsilon + \delta\epsilon$. According to the general formula (1.26') we have

$$d\Omega = \frac{1}{h^{3N}} \frac{\partial \Gamma}{\partial \epsilon} d\epsilon . \quad (20.3)$$

The Gibbs distribution for the gas as a whole has the form

$$dw = \frac{1}{h^{3N}Z} \exp \left[-\frac{p_1^2 + p_2^2 + \dots + p_{3N}^2}{2m\theta} \right] \frac{\partial \Gamma}{\partial \epsilon} d\epsilon. \quad (20.4)$$

Let us find the value of $\partial \Gamma / \partial \epsilon$. The volume of the part of phase space in which the energy of the gas does not exceed ϵ is, by definition, equal to

$$\Gamma = \int dp_1 \dots dp_{3N} dq_1 \dots dq_{3N}. \quad (20.5)$$

In formula (20.5) the integration range is determined in such a way that the condition

$$\frac{p_1^2 + p_2^2 + \dots + p_{3N}^2}{2m} \leq \epsilon(p, q) \quad (20.6)$$

is fulfilled. This condition does not involve the coordinates of the molecules, with respect to which one can integrate directly. This gives

$$\Gamma = V^N \int dp_1 \dots dp_{3N}, \quad (20.7)$$

where $V = \int dq_1 dq_2 dq_3$ is the entire volume of the gas.

Formula (20.6) determines, from the geometrical point of view, in the space of $3N$ dimensions a sphere whose radius is equal to $R = (2m\epsilon)^{1/2}$. Then the integral in (20.7) represents the volume of this sphere. The dependence of the volume of the sphere of $3N$ dimensions on its radius can be found from the consideration of dimensionality. Namely, it must be proportional to the radius to a power equal to the number of dimensions. In the three-dimensional space it is proportional to R^3 , and in the $3N$ -dimensional space it is proportional to R^{3N} . Hence (20.7) can be written in the form

$$\Gamma = \text{const } V^N R^{3N} = \text{const } V^N \epsilon^{\frac{3}{2}N}. \quad (20.8)$$

Differentiating (20.8) we have

$$\frac{\partial \Gamma}{\partial \epsilon} = \text{const } V^N \epsilon^{\frac{3}{2}N-1}. \quad (20.9)$$

The value of the constant in (20.9) is of no particular interest, since it will be cancelled with the same constant arising in calculating Z . Hence, from (20.4) and (20.9) we finally have,

$$dw = \frac{\text{const}}{h^{3N}Z} e^{-\epsilon/\theta} \epsilon^{\frac{3}{2}N-1} V^N d\epsilon. \quad (20.10)$$

The Gibbs distribution function for a system with a large number of particles N has a very sharp maximum, since the factor $\epsilon^{\frac{3}{2}N-1} \approx \epsilon^{\frac{3}{2}N}$ increases very rapidly with increasing ϵ , whereas the factor $\exp(-\epsilon/\theta)$ decreases sharply. We shall find the position, width and height of this maximum.

The maximum of the expression (20.10) is at a point determined by the condition

$$\frac{d}{d\epsilon} e^{-\epsilon/\theta} \epsilon^{\frac{3}{2}N-1} = -\frac{e^{-\epsilon/\theta} \epsilon^{\frac{3}{2}N-1}}{\theta} + \left(\frac{3}{2}N-1\right) e^{-\epsilon/\theta} \epsilon^{\frac{3}{2}N-2} = 0. \quad (20.11)$$

Hence we find that the condition for the maximum reads

$$-\frac{\epsilon_{\text{max}}}{\theta} + \left(\frac{3}{2}N-1\right) = 0$$

or

$$\epsilon_{\text{max}} = \epsilon_{\text{m.p}} = \left(\frac{3}{2}N-1\right) \theta,$$

where ϵ_{max} is the energy at the maximum. Since the number of particles N is very large, unity can be neglected in comparison with $3N$, so that

$$\epsilon_{\text{max}} = \epsilon_{\text{m.p}} \approx \frac{3}{2}N\theta. \quad (20.12)$$

It is easy to show that the quantity $\frac{3}{2}N\theta$ represents the mean energy of the entire gas. By definition,

$$\begin{aligned} \bar{\epsilon} &= \int \epsilon dw = \frac{\text{const}}{h^{3N}Z} V^N \int e^{-\epsilon/\theta} \epsilon^{\frac{3}{2}N-1} \epsilon d\epsilon \approx \\ &= \frac{\text{const } V^N}{h^{3N}} \frac{\int_0^\infty e^{-\epsilon/\theta} \epsilon^{\frac{3}{2}N} d\epsilon}{\frac{\text{const } V^N}{h^{3N}} \int_0^\infty e^{-\epsilon/\theta} \epsilon^{\frac{3}{2}N-1} d\epsilon} = \frac{\partial}{\partial(-\theta^{-1})} \ln \int_0^\infty e^{-\epsilon/\theta} \epsilon^{\frac{3}{2}N-1} d\epsilon. \end{aligned} \quad (20.13)$$

The integral in (20.13) is calculated in Appendix IV. This calculation leads to the relation

$$\bar{\epsilon} = \frac{3}{2}N\theta. \quad (20.14)$$

Comparing the expressions (20.12) and (20.14), we see that the most probable energy lies very close to the mean energy. If N is sufficiently large, then these energies can be identified with each other to a high degree of accuracy. Thus, the subsystem (ideal gas) during an overwhelmingly large part of the time is in the state in which its energy is equal to the mean energy $\bar{\epsilon}$. This property is not possessed by a subsystem containing few particles. For example, for one molecule the difference between the mean and the most probable energy is relatively large.

In order to picture how sharp the maximum in the Gibbs distribution is, i.e. how often the subsystem can get into a state with an energy different from the most probable one ϵ_{\max} , we shall find the form of the distribution function near the maximum. In the vicinity of the maximum, when the difference $\epsilon - \epsilon_{\max}$ is small, the distribution function can be expanded in a series in powers of $\epsilon - \epsilon_{\max}$ and we can restrict ourselves to the first terms of the expansion. If the distribution function (ignoring the immaterial constant) is denoted by f , then

$$f = e^{-\epsilon/\theta} \epsilon^{\frac{3}{2}N-1} = e^{-\epsilon/\theta + (\frac{3}{2}N-1) \ln \epsilon} = e^{\varphi(\epsilon)},$$

where

$$\varphi(\epsilon) = -\frac{\epsilon}{\theta} + \left(\frac{3}{2}N-1\right) \ln \epsilon.$$

Since at the point $\epsilon = \epsilon_{\max}$ the distribution function f and, therefore, also the function φ has a maximum, for $\varphi(\epsilon)$ near this maximum one can write the expansion

$$\begin{aligned} \varphi(\epsilon) &\approx \varphi(\epsilon_{\max}) + \left(\frac{d\varphi}{d\epsilon}\right)_{\epsilon=\epsilon_{\max}} (\epsilon - \epsilon_{\max}) + \\ &+ \frac{1}{2} \left(\frac{d^2\varphi}{d\epsilon^2}\right)_{\epsilon=\epsilon_{\max}} (\epsilon - \epsilon_{\max})^2 + \dots \approx \\ &\approx \varphi(\epsilon_{\max}) + \frac{1}{2} \left(\frac{d^2\varphi}{d\epsilon^2}\right)_{\epsilon=\epsilon_{\max}} (\epsilon - \epsilon_{\max})^2. \end{aligned}$$

It is easy to see that

$$\left(\frac{d^2\varphi}{d\epsilon^2}\right)_{\epsilon=\epsilon_{\max}} = -\left(\frac{3}{2}N-1\right) \frac{1}{\epsilon_{\max}^2}$$

and, consequently,

$$\begin{aligned} f &\approx \exp[\varphi(\epsilon_{\max})] \exp\left[-\left(\frac{3}{2}N-1\right) \frac{(\epsilon-\epsilon_{\max})^2}{2\epsilon_{\max}^2}\right] = \\ &= \exp[-\epsilon_{\max}/\theta] \epsilon_{\max}^{\frac{3}{2}N-1} \times \exp\left[-\left(\frac{3}{2}N-1\right) \frac{(\epsilon-\epsilon_{\max})^2}{2\epsilon_{\max}^2}\right]. \end{aligned}$$

Thus, the probability distribution near the maximum has the form

$$\begin{aligned} dw &= \text{const} \frac{1}{h^{3N}Z} \exp[-\epsilon_{\max}/\theta] \epsilon_{\max}^{\frac{3}{2}N-1} \times \\ &\times \exp\left[-\frac{(\frac{3}{2}N-1)(\epsilon-\epsilon_{\max})^2}{2\epsilon_{\max}^2}\right] d\epsilon. \end{aligned} \quad (20.15)$$

The dependence of the probability distribution on the distance from the maximum $(\epsilon-\epsilon_{\max})$ is characterized by the second exponential factor in (20.15). It represents a symmetric function of the type

$$\exp\left[-\frac{(\epsilon-\epsilon_{\max})^2}{2\delta^2}\right], \quad \text{where} \quad \delta = \frac{\epsilon_{\max}}{(\frac{3}{2}N-1)^{\frac{1}{2}}}.$$

The quantity δ represents the width of the maximum. At the value $(\epsilon-\epsilon_{\max}) = \delta$ the distribution function is e times smaller than at the maximum. The relative width of the maximum is equal to

$$\frac{\delta}{\epsilon_{\max}} \approx \frac{\delta}{\bar{\epsilon}} \approx \frac{1}{(\frac{3}{2}N-1)^{\frac{1}{2}}} \approx \left(\frac{2}{3N}\right)^{\frac{1}{2}} \quad (20.16)$$

For values of N corresponding to the number of molecules in a macroscopic volume ($N \approx 10^{19}$), the width of the maximum of the Gibbs distribution turns out to be very small. This means that the Gibbs distribution has a very sharp maximum at ϵ_{\max} . The gas is, with a high probability, in the state in which its energy is equal to the mean energy $\bar{\epsilon}$. The probability that 1 cm³ of

the gas will be found in a state with an energy differing from $\bar{\epsilon}$, for example an ϵ equal to 99% of $\bar{\epsilon}$, can easily be determined from formula (20.15) or (20.16). Its ratio to the probability of the state $\epsilon = \bar{\epsilon}$ is as

$$1 : \exp \left[\frac{1}{2} \left(\frac{3}{2} N - 1 \right) (0.99 - 1)^2 \right] = 1 : e^{10^{15}}.$$

Thus, an appreciable deviation of the energy of the gas from the mean value does not in practice occur in a gas containing a large number of particles. This conclusion is in complete agreement with what was said in the previous paragraph, as well as with the general theorem of §5. Comparing the relative width of the maximum of (20.16) with the determination of the relative energy fluctuation of §5, we convince ourselves of their complete equivalence.

Statistical and Phenomenological Thermodynamics

§21. The internal energy of a macroscopic system. The first and second laws of thermodynamics

Turning from the apparatus of Gibbs statistics, we now consider the formulation of a theory of the thermal properties of matter. Before proceeding to carry out this programme, it is necessary to dwell briefly on the history of the development of the theory of heat.

The development of technology and the extensive use of heat engines in the first half of the 19th century demanded the development of a theory of thermal processes. However, the ideas of the nature of heat were still very vague. The physics of the first half of the 19th century was still very far from the construction of a theory of thermal processes on the basis of molecular concepts. Hence the development of the theory proceeded in a very unusual way.

Joule's experimental establishment of the mechanical equivalent of heat and the failure of all attempts to create a perpetual motion machine (perpetuum mobile), by means of which it would be possible to obtain useful work without any changes in surrounding bodies, allowed one to postulate a general principle called the first law of thermodynamics. The first law of thermodynamics represents a particular case of the energy conservation law as applied to thermal processes.

If the amount of heat absorbed by a system and expressed in mechanical units is equal to δQ , then the first law of thermodynamics reads:

$$\delta Q = -\delta W + \delta E, \quad (21.1)$$

where $\{-\delta W\}$ is the mechanical work done by external forces on the system absorbing heat. The difference $\delta Q - (-\delta W)$ between the heat absorbed and the work done represents the part of the heat used in changing the internal state of the system.

The quantity E , representing a function of the internal state of the system, is called the internal energy. For a so-called cyclic process, in which the system after all changes comes back into its initial state, the algebraic sum of all heat absorbed and work done is equal to zero. This means that in a cyclic process the system obtains the same amount of heat from without as the mechanical work it gives. Whence it follows that the change in the internal energy of a system in a cyclic process is equal to zero, $\oint dE = 0$. This equality means that the internal energy is a single-valued function of the state of the system. Thus, the relation (21.1) expresses the energy conservation law. It is usually written in the form

$$dE = \delta Q + \delta W.$$

The second basic proposition of phenomenological thermodynamics, called the second law of thermodynamics, also represents a generalization of the results of numerous experimental data. The second law of thermodynamics says that it is impossible to draw heat systematically from a system and to transform it into work without some other changes occurring simultaneously in the system or in the bodies surrounding it.

A machine which, drawing heat from a body, could transform it systematically into work was called a perpetual motion machine of the second kind. It is clear that, if such a machine could be constructed, the bodies surrounding us, for example oceans, could serve as a practically inexhaustible reservoir of work. However, all attempts to construct such a machine failed.

Thus, the second law of thermodynamics, like the first, rested upon numerous reliable experimental data. In what follows, it will be shown how one can pass over from the above qualitative formulation of the second law to its quantitative formulation. It turned out that, based upon the mathematical formulation of the first and second laws of thermodynamics, it was possible to construct a phenomenological theory of thermal processes, called thermo-

dynamics. All deductions of thermodynamics had the same degree of reliability as the first and second laws on which they were based, which made them indisputable.

The reliability and general character of the deductions represent the most important merit of thermodynamical methods of investigation. Their shortcomings lie in the fact that they do not disclose the physical, molecular basis of thermal processes. Hence the construction of a molecular theory of heat and the elucidation of the molecular basis of thermodynamical ideas appeared to be the most important stage in the development of the theory of heat and physics as a whole.

At present thermodynamics and the molecular theory of thermal processes (statistical thermodynamics) make a unified whole.

In what follows we shall be able to convince ourselves by concrete examples that phenomenological and statistical thermodynamics do not contradict, but supplement each other.

We shall base the molecular theory of the thermal properties of matter on the following very natural supposition:

“The internal energy of a macroscopic body is identical with the mean energy \bar{E} calculated according to the laws of statistical physics”.

In the following we shall consider the thermal properties of macroscopic systems which contain a very large number of particles and which are in a state of statistical equilibrium. Since in a system containing a large number of particles and in a state of statistical equilibrium the mean energy \bar{E} is practically the same as its actual energy, this assumption can be formulated differently:

“The internal energy of any macroscopic body represents the energy of thermal motion of the molecules constituting the body”.

It should be noted that at present this assumption is so well substantiated experimentally and theoretically that the term “assumption” appears to be inadequate.

We do not, however, consider it superfluous to stress that the identification of the mean energy \bar{E} of motion of the molecules with the thermodynamic energy E is the basis of our further exposition. All other statements, having a less obvious character, for example the statistical treatment of the second law of thermodynamics, which we shall analyse in later paragraphs, do not need any new assumptions or references to experiment for their substantiation, but appear to be a direct consequence of this unique assumption.

In order actually to calculate the mean energy of the system we have to make use of the general rule of § 16 (eq. (16.16)) which, as applied to the energy, reads

$$\bar{\epsilon} = \frac{\sum \epsilon_i e^{-\epsilon_i/\theta} \Omega(\epsilon_i)}{\sum e^{-\epsilon_i/\theta} \Omega(\epsilon_i)},$$

where the summation is carried out over all energy levels of the system.

The expression for the mean energy $\bar{\epsilon}$ can be rewritten in a more compact form. That is, from the obvious identity

$$\frac{\partial}{\partial(-\theta^{-1})} \sum e^{-\epsilon_i/\theta} \Omega(\epsilon_i) = \frac{\partial Z}{\partial(-\theta^{-1})} = \sum e^{-\epsilon_i/\theta} \epsilon_i \Omega(\epsilon_i)$$

it follows that $\bar{\epsilon}$ can be written in the form

$$\bar{\epsilon} = \frac{\partial}{\partial(-\theta^{-1})} \ln Z = \theta^2 \frac{\partial \ln Z}{\partial \theta}. \quad (21.2)$$

From formula (21.2) it follows that to find the mean energy of the system it is sufficient to know its partition function Z . Because of the assumption of the identity of the mean and thermodynamic energies of a system we shall always write

$$E = \frac{\partial}{\partial(-\theta^{-1})} \ln Z = \theta^2 \frac{\partial \ln Z}{\partial \theta}. \quad (21.3)$$

It follows from the formulae given that the state of a macroscopic system, in particular its internal energy, depends on the temperature θ of the reservoir. In a state of statistical equilibrium the temperature of the system is equal to the temperature of its surroundings (reservoir), so that one can speak about the dependence of the energy of the body on its proper temperature.

The internal energy of a macroscopic system possesses the important property of additivity: the energy of a complex system is equal to the sum of the energies of its macroscopic parts. This statement is, of course, of approximate character. It assumes that the energy of interaction between the parts can be neglected. In the case of macroscopic parts it usually can be neglected, since it has the character of a surface energy (see, for instance, §65).

§ 22. Work and pressure

The state of a body in statistical equilibrium depends on the external conditions as well as the temperature, which are determined by the magnitude of external fields acting on the body.

According to what was said at the beginning of § 8, the volume of a body is also determined by fields of force acting on the surface of the body; the walls of the container represent such a field of force as shown in fig. III.5.

External conditions can be characterized by certain quantities called external parameters. These external parameters of a system are determined by the fields acting on the body or by the position of bodies surrounding it.

Imagine, for example, that our system is a gas confined in a container with a movable cover (a piston). Then the state of the system depends on the position of the piston. This position is an external parameter, since the value of the coordinate of the piston does not depend on the nature and properties of the system in the container. As a second example one can cite a system in an external field of force. If an arbitrary system is in such an external field of force, then its particles possess a certain potential energy. Hence the energy levels will depend on the properties of the field. In a uniform field this dependence is determined only by the position of the system in the field. In this case the position of the system serves as an external parameter.

Thus, the energy levels of a system, in general, depend not only on the properties of the system itself but also on the values of external parameters, the set of which we shall denote by λ . To stress this, we shall sometimes write $\epsilon_i(\lambda)$. However, it should not be forgotten that the values ϵ_i depend not only on λ but also on the properties of the system itself.

Consider the change $\delta\epsilon_i$ in the energy of the system for an infinitely small change $\delta\lambda$ of its external parameters. We confine ourselves from the beginning to such a change of external parameters for which the probability distribution of different states remains unchanged. This means that, when the external parameters are changed, a transition of the system from one state into another does not occur (see below).

We then have

$$\delta\epsilon_i = \frac{\partial\epsilon_i}{\partial\lambda} \delta\lambda. \quad (22.1)$$

The quantity $\partial\epsilon_i/\partial\lambda$ (taken with the opposite sign) can be considered as a generalized force acting on the system. We denote it by $(-f_i)$. Then (22.1) can be written in the form

$$\delta \epsilon_i = -f_i \delta \lambda. \quad (22.2)$$

To find the change in the internal energy we have to find the mean value of the change of each of the energy levels of the system. According to the rules for averaging we have

$$\delta E = \overline{\delta \epsilon} = \sum \delta \epsilon_i w_i = - \sum f_i w_i \delta \lambda = - \Lambda \delta \lambda, \quad (22.3)$$

where Λ stands for the mean force acting overall on the system as the parameter λ changes, $\Lambda = (\sum f_i w_i)_{w_i}$.

The quantity $(-\Lambda d\lambda)$ represents the work done on the system as the parameter λ changes by $d\lambda$. The minus sign shows that the work is done by external forces on the system.

Let δW denote the mean value of the work done on the system as external parameters λ change. Then we have

$$(\delta E)_{w_i} = \delta W. \quad (22.4)$$

Consider, in particular, the important case where the linear dimension of the system, determined by the coordinate x , serves as the generalized coordinate. In this case instead of the generalized force it is convenient to introduce the pressure p , which we shall define as the mean force acting on 1 cm² normal to the surface of the body (the system), i.e.

$$p = \Lambda/S.$$

We then have

$$(\delta E)_{w_i} = \delta W = -pS\delta x = -p\delta V, \quad (22.5)$$

where δV is the change in the volume of the system.

Such a definition of the pressure is not new; we have made use of it in the kinetic theory of gases. In §8 we have defined the pressure as the mean force acting on unit surface of the wall due to gas molecules impinging on it. In a system containing a large number of particles the true force always has a value very close to its mean value. It is this that justifies the introduction of the pressure which, to a high degree of accuracy, can be substituted for the actual force acting on the surface of the body.

It is obvious that $(\delta E)_{w_i}$ does not represent the total possible change in the energy of the system, and is not the total differential of any expression. Indeed, for a given structure of the system the generalized force $\Lambda = \sum f_i w_i$ represents a function of the external parameters λ and the temperature θ . Hence we can write in more detail as follows:

$$(\delta E)_{w_i} = -\Lambda(\lambda, \theta) \delta \lambda. \quad (22.6)$$

The change in the energy as the parameter λ changes in the range from λ_1 to λ_2 , or the work done on the system, is equal in this case to

$$W = - \int_{\lambda_1}^{\lambda_2} \Lambda(\lambda, \theta) \delta \lambda.$$

The meaning of the integral in the above formula obviously depends on the path of integration, i.e. on the character of the transition from λ_1 to λ_2 . In particular, in the case when $\lambda = V$,

$$W = - \int_{V_1}^{V_2} p(V, T) \delta V. \quad (22.7)$$

Since the pressure depends on the volume and temperature, the transition from a volume V_1 to a volume V_2 by a different path of integration, i.e. for a different character of the transition from V_1 to V_2 , leads to a different value for the work W .

§ 23. The change in the energy of a system in the general case of a quasi-static process

Now consider the change in the energy of a subsystem in the more general case when it interacts with bodies surrounding it (the medium), exchanging energy with them by direct contact.

In what follows we shall restrict ourselves to processes in which the state of statistical equilibrium in the system is not violated. Such processes for which the system can be considered to be always in a state of statistical equilibrium or, more precisely, during the course of which the system passes through a sequence of equilibrium states, will be called quasi-static or reversible processes. The question as to how much the state of the system can in fact change without violating the state of equilibrium, i.e. whether quasi-static transitions be realized in the system, will be discussed below.

Since the system is in a state of equilibrium during all the time for which the process occurs, the probability distribution is determined by the Gibbs equilibrium distribution.

The total change in the mean energy can be written

$$\delta E = \delta \left(\sum_i \epsilon_i w_i \right) = \left(\sum_i w_i \delta \epsilon_i \right)_{w_i} + \left(\sum_i \epsilon_i \delta w_i \right)_\lambda, \quad (23.1)$$

where w_i is the Gibbs distribution for a temperature equal to that of the reservoir. The latter, however, need not remain constant in the course of the process.

The first term of formula (23.1) expresses, as before, the work done on the system.

The second term represents that part of the change in the energy of the system through interaction with the medium which is not connected with the change of the external parameters. In other words, the second term of (23.1) is equal to the change in the mean energy of the system due to the direct energy transfer from the particles of the medium to the particles of the system, and which is not accompanied by a change of external fields or the mutual positions of the bodies. This part of the change in the energy will be called the amount of heat absorbed by the system, and will be denoted by δQ . We then have

$$\delta E = \delta W + \delta Q. \quad (23.2)$$

Formula (23.2) represents the energy conservation law for thermal processes (the first law of thermodynamics). It is in this form that the energy conservation law was first established after Joule's experiments.

Statistical physics allows one to reveal the molecular meaning of the quantities entering into (23.2) and also, at least for the simplest systems, makes it possible to calculate them theoretically.

In order to elucidate the molecular meaning of the amount of heat we shall consider an arbitrary unclosed system in which a quasi-static process takes place. For this quasi-static process we can write, making use of the definition (23.2),

$$\delta Q = \left(\sum_i \epsilon_i \delta w_i \right)_\lambda = \delta E - \sum_i w_i \delta \epsilon_i = \delta E - \frac{\sum \exp(-\epsilon_i/\theta) \Omega(\epsilon_i) \delta \epsilon_i}{Z}.$$

The second term can be transformed in the following way. We have the obvious identity *

$$\delta \left(\sum e^{-\epsilon_i/\theta} \Omega(\epsilon_i) \right) = -\frac{1}{\theta} \sum e^{-\epsilon_i/\theta} \Omega(\epsilon_i) \delta \epsilon_i + \sum \epsilon_i e^{-\epsilon_i/\theta} \Omega(\epsilon_i) \frac{\delta \theta}{\theta^2},$$

from which it follows that

$$\begin{aligned} \sum e^{-\epsilon_i/\theta} \Omega(\epsilon_i) \delta \epsilon_i &= \\ &= -\theta \delta \left(\sum e^{-\epsilon_i/\theta} \Omega(\epsilon_i) \right) + \frac{\delta \theta}{\theta} \sum \epsilon_i e^{-\epsilon_i/\theta} \Omega(\epsilon_i), \end{aligned} \quad (23.3)$$

whence, dividing (23.3) by Z , we find

$$\frac{\sum e^{-\epsilon_i/\theta} \Omega(\epsilon_i) \delta \epsilon_i}{Z} = -\frac{\theta \delta Z}{Z} + \frac{\delta \theta}{\theta} \frac{\sum \epsilon_i e^{-\epsilon_i/\theta} \Omega(\epsilon_i)}{Z}. \quad (23.4)$$

The first term of the right-hand side of (23.4) can be written in the form

$$-\theta \frac{\delta Z}{Z} = -\theta \delta \ln Z.$$

In the second term the expression $Z^{-1} \sum \epsilon_i \exp(-\epsilon_i/\theta) \Omega(\epsilon_i)$ can be replaced by $\bar{\epsilon}$ or E . We then have

$$\delta Q = \delta E + \theta \delta \ln Z - E \frac{\delta \theta}{\theta} = \theta \delta \left(\frac{E}{\theta} + \ln Z \right). \quad (23.5)$$

Thus, we arrive at the following important conclusion.

If in a macroscopic system a process takes place, in the course of which the system remains at all times in equilibrium with the reservoir, then the change in its energy can be written in the form

$$\delta E = \delta W + \delta Q = -\Lambda d\lambda + \theta \delta \left(\frac{E}{\theta} + \ln Z \right). \quad (23.6)$$

* In the differentiation the variable quantities are ϵ_i and θ . The number of states corresponding to a given energy obviously remains constant, and is characteristic of a given system of particles.

Formula (23.6), which has a basic significance in what follows, represents a general expression for the change of energy in a quasi-static process.

As is seen from formula (23.6), the change in the energy is resolved into two parts: the work δW done on the system (or by the system), and the amount of heat δQ absorbed (or given up) by the system.

The work done is connected with a change in the values of the allowed energy levels, which, as we have seen in the preceding paragraph [formula (22.1)], is due to a change in the external parameters. If, in particular, the system consists of individual independent particles and one can speak of the energies of the individual particles, then the work done is connected with a change in the energy of the individual particles.

If the external parameters do not change (the work of external forces is equal to zero), then the energy levels of the system remain unchanged. In this case the energy supplied to the system from without contributes to a change in the probability distribution. States with a higher energy become more probable — the system is heated. If, for example, the system represents an ideal gas, then as energy is supplied the number of molecules having relatively large energies increases, whereas that of molecules having small energies decreases. In the case where the system gives up energy, a reverse redistribution of probabilities takes place: states with a lower energy become more probable — the system is cooled.

We shall now discuss the question as to when a process can be considered quasi-static.

If the external conditions in which the system is found are changed, for example if its volume or the fields acting on it are changed, or if it obtains a certain amount of energy from outside by means of direct contact, then the state of equilibrium in the system will be violated. If then the system is isolated, then in the course of time the system will necessarily come into a state of statistical equilibrium. Indeed, we have said that the state of a complex system does not depend on its initial state. Hence, if the time of observation is sufficiently large, then the system spends most of the time in a state of statistical equilibrium, independently of the state in which it was initially. After the lapse of a relaxation time τ the system, which was initially in a non-equilibrium, highly improbable state, passes over into a more probable equilibrium state. The question as to how this transition will proceed and how much time it will take cannot, in general, be answered. Processes going on in the system in this case depend on the nature of the system and on the character of its equilibrium state.

We shall now assume that the change of the external conditions proceeds sufficiently slowly. That is to say, we shall assume that an appreciable

change of external conditions takes place for time intervals which are very large in comparison with the relaxation time. Then at every instant the system will manage to come into a state of equilibrium corresponding to the given external conditions.

We shall illustrate this by a simple example. Consider a process of compression and expansion of a gas under a piston. As the piston moves it does work on the parts of the gas contiguous to it. The corresponding molecules obtain an excessive energy in comparison with the remaining bulk of gas molecules, and the gas becomes non-uniform. Owing to collisions between molecules the non-uniformity will tend to vanish, and the energy supplied will be distributed uniformly between all the molecules of the gas. In order that this process may take place, and that the gas which has been disturbed from an equilibrium state may come back to it, a certain time, which is the characteristic relaxation time for a given process, is needed. If the piston is displaced so slowly (for example, by very weak and rare pushes) that the time needed for the displacement of the piston over an appreciable distance is very large in comparison with the relaxation time, then all perturbations of the uniformity of the gas will be resolved. The gas will at all times be uniform, i.e. will be in a state of equilibrium.

Analogously, in the case of heating, in the region adjacent to the source of heat (for example, adjacent to one of the walls of the container), a change in the velocity distribution of molecules will take place and the percentage of molecules with large velocities will increase. The non-uniformities of the gas will be smoothed out by collisions in a certain relaxation time. If the heating of the gas proceeds so slowly that an appreciable change in the temperature takes place over a time considerably larger than the relaxation time, then the non-uniformities will be resolved and the gas will at all times be in a state of equilibrium.

Thus, the condition of the quasi-static character of a process is the condition of its slowness. To every relaxation time there corresponds a proper rate of change of external conditions for which the process can be assumed to be quasi-static.

It goes without saying that the quasi-static process represents a certain idealization of real processes which always proceed with a finite velocity.

Every quasi-static process is a reversible process. This means that, if in the course of the process the system passed through a given sequence of equilibrium states (direct process), then it can also be brought into its initial state by passing through the same sequence of states in reverse (reverse process). For this the external conditions in which the system is found need only be changed in the reverse order.

It is impossible to do this for non-quasi-static processes. In a non-quasi-static process the equilibrium state of the system is violated. The state of a non-equilibrium system is not determined by giving the external parameters and temperature of the system, but needs the specification of a number of other quantities, for example, the temperature distribution or the density distribution inside the system. The change of the external conditions in the reverse sequence will not mean that the system passes through the same states in the reverse order. Hence non-quasi-static processes are irreversible.

It further goes without saying that a completely reversible process is an idealization. Real processes always proceed with a finite velocity and are accompanied by a violation of the equilibrium of the system. However, it is often possible, to a good enough approximation, to disregard small perturbations of the equilibrium state of the system and to consider the process, which is actually proceeding with a finite velocity, as a reversible process.

§ 24. Entropy and the basic thermodynamic equality

Formula (23.5) shows that for a quasi-static process the amount of heat absorbed or released by the system can be written in the form

$$\delta Q = \theta \delta \sigma, \quad (24.1)$$

where $\delta \sigma$ is the change in a certain function

$$\delta \sigma = \delta \left(\frac{E}{\theta} + \ln Z \right). \quad (24.2)$$

It is obvious that $\delta \sigma$ represents the total differential of the expression in the parentheses

$$\sigma = \frac{E}{\theta} + \ln Z + \text{const}, \quad (24.3)$$

where the constant is arbitrary. The function σ is called the entropy of the system. The physical meaning of this very important quantity will be explained somewhat later.

By means of the entropy the change in the energy of a system for a quasi-static process can be written in the form

$$\delta E = \theta \delta \sigma - \Lambda \delta \lambda. \quad (24.4)$$

The external parameter is most frequently the volume V of the system. Then

$$\delta E = \theta \delta \sigma - p \delta V. \quad (24.5)$$

Formula (24.4), or (24.5), expressing the change in the energy of a system in the most general case of a quasi-static process, is called the basic thermodynamic equality.

We have obtained the basic thermodynamic equality in a purely statistical way. However, this equality, as well as the entropy defined by formula (24.1), were introduced historically in phenomenological thermodynamics (see below).

The basic thermodynamic equality shows that the total change in the energy of a system in a quasi-static process is determined by the change in the external parameter $\delta \lambda$ and the change in the entropy $\delta \sigma$.

Indeed, from formulae (24.4) and (24.5) we find

$$\Lambda = - \left(\frac{\partial E}{\partial \lambda} \right)_{\sigma}, \quad p = - \left(\frac{\partial E}{\partial V} \right)_{\sigma}, \quad \theta = \left(\frac{\partial E}{\partial \sigma} \right)_{\lambda}, \quad (24.6)$$

so that we can write

$$\delta E = \theta \delta \sigma - \Lambda \delta \lambda = \left(\frac{\partial E}{\partial \sigma} \right)_{\lambda} \delta \sigma + \left(\frac{\partial E}{\partial \lambda} \right)_{\sigma} \delta \lambda. \quad (24.7)$$

Thus, the thermodynamic internal energy of a system can be considered as a function of the independent variables σ and λ (or V). As is seen from the equality $\theta = (\partial E / \partial \sigma)_{\lambda}$ and the condition $\theta > 0$, the energy is a monotonic function of the entropy.

The formula for the change in the entropy is similar in its structure to the formula connecting the change in the potential energy with the generalized coordinate in mechanics. For this reason the internal energy is called the thermodynamic potential with respect to the generalized coordinates σ and λ . The quantities θ and Λ play the role of generalized forces.

The quantity δE is a total differential, in contrast to the heat δQ and work δW , which in the general case do not represent the total differentials of any expressions.

Taking the integral over the closed cycle of changes in the state of the system, we find

$$\oint \delta E = 0.$$

This is quite natural, since the internal energy E is a single-valued state function of the system. When the system comes back into its initial state its energy will also assume its initial value.

The work W and the amount of heat Q depend not only on the state but also on the character of the processes taking place in the system. Hence it makes no sense to speak of the amount of heat in the system in a given state. Only the change δQ in the heat has a meaning.

Formula (24.1) shows that the ratio $(\delta Q)/\theta$ is a total differential and, consequently, the entropy σ represents a single-valued state function of the system. For it the condition

$$\oint \delta \sigma = \oint \frac{\delta Q}{\theta} = 0$$

holds.

The temperature θ can be considered from the mathematical point of view as the integrating divisor of the expression δQ .

In order to explain the physical meaning of the entropy, which will be done in the next paragraph, we have also to consider its other properties.

According to formula (24.3), to calculate the entropy it is necessary to know only the partition function Z . In formula (24.3) an integration constant appears. Thus, the entropy is determined only to within an arbitrary constant. It is important, however, as will be shown in §36, that this constant is indeed a constant, depending neither on the temperature of the system nor on any other parameter characterizing the state of the system (the volume, physical and chemical state of the system and so on). This constant can be chosen as zero, and formula (24.3) can be written in the form

$$\sigma = \frac{E}{\theta} + \ln Z. \quad (24.8)$$

We transform the above expression for the entropy, making use of the fact that in a state of statistical equilibrium the system will possess energies ϵ_i close to the mean energy $\bar{\epsilon}$ for an overwhelmingly large part of the time.

We transform the partition function of the system, taking into account that only the most probable state with the energy $\bar{\epsilon}$ gives a significant contribution to it. We can write

$$Z = \sum e^{-\epsilon_i/\theta} \Omega(\epsilon_i) \approx e^{-\bar{\epsilon}/\theta} \Omega(\bar{\epsilon}) = e^{-E/\theta} \Omega(\bar{\epsilon}). \quad (24.9)$$

Here we have retained only the largest term in the sum over the states.

Substituting (24.9) into (24.8), we find

$$\sigma = \ln \Omega(\bar{\epsilon}). \quad (24.10)$$

The entropy of a macroscopic quasi-closed system turns out to be equal to the logarithm of the number of states corresponding to the mean energy of the system, i.e. to the logarithm of the number of states of the system in a state of statistical equilibrium.

Thus, the entropy σ is identical with the function σ which we have introduced in § 16 (formula (16.7)). A very important property of the entropy is its additivity. The entropy of a complex system in an equilibrium state, consisting of n subsystems, is equal to

$$\sigma = \ln \Omega = \ln \prod_n \Omega_n = \sum \ln \Omega_n = \sum \sigma_n. \quad (24.11)$$

The additivity of the entropy follows directly from its definition (16.7) or (24.3).

The degree of accuracy of the statement concerning the additivity of the entropy is the same as that of the statement concerning the additivity of the energy.

§ 25. The law of increase of entropy

In the preceding paragraphs we have considered a quasi-closed system in a state of statistical equilibrium of performing a quasi-static (reversible) process. We have established that the molecular (statistical) interpretation can be given to a number of macroscopic notions: the internal energy, work, amount of heat. The macroscopic quantity entropy also has a molecular interpretation.

Formulae (24.8) and (24.10) allow one to calculate the value of the entropy, but do not shed any light on the meaning of this quantity. In order to elucidate the molecular meaning of entropy one has to consider a system with a simpler statistical behaviour than a quasi-closed system, i.e. a closed system. The simplicity of a closed system will allow us not only to study the

properties of equilibrium systems, but also to include the treatment of non-equilibrium systems.

Imagine a closed macroscopic system as a set of a large number of parts. Each of the parts has dimensions small in comparison with those of the system as a whole, but still contains a large number of particles and is a quasi-closed system. Since our division is quite arbitrary, it can always be made. Assume that all the parts of our complex system have come into a state of statistical equilibrium. Then for each of these one can write the expression (24.10) for the entropy:

$$\sigma_n = \ln \Omega_n(\bar{\epsilon}_n), \quad (25.1)$$

where the index n denotes the number of the part.

However, we shall not assume that there is statistical equilibrium between the parts of the system. For example, different parts of the system may have different temperatures although the proper temperature of each of the parts is constant. The entire closed system as a whole will be in a non-equilibrium state.

We shall determine the entropy of the closed non-equilibrium system.

According to the very meaning of the concept the entropy of a complex system should be assumed to be made up additively of the entropies of all parts constituting it, i.e.

$$\sigma = \sum_n \sigma_n. \quad (25.2)$$

As we have seen above, this formula is trivial for the case of a system in which there is equilibrium between the parts. It represents a natural generalization of the notion of entropy to the case of a non-equilibrium system.

For each of the parts of the system the equilibrium value of the entropy can be written from formula (24.10). We then have

$$\sigma = \sum \sigma_n = \sum \ln \Omega_n(\bar{\epsilon}) = \ln \prod_n \Omega_n(\bar{\epsilon}_n) = \ln \Omega, \quad (25.3)$$

where $\Omega = \prod_{n=1}^N \Omega_n(\bar{\epsilon}_n)$ is the total number of states of a system consisting of N independent parts.

We see that the entropy of a closed system turns out to be equal to the logarithm of the number of states of the system. This may not be the same as the logarithm of the number of states $\Omega(\bar{\epsilon})$ of the entire system when it is in

a state of statistical equilibrium (which always holds for each of its parts or for the entire system in a state of statistical equilibrium).

In the closed system considered here the microcanonical distribution (16.1) holds, connecting the probability of a state of the closed system with the number of its states Ω . Expressing Ω in terms of w , we find

$$\sigma = \ln w + \text{const.} \quad (25.4)$$

Formula (25.4), representing the basis of the statistical treatment of thermodynamics, is called the Boltzmann formula.

The Boltzmann formula connects the value of the entropy for a given state of a closed system with the probability of that state. The change in the entropy as the closed system passes from one state into another is equal to

$$\sigma_2 - \sigma_1 = \Delta\sigma = \ln \frac{w_2}{w_1}, \quad (25.5)$$

where w_1 and w_2 , σ_1 and σ_2 are the probabilities and entropies of the first and second state, respectively.

The entropy of a quasi-closed system can be expressed in terms of the probability density $\rho(p, q)$ entering into the classical Gibbs distribution (19.4) in the following way.

The function ρ satisfies the normalization condition

$$\int \rho d\Omega = 1.$$

Taking into account that $\rho(\epsilon)$ has a sharp maximum at $\epsilon = \bar{\epsilon}$, we have approximately:

$$\int \rho d\Omega \approx \rho(\bar{\epsilon}) \Omega(\bar{\epsilon}) = Z^{-1} e^{-\bar{\epsilon}/\theta} \Omega(\bar{\epsilon}) = 1.$$

Hence the entropy of the system, on the basis of (24.10), is equal to

$$\sigma = \ln \Omega(\bar{\epsilon}) = \ln \frac{1}{\rho(\bar{\epsilon})} = -\ln \rho(\bar{\epsilon}) = \ln Z + \frac{\bar{\epsilon}}{\theta}.$$

On the other hand, one can write

$$\overline{\ln \frac{1}{\rho(\epsilon)}} = \int \rho(\epsilon) \ln \frac{1}{\rho(\epsilon)} d\Omega = \int \rho(\epsilon) \left(\ln Z + \frac{\epsilon}{\theta} \right) d\Omega = \ln Z + \frac{\bar{\epsilon}}{\theta}.$$

Hence the entropy σ of a quasi-closed system can be written in the form

$$\sigma = \ln \frac{1}{\rho(\epsilon)}. \quad (25.6)$$

We shall need this formula in what follows.

We shall return to the Boltzmann formula (25.4) and see how, by means of it, the laws of the change of state of a closed system in time can be established.

Assume that the closed system was initially in a certain non-equilibrium state. Then w_1 stands for the probability of the initial non-equilibrium state. After the lapse of the relaxation time the system will pass over from the non-equilibrium state into a state of statistical equilibrium. This transition takes place due to a weak, but ever present, interaction between its parts. Without going into the question of how and in what time the equilibrium is established (this is a problem of physical kinetics), we can state that this transition occurs inevitably in any macroscopic system after the lapse of the relaxation time. By definition, the probability w_2 of the state of statistical equilibrium (in which the macroscopic system spends almost all its time) has the maximum value, so that $w_2 > w_1$. From formula (25.5) it follows that the entropy of a closed system increases as the latter passes from a non-equilibrium state to an equilibrium state. Thus, the increase in the entropy of a closed system turns out to be connected with its transition from a less probable state into a more probable one. The entropy of a system in a state of total statistical equilibrium has the highest value. The result obtained can be formulated in the following way.

If a closed macroscopic system is initially in a non-equilibrium state, the probability of this state and hence its entropy do not have the highest possible values.

The behaviour of the system which is most probable is that in which it will pass, after the lapse of the relaxation time, into its most probable state, whose entropy is a maximum.

It can be shown that, on the average, this transition will be performed monotonically, i.e. that the system comes into a state of statistical equilibrium by passing successively through a number of more and more probable states until it reaches the state of complete equilibrium. The entropy of the system increases progressively, attaining its maximum value in the most probable equilibrium state. Thus, the change of entropy in time proceeds as is shown in fig. III.12 by the solid (not the dotted!) curve.

Now imagine a case where a closed system is initially already in the state

Fig. III.12

of total statistical equilibrium, in which its entropy has the maximum value. Then in the course of a very long time, exceeding the relaxation time, the system will remain in its equilibrium state, and the entropy will preserve its maximum value. In general, it can be said that the most probable trend of processes in a closed macroscopic system is that in which the entropy increases or remains constant:

$$\Delta\sigma \geq 0, \quad (25.7)$$

where the inequality sign refers to processes bringing the system nearer to a state of statistical equilibrium, and the equality sign refers to processes taking place in a system which is already in a state of equilibrium.

We know, however, that probability predictions, as applied to macroscopic systems, are practically speaking of a completely reliable character. Hence, leaving the problem of a more complete and deeper treatment of the law of increase of entropy until §36, we shall take into account only the most probable trend of the entropy and assume that formula (25.7) does not have simply a likely character, but a completely reliable one.

Then the change or the constancy of the entropy can be considered as a criterion of irreversibility or reversibility of the processes taking place in a closed system. In irreversible processes, in the course of which the system approaches an equilibrium state, the entropy increases, whereas in reversible processes it remains constant.

As an important example of an irreversible process taking place in a closed system, we shall consider a process occurring when parts of the system having different temperatures are brought into contact.

If two parts of the system, having temperatures θ_1 and θ_2 (for concreteness we assume that $\theta_2 > \theta_1$) are in contact, then the change in the entropy of the closed system is equal to

$$\delta\sigma = \delta\sigma_1 + \delta\sigma_2 = \frac{\partial\sigma_1}{\partial E_1} \delta E_1 + \frac{\partial\sigma_2}{\partial E_2} \delta E_2 = \frac{\delta E_1}{\theta_1} + \frac{\delta E_2}{\theta_2} \geq 0.$$

Since the system is closed, its total energy is conserved, so that

$$\delta E = \delta E_1 + \delta E_2 = 0.$$

Consequently,

$$\delta\sigma = \delta E_1 \left(\frac{1}{\theta_1} - \frac{1}{\theta_2} \right) \geq 0. \quad (25.8)$$

Formula (25.8) shows that, if $\theta_2 > \theta_1$, then it follows from the law of increase of entropy that $\delta E_1 \geq 0$. This means that the first part, having a lower temperature, absorbs energy from the second part. In other words, heat always passes from a hotter body to a colder one.

§26. The basic thermodynamic inequality

It is natural to generalize the law of increase of entropy to the case of open systems.

Such a generalization can easily be made in the case of system which are not closed but are thermally isolated. We shall understand thermally isolated systems to be those for which the interaction with surrounding bodies reduces to an action due to external fields, i.e. to a change of the external parameters.

A change in the external fields, as was explained in §22, can lead to a change in the energy levels of the system (or to a change in the energy of individual particles in the case of gases), but it does not lead to any change in the probability distribution. Hence the transitions from less probable states to more probable ones in a thermally isolated system obey the same laws as in a closed system. The results of the preceding section can be applied directly to the case of systems which are thermally isolated but not closed, by writing the law of increase of entropy for these as

$$\delta\sigma \geq 0. \quad (26.1)$$

In the general case of open systems exchanging energy in an arbitrary way with bodies surrounding them the following inequality can be written:

$$\delta\sigma \geq \frac{\delta Q}{\theta}. \quad (26.2)$$

For quasi-static processes this goes over into the equality (24.1), while in the transition to a thermally isolated system it goes over into the inequality (26.1).

The inequality (26.2) means physically that in irreversible processes the entropy of the system increases by an amount larger than $(\delta Q)/\theta$ which is the amount by which the entropy increases because the system absorbs heat. This excess of the entropy increase in comparison with $(\delta Q)/\theta$ is associated with the transition to a more probable state, i.e. with the approach to equilibrium.

Combining (26.2) with the basic thermodynamic equality, one can write the following basic thermodynamic inequality for the general case of arbitrary processes in open systems:

$$\delta E \leq \theta \delta\sigma + \delta W, \quad (26.3)$$

where the equality sign refers to reversible processes, while the inequality sign refers to irreversible processes.

The basic thermodynamic inequality unifies the concepts of the energy conservation law and the entropy increase law, and can be called the unified form of the expression of the first and second laws of thermodynamics.

The relations obtained allow us to point the way to determine the scale of the statistical and absolute temperature.

The statistical temperature is measured in ergs, whereas in practice, for the measurement of the temperature, use is made of another system of units: degrees.

Of great importance is the absolute scale of temperature, in which the temperature is measured from an absolute zero and which is, essentially, identical with the statistical temperature.

To establish the relationship between the statistical and absolute temperatures it is only necessary to find the numerical expression of the units of energy in terms of degrees. Thus, one can write

$$\theta = kT, \quad (26.4)$$

where the constant k represents the conversion factor relating ergs to degrees. It appears to be a universal constant the numerical value of which can be obtained only from experiment.

The quantity k is called Boltzmann's constant. Measurements (for example, of the thermal capacity of gases) show that $k = 1.38 \times 10^{-16}$ erg deg $^{-1}$.

Making use of the absolute scale of temperatures and introducing the entropy expressed in erg deg $^{-1}$, $S = k\sigma$, we can rewrite formulae (25.4), (24.3) and (24.5) in the form

$$S = k \ln w + \text{const} = \frac{E}{T} + k \ln Z + \text{const}, \quad (26.5)$$

$$\delta E = T\delta S - p\delta V. \quad (26.6)$$

§ 27. The maximum work to be obtained from thermal processes. The impossibility of constructing a perpetual motion machine of the second kind. Phenomenological definition of the entropy

We can now consider problems whose study was, historically, a stimulus to the development of phenomenological thermodynamics. The objective is to calculate the amount of useful work which can be obtained in changing the internal energy of a system. In thermodynamics we call devices for obtaining work, heat engines.

All heat engines can be divided into two types. Engines of the first type produce useful work by a sequence of closed cycles. These include steam-engines, steam turbines and gas turbines, compressors, internal-combustion engines etc. At the end of each cycle the engine comes back to the initial state.

Hence the engine itself serves as a kind of transmission mechanism conducive to the transformation of the internal energy of the work substance into work.

Engines of the second type perform non-cyclic processes and produce useful work. Such an engine — a system which is initially in a non-equilibrium state — comes into an equilibrium state. The transition to the equilibrium state yields useful work.

All engines of a once-only action belong to this type. In such engines the useful work is most often obtained from chemical reactions going on in the system. As an example we can cite galvanic cells, rockets etc.

We shall first consider heat engines performing closed cycles (those of the first type).

Within the framework of this book we cannot, of course, study in detail the theory of the action of particular heat engines. This is a problem of technical thermodynamics. We shall confine ourselves only to the explanation of the principal aspect of the problem.

That is, we shall consider, first of all, the question as to whether the internal energy — the energy of thermal motion of the particles constituting the body — can be transformed directly into useful work.

We shall show that the existence of such an engine, which we have called above a perpetual-motion machine of the second kind, contradicts the law of increase of entropy and is hence impossible. For this we shall consider an arbitrary thermally isolated system having an initial energy E_0 , entropy S_0 and external parameters λ_0 . We assume that the system, remaining thermally isolated, passes over in a non-quasi-static way on account of a change in the external parameters into a new state with an energy E' , entropy S' and parameters λ' . Thereafter the system returns in a quasi-static way to the state with external parameters λ_0 . However, in the final state it will have entropy S' and energy E' differing from the initial values of the entropy and energy.

According to the law of increase of entropy, $S' \geq S_0$, for a thermally isolated system. But from the condition $(\partial E / \partial S)_\lambda = T > 0$, expressing the monotonic behaviour of the energy as a function of the entropy, it follows that an increase in the internal energy of the body, i.e. $E' \geq E_0$, corresponds to an increase in the entropy.

In the course of the process considered the energy of the thermally isolated body must increase. An increase in the energy can take place only at the expense of work done on the system by external bodies.

Thus, from the law of increase of entropy it follows that the system considered not only cannot serve as a source of useful work but, that on the contrary, work must be done on the system when it goes over irreversibly into a state with a new energy.

Hence we can state that the law of increase of entropy is equivalent to the proposition of the impossibility of creating a perpetual-motion machine of the second kind.

Of course, the reverse statement is also valid: from the impossibility of creating a perpetual-motion machine of the second kind there follows unambiguously the existence of a monotonically increasing state function, the entropy, for a closed system (see below).

Proceeding from this principle, one could introduce into thermodynamics the entropy and the law of its increase as a quantitative expression of the

second law of thermodynamics. It is in just this way that thermodynamics developed, and this historical order of developing thermodynamics is also preserved in contemporary text-books. Thus, the historical development of thermodynamics was in the reverse of the order in which we develop the material in this book.

Returning to the consideration of the problem of obtaining work, we note that to obtain useful work it is necessary to have at least two bodies at different temperatures T_1 and T_2 , i.e. a system of bodies which are not in equilibrium.

Before calculating the work obtained, we shall show that the maximum work is obtained in a reversible (quasi-static) process.

Let the change in the energy in the general case be equal to

$$\delta E = \delta Q + \delta W.$$

For a reversible process the same change in the energy can be written in the form

$$\delta E = T\delta S + \delta W'.$$

Subtracting, we find

$$\delta W' - \delta W = T\delta S - \delta Q.$$

But $T\delta S > \delta Q$, so that

$$\delta W' - \delta W > 0,$$

or

$$\delta W' > \delta W. \quad (27.1)$$

The maximum work is obtained in a reversible (quasi-static) transition. To calculate this work we first note that the establishment of thermal contact between bodies at different temperatures leads to an irreversible heat transfer and to no useful work.

Hence the working engine must contain three elements:

- (1) a system with a temperature T_2 (a hot reservoir),
- (2) an auxiliary system by means of which the energy is transferred from a warmer body to colder one without direct contact between them (a working substance),
- (3) a system with a temperature $T_1 < T_2$ (a cold reservoir).

An energy $\delta E_2 = \delta Q_2$ is transferred from the hot reservoir to the working substance in a reversible way. For this it is necessary that the temperature of the hot reservoir should be equal to that of the working substance during the course of the entire process of heat transfer (isothermal process). Then $\delta Q_2 = T_2 \delta S_2$.

A part of the energy obtained from the hot reservoir must be transferred to the cold reservoir (otherwise we would obtain a perpetual-motion machine of the second kind), while another part of the energy is transformed into useful work. The energy balance reads:

$$\delta Q_2 + \delta Q_1 = -\delta W.$$

In order that irreversible processes may be avoided the heat δQ_1 must be transferred to the cold reservoir in an isothermal way at the temperature T_1 of the cold reservoir. Hence the working substance must pass over from a temperature T_2 to a temperature T_1 in a thermally isolated and reversible way, and thereupon it must transfer to the cold reservoir an amount of heat δQ_1 in a quasi-static way. In order that the process may be repeated the working substance must return in a thermally isolated way (adiabatically) to the temperature T_2 . This closed cycle is called the Carnot cycle.

Since all processes in the system (hot reservoir+working substance+cold reservoir) are reversible, the total change in the entropy is

$$\delta S = \delta S_1 + \delta S_2 = 0.$$

For the work done one can write that

$$\begin{aligned} -\delta W &= \delta Q_2 + \delta Q_1 = T_2 \delta S_2 + T_1 \delta S_1 \\ &= (T_2 - T_1) \delta S_2 = \frac{T_2 - T_1}{T_2} \delta Q_2 = \frac{T_2 - T_1}{T_2} \delta E_2. \end{aligned}$$

The ratio of the work done to the amount of energy absorbed from the hot reservoir is called the efficiency η . In our case

$$\eta = \eta_{\max} = \frac{-\delta W}{\delta E_2} = \frac{\delta Q_2 + \delta Q_1}{\delta Q_2} = \frac{T_2 - T_1}{T_2}. \quad (27.2)$$

It is clear from the nature of the above derivation that the efficiency obtained has the maximum possible value. If irreversible processes take place in the heat engine then we will always have $\eta < \eta_{\max}$.

Thus, the maximum efficiency is possessed by a reversible engine working according to the closed Carnot cycle. The value of the efficiency does not depend on the nature of the working substance and is determined solely by the ratio of the temperature drop $T_2 - T_1$ to the temperature of the hot reservoir T_2 .

We shall now reproduce briefly the train of reasoning which led to the introduction of the notion of entropy into phenomenological thermodynamics. It was, to a certain degree, the reverse of ours.

From the relation (27.2) it follows that

$$\frac{\delta Q_2}{T_2} + \frac{\delta Q_1}{T_1} = 0. \quad (27.3)$$

The ratio of the amount of heat δQ obtained at a certain temperature T to the value of the temperature, $T^{-1}\delta Q$, was called by Clausius the reduced heat. Consequently, the algebraic sum of reduced heats for the Carnot cycle is equal to zero. We have obtained this result by means of formulae relating a change in the amount of heat to the absolute temperature and entropy. However, for an ideal gas the amount of heat absorbed or released in an isothermal process and the change in the temperature in an adiabatic process can be found directly. This allows one to find the efficiency of a reversible engine operating according to the Carnot cycle with an ideal gas as the working substance, and the result agrees, of course, with (27.2). Thus, formulae (27.2) and (27.3) can also be obtained without introducing the entropy.

Now let us consider a heat engine performing an arbitrary reversible cycle. This cycle can be divided into an infinitely large number of infinitely small Carnot cycles. Summing the relation (27.3) over all the elementary cycles, we can write

$$\oint \frac{dQ}{T} = 0. \quad (27.4)$$

Hence it follows that the quantity $T^{-1}dQ$ represents the total differential of a certain state function S of the system. For a cyclic process the total change in the function S is equal to zero. The function S is called the entropy.

The law of the constancy of the entropy for a reversible process in a closed system (which does not absorb or release any heat) follows directly

from the definition of entropy. To find the change in the entropy in an irreversible process, the transition from a certain initial state A into a final state B is considered for two modes, a reversible and an irreversible one. The change in the internal energy, which is also a state function, is equal to

$$\delta E = E_A - E_B$$

and does not depend on the mode of the transition.

The change in the entropy for a reversible mode is connected with the heat δQ absorbed, by the relation $\delta S = T^{-1}\delta Q$. Hence for a reversible change

$$\delta E = T\delta S + \delta W_{\text{rev}} = T\delta S - |\delta W_{\text{rev}}|, \quad (27.5)$$

where $|\delta W_{\text{rev}}|$ is the work done by the system on external bodies. For a transition in an irreversible mode the work produced will be smaller than in the case of a reversible mode (otherwise the efficiency of the irreversible closed cycle would be greater than that of the Carnot cycle). Hence, taking into account that

$$\delta E = \delta Q + \delta W_{\text{irrev}} = \delta Q - |\delta W_{\text{irrev}}|, \quad (27.6)$$

and subtracting (27.5) from (27.6), we find

$$T\delta S = \delta Q + |\delta W_{\text{rev}}| - |\delta W_{\text{irrev}}|,$$

or, since $|\delta W_{\text{rev}}| > |\delta W_{\text{irrev}}|$,

$$T\delta S > \delta Q. \quad (27.7)$$

Hence it follows that the change in the entropy for a transition $A \rightarrow B$ in an irreversible mode is

$$\delta S > \frac{\delta Q}{T}. \quad (27.8)$$

In a closed system an irreversible transition is accompanied by an increase in the entropy:

$$\delta S > 0. \quad (27.9)$$

Thus, proceeding from the fact of the impossibility of creating a perpetual-motion machine of the second kind, we arrive at the condition (27.3). The law of increase of entropy is obtained from (27.3) as a direct consequence, and is hence equivalent to the initial premise.

§28. The maximum work in non-cyclic processes and the thermodynamic potentials

We shall now consider the problem of the maximum work which can be done by a system performing a non-cyclic process (a heat engine of the second kind). Let a certain system (which we shall call the basic system) be in a hot reservoir in which a constant temperature T_0 and pressure p_0 are maintained. There is an interaction between the system and the reservoir, an exchange of heat and work. In addition to the basic system and the reservoir let there also be a thermally isolated body on which the system can do mechanical work. We shall call this body the object of the work, and the work done on it the useful work.

Let the basic system pass from an initial state into a certain final state, doing useful work $(-\delta W)$.

If the system did not interact with the reservoir the useful work $(-\delta W)$ would be equal to the change in its energy δE . However, the continuous interaction of the basic system with the reservoir as it does the useful work changes this relationship in an important way. That is, while the basic system does useful work the reservoir can in its turn exchange energy with the system.

Therefore the energy balance in the closed system (basic system+reservoir+object of the work) should be written in the form

$$\delta E + \delta E_0 = \delta W, \quad (28.1)$$

where δE_0 is the change in the energy of the reservoir, which can be written as

$$\delta E_0 = \delta Q_0 + \delta W_0.$$

Here δQ_0 is the heat transferred by the reservoir to the basic system, and δW_0 is the work done by the reservoir on the system. The size of the reservoir is so large that for any interaction with the system an infinitely slow quasi-static process takes place in it. The reservoir is in an equilibrium state

with temperature T_0 and pressure p_0 , which is not violated for any process in the basic system.

Hence for the reservoir one can write that

$$\delta E_0 = T_0 \delta S_0 - p_0 \delta V_0. \quad (28.2)$$

Since the volume of a closed system (a basic system+reservoir) must remain constant, we have

$$\delta V_0 + \delta V = 0. \quad (28.3)$$

From (28.1), (28.2) and (28.3) we find

$$-\delta W \geq \delta E - T_0 \delta S_0 + p_0 \delta V. \quad (28.4)$$

We write the law of increase of entropy in the closed system (basic system+reservoir) in the form

$$\delta S + \delta S_0 \geq 0.$$

Replacing δS_0 in (28.4) by δS , we find

$$-\delta W \geq \delta E - T_0 \delta S + p_0 \delta V = \delta R, \quad (28.5)$$

where the quantity R is equal to

$$R = E + p_0 V - T_0 S. \quad (28.6)$$

From what was said in the preceding paragraph, the maximum amount of useful work can be done on the object of the work in a reversible process, in the given case a reversible process in the system, since any process in the reservoir is always a reversible one. In this case in (28.4) only the equality sign should be retained, and we arrive at the relation

$$(\delta W)_{\max} = - \{ \delta E + p_0 \delta V - T_0 \delta S \} = - \delta R. \quad (28.7)$$

Thus, the maximum useful work is, in its absolute value, equal to the decrease in R . R involves quantities referring to the system (namely: E, V, S) as well as those referring to the reservoir (p_0, T_0).

A concrete expression for δW_{\max} containing only the characteristic parameters of the system can be obtained only for processes of a special type taking place in the system.

Assume that a system performs an isothermal process $T = T_0 = \text{const}$ and that the volume of the system does not change. In the case of a system in an external field of force at given T and V the state of the system is completely determined. If, however, the system is in an external field or is non-homogeneous, for example represents a mixture of reactants, then for given T and V the state of the system can change. Then the work obtained is

$$-\delta W \geq \delta(E - TS) = \delta F, \quad (28.8)$$

where

$$F = E - TS. \quad (28.9)$$

The quantity F , which is a measure of the work that can be obtained in an isothermal-isovolumic process taking place in a system interacting with a reservoir is called the free energy of the system. We see that only a part of the internal energy of the system can be used to obtain useful work. A part equal to TS and called the bound energy remains in the system.

Another important case is a process taking place at a constant temperature $T = T_0$ and a constant pressure $p = p_0$. In this case

$$-\delta W \geq \delta(E + pV - TS) = \delta G, \quad (28.10)$$

where

$$G = E + pV - TS, \quad (28.11)$$

is called the Gibbs thermodynamic potential.

The thermodynamic potential is a measure of the work done in an isothermal-isobaric process, just as the free energy is a measure of the work done in an isothermal-isovolumic process and the internal energy is a measure of the work in a thermally insulated system.

It can easily be shown that the expressions obtained are valid not only at constant temperature and pressure or volume but also in the case where the equalities $T = T_0$ and $p = p_0$ or $T = T_0$ and $\Delta V = 0$ hold only in the initial and final state of the system. Indeed, for example, for $T_{\text{init}} = T_{\text{fin}} = T_0$ and $V_{\text{init}} = V_{\text{fin}}$ we have

$$-\Delta W = (E - T_0 S + p_0 V_{\text{fin}}) - (E - T_0 S + p_0 V_{\text{init}}) = \Delta F.$$

§ 29. Properties of the thermodynamic potentials

Consider the case when the work $-\delta W$ done by a system in contact with a reservoir is equal to zero.

$$\delta R = \delta(E - T_0 S + p_0 V) \leq 0. \quad (29.1)$$

The equality sign refers to reversible processes, while the inequality sign refers to irreversible processes. The quantity R does not increase in any processes taking place in a system interacting with its reservoir.

For particular cases expression (29.1) is simplified.

For a closed system $\delta E = 0$ and $\delta V = 0$, so that (29.1) goes over into the previous relation:

$$\delta S \geq 0. \quad (29.2)$$

Other important cases are the isothermal-isovolumic process and the isothermal-isobaric process taking place in a system when the temperature or pressure of the system are equal to the corresponding quantities for the reservoir. In the first case $T = T_0$ and $\delta V = 0$, so that the inequality

$$\delta(E - T_0 S) = \delta F \leq 0. \quad (29.3)$$

holds. In the second case $T = T_0$ and $p = p_0$. Then

$$\delta(E - T_0 S + p_0 V) = \delta G \leq 0. \quad (29.4)$$

Thus, in an irreversible isothermal-isovolumic process taking place in a system interacting with the reservoirs its free energy decreases. In a reversible isothermal-isovolumic process the free energy remains constant. The free energy is an analogue of the entropy and, like the entropy, serves as a criterion of the reversibility or irreversibility of a process.

If, for example, a substance dissolves isothermally in a considerable volume of a solvent, then the temperature and volume of the system remain constant. The free energy of the solution will be smaller than that of the solvent and the substance dissolved, so that the process is irreversible.

Analogous properties are possessed by the thermodynamic potential for the isothermal-isobaric process. Isothermal-isobaric processes are in practice encountered rather frequently, because from the experimental point of view it is always easier to realize conditions for maintaining a constant pressure than those for maintaining a constant volume. For example, in the case of chemical reactions it is much simpler to preserve a constant pressure in the reaction vessel than to maintain a constant volume of the mixture of reagents.

The free energy and the thermodynamic potential play a fundamental role in thermodynamics. From the inequalities (29.3) and (29.4) it is seen that they replace the entropy in the case of open systems, while from (28.8) and (28.10) it follows that they are at the same time analogues of the internal energy.

Let us write the expressions for the changes in the free energy and the thermodynamic potential in a reversible process. In the general case formula (26.6) has the form

$$\delta E = T\delta S - p\delta V. \quad (29.5)$$

If we subtract from it $\delta(TS)$, then according to the definition of the free energy, we find

$$\delta F = -S\delta T - p\delta V. \quad (29.6)$$

Thus, the free energy is a function of the variables T and V (or λ). From formula (29.6) we obtain

$$S = -\left(\frac{\partial F}{\partial T}\right)_V, \quad (29.7)$$

$$p = -\left(\frac{\partial F}{\partial V}\right)_T. \quad (29.8)$$

These formulae are analogous to formulae (24.6).

Hence the free energy is a potential with respect to the variables T , V and λ . The quantities S , p and Δ , obtained from F by differentiation, play the role of generalized forces.

Formula (29.8) is particularly important. It determines the dependence of the pressure on the volume and temperature, i.e. it represents an equation of state.

Adding the total differential $\delta(pV)$ to (29.6) and taking into account the definition of the thermodynamic potential, we have

$$dG = \delta(E - TS + pV) = -S\delta T + V\delta p. \quad (29.9)$$

Thus, the Gibbs thermodynamic potential is a potential with respect to the variables T and p . The quantities S and V play the role of generalized forces:

$$S = -\left(\frac{\partial G}{\partial T}\right)_p, \quad (29.10)$$

$$V = \left(\frac{\partial G}{\partial p}\right)_T. \quad (29.11)$$

Since in practice it is most convenient to change or maintain temperature and pressure constant, the Gibbs thermodynamic potential is used especially often and is sometimes called the basic potential.

The quantity

$$H = E + pV \quad (29.12)$$

called the enthalpy is the potential with respect to the pair of variables p and S . From the enthalpy it is easy to obtain

$$\delta H = T\delta S + V\delta p. \quad (29.13)$$

Hence

$$T = \left(\frac{\partial H}{\partial S}\right)_p, \quad (29.14)$$

$$V = \left(\frac{\partial H}{\partial p}\right)_S. \quad (29.15)$$

If the state of the system depends on other external parameters λ , besides the volume, then formulae (29.6), (29.9) and (29.13) can be generalized and written in the form

$$\delta F = -S\delta T - p\delta V - \Lambda\delta\lambda, \quad (29.16)$$

$$\delta G = -S\delta T + V\delta p - \Lambda\delta\lambda, \quad (29.17)$$

$$\delta H = T\delta S + V\delta p - \Lambda\delta\lambda, \quad (29.18)$$

and, correspondingly,

$$\Lambda = -\left(\frac{\partial F}{\partial \lambda}\right)_{T,V} = -\left(\frac{\partial G}{\partial \lambda}\right)_{S,V} = -\left(\frac{\partial H}{\partial \lambda}\right)_{T,p}. \quad (29.19)$$

As will be seen from what follows, thermodynamic potentials and their derivatives completely determine the thermodynamic behaviour of an arbitrary system. We shall consider below the methods of determining the thermodynamic potentials theoretically and experimentally. However, it is necessary to obtain beforehand a number of thermodynamic relations connecting thermodynamic potentials and their derivatives with each other and with directly measured quantities.

§30. Some thermodynamic relations

The heat capacity at a constant volume C_V and the heat capacity at a constant pressure C_p , which are defined by the relations

$$C_V = \left(\frac{\partial E}{\partial T}\right)_V, \quad (30.1)$$

$$C_p = \left(\frac{\partial H}{\partial T}\right)_p \quad (30.2)$$

play a very important role in thermodynamics. Making use of formula (26.6), we find

$$C_V = \left(\frac{\partial Q}{\partial T}\right)_V = T\left(\frac{\partial S}{\partial T}\right)_V. \quad (30.3)$$

Analogously,

$$C_p = \left(\frac{\partial Q}{\partial T}\right)_p = T\left(\frac{\partial S}{\partial T}\right)_p. \quad (30.4)$$

From the definitions of the heat capacities it is clear that they are additive quantities. It is usually convenient to make use of molar heat capacities related to 1 gram-mole of a substance. In what follows, if not specified otherwise, we shall make use of molar heat capacities. The heat capacities represent thermodynamic characteristics of a substance which can be measured directly.

Another important relation is formula (29.8). Since the free energy is a function of the independent variables T and V , formula (29.8) can be written in the form

$$p = -\left(\frac{\partial F}{\partial V}\right)_T = f(T, V). \quad (30.5)$$

It determines the dependence of the pressure on the temperature and volume, i.e. it represents the equation of state of the body.

We now differentiate formulae (24.6), (29.7), (29.10) and (29.14) for the second time, forming mixed second derivatives. We have, obviously,

$$\left(\frac{\partial T}{\partial V}\right)_S = \frac{\partial}{\partial V} \left(\frac{\partial E}{\partial S}\right) = \frac{\partial}{\partial S} \left(\frac{\partial E}{\partial V}\right) = -\left(\frac{\partial p}{\partial S}\right)_V, \quad (30.6)$$

and, analogously,

$$\left(\frac{\partial S}{\partial V}\right)_T = -\frac{\partial^2 F}{\partial V \partial T} = \left(\frac{\partial p}{\partial T}\right)_V, \quad (30.7)$$

$$\left(\frac{\partial S}{\partial p}\right)_T = -\frac{\partial^2 G}{\partial p \partial T} = -\left(\frac{\partial V}{\partial T}\right)_p, \quad (30.8)$$

$$\left(\frac{\partial T}{\partial p}\right)_S = \frac{\partial^2 H}{\partial p \partial S} = \left(\frac{\partial V}{\partial S}\right)_p. \quad (30.9)$$

Formulae (30.6)–(30.9) are called Maxwell's relations.

The second and third of these relations are particularly important. They relate the derivatives of the entropy to the quantities $(\partial p/\partial T)_V$ and $(\partial V/\partial T)_p$ which can be measured directly.

The thermodynamic potentials E and F , and H and G , are not independent of each other. It is easy to establish the relations between them if use is made of their definitions and the definition of the entropy. Thus, from (28.9) and (29.7) we find

$$E = F + TS = F - T \left(\frac{\partial F}{\partial T} \right)_V. \quad (30.10)$$

Analogously,

$$H = G - T \left(\frac{\partial G}{\partial T} \right)_p. \quad (30.11)$$

Formulae (30.10) and (30.11) are called the Gibbs–Helmholtz equations.

The Gibbs–Helmholtz equations can also be written in the forms

$$\left(\frac{\partial(F/T)}{\partial T} \right)_V = - \frac{E}{T^2}, \quad (30.12)$$

$$\left(\frac{\partial(G/T)}{\partial T} \right)_p = - \frac{H}{T^2}. \quad (30.13)$$

If the dependences of the energy and enthalpy on the temperature are known, the integration of the Gibbs–Helmholtz equations allows one to find the dependence of the free energy and thermodynamic potential on the temperature:

$$F = -T \int \frac{E}{T^2} dT + \text{const} \cdot T, \quad (30.14)$$

$$G = -T \int \frac{H}{T^2} dT + \text{const} \cdot T. \quad (30.15)$$

§31. Methods for the transformation of thermodynamic quantities

In thermodynamics one often has to carry out transformations of thermodynamic quantities, for example, the transformations of variables or the replacement of certain quantities maintained constant in the course of a process by other quantities. Such transformations must be carried out according to the general rules for the substitution of variables when differentiating with respect to several variables. We shall present here one of the methods for such transformations*.

* For footnote see next page.

Let three variable quantities x, y, z be given such that each of them can be considered to be a single-valued function of the other two variables, i.e.

$$z = z(x, y), \quad y = y(x, z), \quad x = x(y, z).$$

We shall find the relation between the derivatives $(\partial z / \partial x)_y$ and $(\partial z / \partial y)_x$. For this we write the obvious equations

$$dz(x, y) = \left(\frac{\partial z}{\partial x} \right)_y dx + \left(\frac{\partial z}{\partial y} \right)_x dy, \quad (31.1)$$

$$dx = \left(\frac{\partial x}{\partial y} \right)_z dy + \left(\frac{\partial x}{\partial z} \right)_y dz.$$

Substituting dx from the lower equation into the upper one, we have

$$\begin{aligned} dz &= \left(\frac{\partial z}{\partial x} \right)_y \left(\frac{\partial x}{\partial y} \right)_z dy + \left(\frac{\partial z}{\partial x} \right)_y \left(\frac{\partial x}{\partial z} \right)_y dz + \left(\frac{\partial z}{\partial y} \right)_x dy = \\ &= \left[\left(\frac{\partial z}{\partial x} \right)_y \left(\frac{\partial x}{\partial y} \right)_z + \left(\frac{\partial z}{\partial y} \right)_x \right] dy + dz. \end{aligned} \quad (31.2)$$

Since dy is an arbitrary infinitesimal quantity, it is necessary for the fulfilment of (31.2) that

$$\left(\frac{\partial z}{\partial x} \right)_y \left(\frac{\partial x}{\partial y} \right)_z + \left(\frac{\partial z}{\partial y} \right)_x = 0.$$

Whence the relation sought follows:

$$\frac{(\partial z / \partial x)_y}{(\partial z / \partial y)_x} = - \left(\frac{\partial y}{\partial x} \right)_z. \quad (31.3)$$

Consider further the case when there are four quantities x, y, z, t , each pair of the quantities being completely determined if the other pair is defined, i.e.

* For another method, based on the use of the properties of Jacobians, see L.D. Landau and E.M. Lifshitz, *Course of theoretical physics*, Vol. 5, *Statistical Physics* (Pergamon, London, 1958).

$$t = t(x, y) = t(y, z) = t(x, z)$$

and so on.

Writing t as a function of the pair of variables x and y , we have

$$dt = \left(\frac{\partial t}{\partial x} \right)_y dx + \left(\frac{\partial t}{\partial y} \right)_x dy. \quad (31.4)$$

The same change in the quantity t as a function of y and z can be written in the form

$$dt = \left(\frac{\partial t}{\partial y} \right)_z dy + \left(\frac{\partial t}{\partial z} \right)_y dz. \quad (31.5)$$

Substituting the expression for dx from (31.1) into (31.4), we get

$$\begin{aligned} dt &= \left[\left(\frac{\partial t}{\partial x} \right)_y \left(\frac{\partial x}{\partial y} \right)_z + \left(\frac{\partial t}{\partial y} \right)_x \right] dy + \left(\frac{\partial t}{\partial x} \right)_y \left(\frac{\partial x}{\partial z} \right)_y dz = \\ &= \left[\left(\frac{\partial t}{\partial x} \right)_y \left(\frac{\partial x}{\partial y} \right)_z + \left(\frac{\partial t}{\partial y} \right)_x \right] dy + \left(\frac{\partial t}{\partial z} \right)_y dz. \end{aligned} \quad (31.6)$$

Comparing (31.5) and (31.6), we find

$$\left(\frac{\partial t}{\partial y} \right)_z = \left(\frac{\partial t}{\partial y} \right)_x + \left(\frac{\partial t}{\partial x} \right)_y \left(\frac{\partial x}{\partial y} \right)_z. \quad (31.7)$$

We shall present several examples of the use of the relations (31.3) and (31.7).

1. Find the relation between the derivatives $(\partial S / \partial V)_T$ and $(\partial S / \partial T)_V$, and between the derivatives $(\partial S / \partial p)_T$ and $(\partial S / \partial T)_p$.

According to formula (31.3) we have

$$\left. \begin{aligned} \frac{(\partial S / \partial V)_T}{(\partial S / \partial T)_V} &= - \left(\frac{\partial T}{\partial V} \right)_S; \\ \frac{(\partial S / \partial p)_T}{(\partial S / \partial T)_p} &= - \left(\frac{\partial T}{\partial p} \right)_S. \end{aligned} \right\} \quad (31.8)$$

2. The following quantities are called thermal coefficients:

$$\alpha = \frac{1}{V} \left(\frac{\partial V}{\partial T} \right)_p \quad \text{the coefficient of thermal expansion ,}$$

$$\beta = \frac{1}{p} \left(\frac{\partial p}{\partial T} \right)_V \quad \text{the thermal coefficient of pressure ,}$$

$$\kappa_T = - \frac{1}{V} \left(\frac{\partial V}{\partial p} \right)_T \quad \text{the isothermal compressibility .}$$

Find the relation between them.

From the definitions of α and β and (31.3) it follows that

$$\frac{\alpha}{\kappa_T} = - \frac{(\partial V / \partial T)_p}{(\partial V / \partial p)_T} = \left(\frac{\partial p}{\partial T} \right)_V = p\beta . \quad (31.9)$$

3. Find the ratio of the adiabatic compressibility to the isothermal compressibility, expressing it in terms of heat capacities.

The adiabatic compressibility is defined as

$$\kappa_S = - \frac{1}{V} \left(\frac{\partial V}{\partial p} \right)_S . \quad (31.10)$$

Analogously, the isothermal compressibility is

$$\kappa_T = - \frac{1}{V} \left(\frac{\partial V}{\partial p} \right)_T . \quad (31.11)$$

According to formula (31.3) we find

$$\left(\frac{\partial V}{\partial p} \right)_S = - \frac{(\partial S / \partial p)_V}{(\partial S / \partial V)_p} ; \quad \left(\frac{\partial V}{\partial p} \right)_T = - \frac{(\partial T / \partial p)_V}{(\partial T / \partial V)_p} .$$

Dividing the first equality by the second one, we have

$$\frac{\kappa_S}{\kappa_T} = \frac{(\partial V / \partial p)_S}{(\partial V / \partial p)_T} = \frac{(\partial S / \partial p)_V}{(\partial T / \partial p)_V} \frac{(\partial T / \partial V)_p}{(\partial S / \partial V)_p} = \frac{(\partial S / \partial T)_V}{(\partial S / \partial T)_p} = \frac{C_V}{C_p} . \quad (31.12)$$

4. Find the relation between $(\partial H/\partial p)_T$ and $(\partial H/\partial T)_p$.

According to formula (31.3) we have

$$\frac{(\partial H/\partial p)_T}{(\partial H/\partial T)_p} = -\left(\frac{\partial T}{\partial p}\right)_H. \quad (31.13)$$

5. Find the relation between the heat capacities $C_p = T(\partial S/\partial T)_p$ and $C_V = T(\partial S/\partial T)_V$.

Since the relation between four quantities S , T , p and V is to be established, use should be made of formula (31.7). It gives

$$\left(\frac{\partial S}{\partial T}\right)_p = \left(\frac{\partial S}{\partial T}\right)_V + \left(\frac{\partial S}{\partial V}\right)_T \left(\frac{\partial V}{\partial T}\right)_p.$$

From the Maxwell relation (30.7) and the definition of the heat capacities we find

$$C_p = C_V + T\left(\frac{\partial p}{\partial T}\right)_V \left(\frac{\partial V}{\partial T}\right)_p. \quad (31.14)$$

By means of (31.9) we can write

$$C_p = C_V - \frac{T(\partial V/\partial T)_p^2}{(\partial V/\partial p)_T} = C_V + \frac{\alpha^2 TV}{\kappa_T}. \quad (31.15)$$

6. Find the relation between the isothermal compressibility $\kappa_T = -V^{-1}(\partial V/\partial p)_T$ and the adiabatic compressibility $\kappa_S = -V^{-1}(\partial V/\partial p)_S$.

Making use of (31.7), we have

$$\left(\frac{\partial V}{\partial p}\right)_T = \left(\frac{\partial V}{\partial p}\right)_S + \left(\frac{\partial V}{\partial S}\right)_p \left(\frac{\partial S}{\partial p}\right)_T.$$

By means of formula (30.8) and the equality

$$\left(\frac{\partial S}{\partial V}\right)_p = \left(\frac{\partial S}{\partial T}\right)_p \left(\frac{\partial T}{\partial V}\right)_p$$

we obtain

$$\left(\frac{\partial V}{\partial p}\right)_T = \left(\frac{\partial V}{\partial p}\right)_S - \frac{T}{C_p} \left(\frac{\partial V}{\partial T}\right)_p^2 = \left(\frac{\partial V}{\partial p}\right)_S - \frac{TV^2\alpha^2}{C_p},$$

or

$$\kappa_T = \kappa_S + \frac{TV\alpha^2}{C_p}. \quad (31.16)$$

§ 32. The determination of thermodynamic quantities by the methods of statistical physics

For the determination of the thermodynamic quantities which we have introduced there are two possibilities:

- (1) to calculate them by the methods of statistical physics,
- (2) to find them on the basis of certain thermal measurements.

We shall begin with the analysis of methods of calculating thermodynamic quantities.

As can be seen from formula (21.3), the internal energy of any body can be found if its partition function Z is known. According to (24.8), it is also necessary to calculate the partition function to find the entropy.

Substituting the value of S using (24.8) into the definition of the free energy, we have

$$F = E - TS = -kT \ln Z. \quad (32.1)$$

The expression of F in terms of Z turns out to be particularly simple.

In addition we write an explicit expression for the pressure. According to (22.5) and (22.3) we can write

$$-p\delta V = \sum (w_i \delta \epsilon_i)_{w_i},$$

hence

$$p = -\frac{1}{Z} \sum \frac{\partial \epsilon_i}{\partial V} e^{-\epsilon_i/\theta} \Omega(\epsilon_i). \quad (32.2)$$

We have made use of the fact that the probability distribution remains unchanged, and have put in its explicit expression. Formula (32.2) can be re-

written in a standard form, expressing it in terms of the partition function Z . For this we note that

$$\frac{\partial Z}{\partial V} = \frac{\partial}{\partial V} \sum e^{-\epsilon_i/\theta} \Omega(\epsilon_i) = -\frac{1}{\theta} \sum e^{-\epsilon_i/\theta} \frac{\partial \epsilon_i}{\partial V} \Omega(\epsilon_i) \quad (32.3)$$

and, consequently,

$$\frac{\partial \ln Z}{\partial V} = \frac{1}{Z} \frac{\partial Z}{\partial V} = -\frac{1}{\theta Z} \sum \frac{\partial \epsilon_i}{\partial V} e^{-\epsilon_i/\theta} \Omega(\epsilon_i). \quad (32.4)$$

Comparing (32.4) and (32.2) we see that the pressure can be written in the form

$$p = \theta \frac{\partial \ln Z}{\partial V} = kT \frac{\partial \ln Z}{\partial V}. \quad (32.5)$$

Comparing the expression (32.5) with the expression (32.1) for the free energy, we find, in correspondence with (29.8),

$$p = -\left(\frac{\partial F}{\partial V}\right)_T. \quad (32.6)$$

From formula (32.6) it follows that, knowing the partition function Z of the system, one can find the equation of state. Indeed, since $F = f(V, T)$, formula (32.6) establishes the relation between the pressure, volume and temperature of the system.

From the method of proof it can be seen that the mean value of the derivative $\partial \epsilon_i / \partial V$, i.e. $\overline{\partial \epsilon_i / \partial V}$, cannot be identified with the derivative of the mean energy with respect to the volume $\partial \bar{\epsilon} / \partial V$, i.e. with $\partial E / \partial V$. The latter is by virtue of (30.10) and (29.8) obviously equal to

$$\frac{\partial E}{\partial V} = \frac{\partial}{\partial V} \left(F - T \frac{\partial F}{\partial T} \right) = -p + T \frac{\partial p}{\partial T}.$$

The Gibbs thermodynamic potential G will play an important role in further developments. We shall find its statistical expression. From the definition of the thermodynamic potential it follows that, in contrast to the free energy, it is a function of the pressure and not of the volume. In other words, G is a function of the generalized force $\Lambda = p$ and not of the generalized

coordinate $\lambda = V$. It is with this fact that the important role of G in thermodynamics is associated: in practice it is simpler to maintain a constant value of the pressure and other generalized forces than to maintain a constant value of the volume and corresponding generalized coordinates.

To obtain a statistical expression for G it is necessary to find the dependence of the partition function Z on the generalized force (the pressure p) as an independent variable, i.e.

$$Z = Z(T, p) .$$

In the course of the foregoing discussion we have assumed the energy levels of the system to depend on the parameter λ , i.e. $\epsilon_i = \epsilon_i(\lambda)$. We shall now assume the force Λ to be a variable, and λ to be a function of Λ .

Consider as an example an ideal gas in a container having a movable wall. If the independent variable is an external parameter (the volume of the container), then the system is the gas in the container. But if the independent variable is an acting force (an external pressure) then the movable wall should be included as a part of the system.

Thus, the subsystem is formed by N gas molecules and the movable wall of the container, so that the subsystem has altogether $3N + 1$ degrees of freedom. Its state is characterized by the coordinates and momenta of all the molecules, as well as by the position and momentum of the movable wall.

The movable wall is acted upon by a pressure p . A change in the pressure will lead to a change in the volume of the system. The latter in its turn leads to a shift of the energy levels of the system. We write the energy of the system (a gas + a movable wall) in the form

$$\epsilon_i(p) = \epsilon_i + (\epsilon_{\text{kin}} + \epsilon_{\text{pot}}) ,$$

where ϵ_i is the energy of the gas, and $(\epsilon_{\text{kin}} + \epsilon_{\text{pot}})$ is the energy of the wall.

To find the potential energy ϵ_{pot} of the wall we note that the work produced on the system as the external parameter p changes by an amount δp is equal to

$$\delta W_p = -V \delta p .$$

Hence for ϵ_{pot} we can write

$$\epsilon_{\text{pot}} = Vp .$$

The kinetic energy of the thermal motion of the wall ϵ_{kin} can be disregarded in comparison with the kinetic energy of the gas molecules (since the number of the latter is very large). Hence finally we have

$$\epsilon_i(p) = \epsilon_i + pV.$$

The partition function of the system has the form

$$Z(p, T) = \int \sum_i \exp\left(-\frac{\epsilon_i + pV}{kT}\right) \Omega(\epsilon_i) dV, \quad (32.7)$$

where the summation is carried out over all levels of the system (the value of ϵ_i depends on V), while the integration is carried out over the entire volume of the system. In analogy with (32.1) we can write

$$G = -kT \ln Z(p, T). \quad (32.8)$$

Formula (32.8) shows that the logarithm of the partition function represents the free energy in the broad sense: F in the case of the variable V , and G in the case of the variable p . Since neither the concrete nature of the system nor the character of the generalized force have figured in the foregoing reasoning, the expression obtained for G remains valid for any system and for any generalized force.

From formula (32.8) one can find the mean volume of the system:

$$V = \left(\frac{\partial G}{\partial p}\right)_T = -kT \frac{\partial \ln Z(p, T)}{\partial p}. \quad (32.9)$$

The relations obtained allow one to express thermodynamic functions — the internal energy of a body, its free energy, entropy and pressure — directly in terms of the partition function Z . The value of the partition function is determined by the molecular properties of the system — its possible energy states — as well as by the temperature T and volume or pressure. Thus, we arrive at the important conclusion:

Statistical physics allows one to find the values of thermodynamic quantities in a purely mathematical way, provided the energy levels of the system and the statistical weights of the corresponding states are known.

However, the role and significance of statistical physics do not reduce to this very important but nevertheless partial result. Statistical physics allows one to attach a more profound meaning to thermodynamic quantities and

ideas, and reveals the physical laws underlying the thermodynamic behaviour of a system. Thus, we have seen that the ideas of thermodynamic energy, work, entropy and amount of heat were given a clear physical interpretation. All these concepts have been associated with molecular processes taking place in the system. The general statement that heat is a form of motion has found its mathematical expression in the formulae obtained.

True, up to now we have not considered real physical systems and have not detailed the character of the molecular motion and quantum states of the system. The following chapters, in which the general laws of statistical physics will be applied to different physical systems, are devoted to the application of the laws found.

The general character of our formulation of statistical laws has very important advantages. Namely, owing to their general character, statistical laws, which were originally found for systems obeying the laws of classical mechanics, are still valid, and have undergone only small modifications associated with the replacement of classical systems by quantum systems. The general character of the laws of statistical mechanics do not restrict the sphere of its considerations to purely thermal processes, which constitute the primary basis of statistics, but include also the most diverse properties of matter — electric, magnetic, chemical and so on. These properties of matter will be considered in Part IV of the book. In the meanwhile we shall confine ourselves to the study of the thermal properties of matter.

§ 33. The determination of thermodynamic quantities from experimental data

We shall now consider the general methods of finding thermodynamic quantities from experimental data. Before passing on to thermodynamic potentials, we shall discuss the problem of establishing a scale of absolute temperature. To obtain this scale it is necessary to find a relationship between the absolute temperature and the empirical temperature measured on an arbitrary scale by any thermometer.

We find the relation between the quantities $(\partial E/\partial V)_T$ and $(\partial E/\partial V)_S$, making use of formula (31.7):

$$\left(\frac{\partial E}{\partial V}\right)_T = \left(\frac{\partial E}{\partial V}\right)_S + \left(\frac{\partial E}{\partial S}\right)_V \left(\frac{\partial S}{\partial V}\right)_T.$$

Making use of (24.6) and (30.7), we have

$$\left(\frac{\partial E}{\partial V}\right)_T = -p + T\left(\frac{\partial p}{\partial T}\right)_V.$$

Now let the temperature be measured on an arbitrary empirical scale of temperatures t , for which one can write that

$$t = f(T) \quad \text{or} \quad T = \varphi(t),$$

where f is an unknown function. Then, obviously

$$\left(\frac{\partial E}{\partial V}\right)_T = \left(\frac{\partial E}{\partial V}\right)_t, \quad \left(\frac{\partial p}{\partial T}\right)_V = \left(\frac{\partial p}{\partial t}\right)_V \frac{dt}{dT}.$$

Consequently,

$$\left(\frac{\partial E}{\partial V}\right)_t = -p + \left(\frac{\partial p}{\partial t}\right)_V \frac{dt}{d \ln T},$$

hence

$$\frac{d \ln T}{dt} = \frac{(\partial p / \partial t)_V}{(\partial E / \partial V)_t + p} = \psi(t, V). \quad (33.1)$$

Only quantities which can be measured directly and expressed in terms of the volume V and empirical temperature t stand on the right-hand side of eq. (33.1). Hence the dependence of T on t can be found by integrating (33.1) upon determining the function $\psi(t, V)$ experimentally. In fact, for the establishment of the absolute temperature scale, for example, at temperatures close to the absolute zero or at very high temperatures, use is made not only of thermal methods of measurement but also of magnetic or optical ones.

We now pass on to methods of finding thermodynamic quantities. The determination of the enthalpy is the simplest.

At constant pressure

$$dH = TdS = C_p dT.$$

On integrating we have

$$H = \int_{T_1}^T C_p(T) dT + H_1. \quad (33.2)$$

In order to find $H(T)$ experimentally it is necessary to measure the heat capacity C_p in the entire temperature range and to know H_1 at a certain temperature. If, as is usually the case, we are interested in the change of the heat content, then

$$\Delta H = H(T) - H(T_1) = \int_{T_1}^T C_p(T) dT$$

and the constant H_1 drops out.

For the absolute measurement of H it is necessary to make use of the properties of H at absolute zero, which are established by the third law of thermodynamics (see §35 below).

In melting and evaporation the enthalpy increases at a fixed temperature (see §62).

The entropy is found from the values of the heat capacity:

$$S = \int_{T_1}^T \frac{C_p dT}{T} + S_1 = \int_{T_1}^T C_p d \ln T + S_1.$$

The value of S is obtained by the graphical integration of the curve $C_p = f(\ln T)$. The change in the entropy is

$$\Delta S = S(T) - S(T_1) = \int_{T_1}^T C_p d \ln T. \quad (33.3)$$

The value of $S(0)$ is determined by the third law of thermodynamics (see §35).

To find the entropy of a liquid and vapour it is necessary to take into account the change in the entropy as the latent heat of melting and vaporization is absorbed (see §62).

The dependence of the entropy on the pressure is determined from formula (30.8):

$$\left(\frac{\partial S}{\partial p} \right)_T = - \left(\frac{\partial V}{\partial T} \right)_p = -\alpha V.$$

Integrating, we find

$$S(T, p) = - \int_{p_1}^p \alpha V dp + S(T, p_1) \quad (33.4)$$

or, for the change in the entropy,

$$S(T, p) - S(T, p_1) = - \int_{p_1}^p \alpha V dp. \quad (33.5)$$

Knowing the equation of state $V = V(T, p)$ one can find the coefficient of thermal expansion α and, by means of formula (33.5), the dependence of the entropy on the pressure.

Knowing H , S and the equation of state one can find all the other thermodynamic potentials:

$$E = H - pV, \quad F = E - TS, \quad G = F + pV.$$

Thus, in order to find all the thermodynamic potentials of a given substance it is necessary:

- (1) to measure the heat capacity over the entire temperature interval of interest,
- (2) to measure the coefficient of thermal expansion, and
- (3) to determine the equation of state.

H , E and S are determined to within constants representing the value of these quantities at a certain temperature, while F and G are determined to within a linear function of the temperature.

In conclusion we should discuss the thermodynamic potentials of chemical compounds. As a chemical compound is formed changes in the enthalpy ΔH and the entropy $\Delta S = T^{-1} \Delta H$ take place (§67). Correspondingly, the thermodynamic potentials of chemical compounds are the sum of their values for the initial substances and their changes in the course of the reaction.

The introduction of thermodynamic potentials allows one, in principle, to determine the thermodynamic potentials of complex substances, if the thermodynamic potentials of the elements constituting them and the heats of the chemical reactions of formation of the compounds are known.

§34. Throttling

The process in which a gas initially occupying a volume V_1 at a constant pressure p_1 passes out of its container into a container with a volume V_2 at a constant pressure p_2 , plays an important role in contemporary technology. This process is called the throttling process or the Joule–Thompson process.

The throttling process is one of the basic methods of obtaining low temperatures in contemporary cryogenic techniques. In practice the throttling process is carried out by slowly forcing the gas from one container into another through a system of thin capillary tubes offering a great hydrodynamic impedance to the flow of the gas. This great hydrodynamic impedance ensures a small macroscopic velocity of motion of the gas. The forcing through of the gas is carried out in adiabatic conditions, for which the apparatus is enclosed by thermally insulating material.

Since no heat is supplied to the system, and the energy dissipation due to friction can be disregarded (in view of the small velocity of motion of the gas), the change in the internal energy of the gas ΔE is equal to the mechanical work done on the gas:

$$\Delta E = E_2 - E_1 = W,$$

where E_1 and E_2 are respectively the energy of the gas in the initial and final states. The latter is made up of the work of compression done on the gas at a pressure p_1 (from the initial volume V_1 to the final volume equal to zero) and the work of expansion produced by the gas at a pressure p_2 (from the initial volume equal to zero to the final volume V_2), i.e.

$$W = -\left(\int_{V_1}^0 p_1 dV + \int_0^{V_2} p_2 dV \right) = -(p_2 V_2 - p_1 V_1).$$

Hence for the throttling process one can write that

$$E_1 + p_1 V_1 = E_2 + p_2 V_2,$$

or

$$H_1 = H_2. \quad (34.1)$$

Thus, the throttling process represents a process at constant enthalpy of the gas.

Assuming p_1 and p_2 to be very close to each other (and $p_2 < p_1$, $\Delta p < 0$), we find the change in the temperature of the gas as the pressure changes in the throttling process. This change is characterized by the derivative $\mu = (\partial T / \partial p)_H$ called the Joule–Thompson coefficient. The value of the latter has been found above (see (31.13)). We write (31.13) in the form

$$\begin{aligned}
 \mu &= \left(\frac{\partial T}{\partial p} \right)_H = - \frac{(\partial H / \partial p)_T}{(\partial H / \partial T)_p} = - \frac{(\partial (G + TS) / \partial p)_T}{C_p} \\
 &= - \frac{V + T(\partial S / \partial p)_T}{C_p} = - \frac{-T(\partial V / \partial T)_p + V}{C_p}. \quad (34.2)
 \end{aligned}$$

We apply formula (34.2) first of all to an ideal gas. In this case, obviously,

$$\mu = \left(\frac{\partial T}{\partial p} \right)_H = 0.$$

When an ideal gas is throttled no change in its temperature takes place. The meaning of this is obvious: the internal energy of an ideal gas does not depend on the volume and does not change as the gas expands. The situation is different in the case of a real gas for which the energy of interaction between molecules and, consequently, the internal energy, depends on the volume. The theory of a real gas will be expounded in §46–47.

In the approximation of eq. (46.18) we find

$$\mu = - \frac{-T(dV/dT)_p + V}{C_p} \approx \frac{N[\beta - T(d\beta/dT)]}{2C_p},$$

where β is the constant contained in the Van der Waals equation. Since $C_p > 0$, the sign of μ is determined by that of the numerator. From the definition (46.14) of β we find

$$\beta - T \frac{d\beta}{dT} = \int \left[e^{-u(r)/kT} \left(1 - \frac{u(r)}{kT} \right) - 1 \right] dV. \quad (34.3)$$

At high temperatures in the region of attraction $r > d$, $u(r) \ll kT$ and $e^{-u/kT} \approx 1$. In the region of repulsion $r < d$, $u(r) \gg kT$ and $e^{-u/kT} \ll 1$. In this case the entire integrand in the expression (34.3) is negative, and $\beta - T(d\beta/dT) < 0$. At low temperatures in the region of attraction $r > d$, $|u(r)| \gg kT$ and $u(r)/kT \gg 1$. In this case the integrand is positive, and $\beta - T(d\beta/dT) > 0$.

Thus, in throttling at high temperatures $\mu < 0$ and the temperature of the gas increases, whereas in throttling at low temperatures $\mu > 0$ and the temperature of the gas decreases. At a certain temperature, called the inversion point of a given gas, its coefficient $\mu = 0$. Carrying out the throttling at temperatures lower than the inversion point, one can cool gases to very low temperatures. Throttling is one of the most widely used methods of cooling gases.

§35. The third law of thermodynamics

Consider the behaviour of a certain macroscopic (thermodynamic) system at very low temperatures. We assume that the system is in a state of statistical equilibrium with an energy $\bar{\epsilon}$, so that its entropy is determined by the Boltzmann formula. Let the possible values of the energy of the system (its energy levels) form a sequence $\epsilon_0, \epsilon_1, \epsilon_2, \epsilon_3, \dots$, where ϵ_0 is the lowest possible energy (the normal level of the system), and $\epsilon_1, \epsilon_2, \epsilon_3, \dots$, are excited energy levels. The energy levels get closer together very rapidly as the excitation energy increases. However, the fact that the spacing $\epsilon_1 - \epsilon_0 = \Delta\epsilon$ between the normal level and the first excited level is a finite, if only an extremely small quantity, is of great importance.

If the temperature of the system is sufficiently low, so that the thermal energy, kT , is considerably smaller than the spacing between the lowest level and the first excited level, i.e. $kT \ll \Delta\epsilon$, then the thermal excitations of the system are insufficient for the system to get into the state ϵ_1 . Hence at a very low temperature the system must be in the state with the lowest energy ϵ_0 . The thermodynamic energy of the system is obviously equal to

$$E_0 = \epsilon_0, \quad (35.1)$$

and does not depend on the temperature (for $T \ll k^{-1}\Delta\epsilon$). Hence it follows that the heat capacity of the system at constant volume is

$$C_V = \left(\frac{\partial E}{\partial T} \right)_V = \left(\frac{\partial \epsilon_0}{\partial T} \right)_V = 0. \quad (35.2)$$

Now we find the entropy of the system. According to the Boltzmann formula the entropy is equal to

$$S = k \ln \Omega_0, \quad (35.3)$$

where Ω_0 is the number of states of the system with the energy ϵ_0 . But at absolute zero an equilibrium system is in a quite definite state the energy of which is exactly equal to E_0 . We know, however, that if the energy of the system is exactly defined, then by this very fact the state of the system is also defined. Hence the number of states with energy ϵ_0 is simply equal to unity*. Then from formula (35.3) it follows that the entropy of the system at absolute zero is equal to zero:

* For footnote see next page.

$$S = 0 \quad \text{as} \quad T \rightarrow 0. \quad (35.4)$$

The condition (35.4) was first established by Nernst, and is called the third law of thermodynamics, or the Nernst heat theorem. It was introduced, not statistically, but on the basis of an analysis of experimental data, in particular, the thermal effects of chemical reactions at low temperatures.

The condition (35.4) is not a consequence of the first and second laws of thermodynamics. Its role in contemporary thermodynamics is very important.

As we have pointed out already in §33, in order to determine the values of thermodynamic potentials from empirical or statistical data it is necessary to know their value at absolute zero. The third law of thermodynamics allows one to do this.

It should be stressed that the third law of thermodynamics is closely associated with the quantum character of the system. If the system considered obeyed the laws of classical mechanics, then its energy would change continuously. Hence, however low the temperature T may be, the energy of thermal excitation kT of the system would be infinitely large in comparison with the infinitesimal small spacing between energy levels in the classical system. To a finite energy interval kT there would correspond an infinitely large number of possible states Ω . The entropy would be large at as low (but finite) a temperature as one wished.

The quantum character of real systems, which is shown very weakly at high temperatures, assumes, as we see, paramount importance at very low temperatures. This is in complete agreement with the general propositions stated in §1.

In addition a few words should be said apropos the constant entropy. Although we write $S = 0$ as $T \rightarrow 0$, in fact formula (35.4) should be written in the form (see §24)

$$S \rightarrow \text{const} \quad \text{as} \quad T \rightarrow 0. \quad (35.5)$$

The constant in formula (35.5) cannot be determined, since it is an arbitrary integration constant.

The value of the constant in (35.5) does not depend on the pressure, volume and other parameters characterizing the state of the system. Whatever the state in which the substance may be – in the form of a chemical com-

* If the state with energy ϵ_0 is accidentally degenerate and the energy ϵ_0 is possessed by several states, then the situation is not changed. If $\Omega_0(\epsilon_0)$ is not a large number, then $k \ln \Omega_0(\epsilon_0)$ is practically equal to zero, in view of the extreme smallness of k .

pound or a pure element, with a high or low density and so on — the value of this constant will be the same.

The difference between the entropies of two thermodynamic states of a system, which differ by different values of the parameters, tends to zero as $T \rightarrow 0$. Thus, for example, the entropy S_1 of a mixture of two moles of elements A and B is equal to the entropy S_2 of one mole of their compound AB as $T \rightarrow 0$.

Such a statement follows from those experimental data which established the third law of thermodynamics. One rather frequently encounters the statement that by means of the third law of thermodynamics the integration constant in the formula for the entropy can be determined and that by this very fact its absolute value can be determined. The reasoning of this paragraph and §24 shows clearly that the absolute value of the entropy has no physical meaning: the entropy is determined in essence only to within an arbitrary constant.

The meaning of the third law does not lie in the fact that it allows one to find the absolute value of the entropy but in the fact that it establishes the constancy of the entropy as $T \rightarrow 0$ (in the sense of the independence from the parameters which characterize the state). The value of this constant can be chosen as zero entropy.

The third law of thermodynamics is often formulated as the principle of the unattainability of absolute zero. Such a formulation follows from condition (35.4). If the entropy of the system is $S = 0$, then by means of it and a cycle of two adiabatic lines $S = S_1$ and $S = S_2$ connected by the isothermal line $T = 0$ (on which $S = 0$) and another arbitrary isothermal line a perpetual motion machine of the second kind can be constructed. However, it should be noted that the unattainability of absolute zero does not contradict the possibility of obtaining in principle temperatures differing from $T = 0$ by as little as one wishes.

In the foregoing reasoning it has been assumed that the system is in an equilibrium state. However, we have not made any assumptions concerning its state of aggregation. The expression (35.4) must be equally valid for solid, liquid or gaseous systems.

There exists only one system which remains liquid near absolute zero: helium II. As to gases, all ordinary gases at a sufficient pressure are condensed long before those low temperatures at which the entropy tends to zero. Hence the pressure of the saturated vapour above the solid body is negligible as $T \rightarrow 0$. However, there exist systems which can conditionally be assumed to be gaseous as $T \rightarrow 0$. There is, first of all, the electron gas in metals, the properties of which will be considered in more detail in ch. 7 of Part IV.

Table 1
The entropy of HCl from experimental calorimetric data

State of aggregation	Temperature interval (K)	Method of determination	Entropy ($\text{J mol}^{-1} \text{K}^{-1}$)
Solid	0–16	Extrapolation of the curve obtained at higher temperatures	1.26
	16–98.36	From measured values of the heat capacity	29.6
	98.36	Latent heat	12.1
	Phase transition into another crystal modification		
	98.36–158.91	From the heat capacity	21.1
	158.91	Latent heat	12.6
Liquid	Melting		
	158.91–188.07	From the heat capacity	9.84
	188.07	Latent heat	85.89
	Boiling		total 172.3
Gaseous	188.17	Measured entropy	172.5
	188.17	Entropy calculated theoretically with the correction for the fact that the gas is not an ideal gas	172.9

However, all ordinary substances pass over into the solid state at a sufficiently low temperature. It should be noted that, in addition to true solid bodies, i.e. crystals, a rather large number of substances are in the solid, or amorphous, state. Although amorphous bodies can possess a number of properties very similar to those of true solid bodies, they in reality represent supercooled liquids. We shall dwell on the properties of supercooled liquids somewhat later.

The validity of the third law of thermodynamics was checked experimentally by different methods for a large number of substances. Although the experimental data confirming the validity of the third law of thermodynamics are not yet so numerous and versatile as those confirming the second law, they remove all doubts as to its validity. The most accurate method of checking it is the investigation of chemical equilibria at low temperatures.

For a number of substances direct measurements of the heat capacity have been carried out, on the basis of which the values of the entropy have been found. The latter were compared with those calculated theoretically on the basis of the assumption that $S = 0$ as $T \rightarrow 0$. Table 1 is an example of such a direct check.

Finally, an experimental verification of certain consequences of the third law of thermodynamics has been carried out for many substances. Thus, for example, from the condition (35.4) it follows also that

$$\left(\frac{\partial S}{\partial p}\right)_T = 0 \quad \text{as} \quad T \rightarrow 0.$$

But

$$\left(\frac{\partial S}{\partial p}\right)_T = -\frac{\partial^2 G}{\partial p \partial T} = -\left(\frac{\partial V}{\partial T}\right)_p.$$

Hence from the third law of thermodynamics it follows that the coefficient of thermal expansion must reduce to zero as $T \rightarrow 0$. The measurements of this coefficient for a number of crystals (diamond, HCl, Cu and so on) confirm this conclusion.

However, for a number of substances the measurements of the entropy showed the condition $S = 0$ as $T = 0$ to be unfulfilled. The number of such substances is relatively large. They are amorphous bodies, alloys, and a number of chemical compounds: CO, NO, H₂O and others. The existence of so many exceptions to the third law led to doubts as to its general applicability. However the statistical interpretation of the third law allowed one to explain the true origin of these violations.

In deriving the third law we have assumed that our system at absolute zero is in an equilibrium state and that it goes over into the state with the lowest energy ϵ_0 as the temperature tends to zero. However, there are systems which are not in an equilibrium state as $T \approx 0$, to which the third law of thermodynamics is inapplicable. These systems possess an entropy different from zero at absolute zero.

We have already said that the relaxation time can vary within an extremely large range, and that in a number of cases it can have very large values. This holds particularly at low temperatures, when the thermal energy is not large. In this case the establishment of an equilibrium state proceeds particularly slowly. For concreteness we imagine that our system is made of diatomic molecules (for example, CO molecules) forming a regular crystal lattice. In

Fig. III.13

fig. III.13 each molecule is presented schematically by an arrow one end of which represents a carbon atom and whose other end represents an oxygen atom. Two types of orientation of CO molecules in the lattice are possible, shown schematically in figs. III.13a and b. In one case there is a completely random orientation of the molecules, and in the other case there is a regular orientation of the molecules. All properties of carbon atoms are so similar to those of oxygen atoms that there is a negligible difference between the two forms of the crystal, with regularly and chaotically oriented molecules. Their symmetry and basic properties are completely identical. The difference between the energies of the two states is very small. The state with the regular orientation of the molecules corresponds to total equilibrium as $T \rightarrow 0$, for the energy of this turns out to be somewhat lower than that of the state with the random orientation. However, at higher temperatures the random orientation of the molecules becomes the equilibrium orientation. CO crystallizes at a relatively high temperature, when the random orientation is the equilibrium orientation. As the temperature is lowered down to $T \ll k^{-1} \Delta \epsilon$ the random orientation becomes non-equilibrium, so that the molecules should pass over into the state with the regular orientation. However, the transition of the molecules from a random distribution to a regular distribution at low temperatures proceeds so slowly that even for reasonably large observation times total equilibrium does not have sufficient time to be established. The system, at as low a temperature as one wishes, will be in a state with a random orientation of the molecules. This state will be the one with the lowest realizable energy. It is not an equilibrium state, since for a regular orientation the energy of the system would be even lower, but at the same time at low temperatures, when the velocity of the process of orientation becomes very small, the system can be in this state for an extremely long time (practically as long as one wants). The state with a random distribution of molecular orientations is, thus, a metastable state. The reasoning presented above is inapplicable to a system in a metastable state, and hence its entropy does not satisfy the condition (35.4).

Finding the entropy of a system with a completely random arrangement of molecules presents no difficulty. Each molecule can, with equal proba-

bility be in two states differing only by their orientation. If the system contains N molecules, then the total number of states is obviously equal to $\Omega_0 = 2^N$ (in view of the simplicity of the problem there is no need to express this number in terms of the phase volume). The entropy of the system at absolute zero is equal to

$$S_{T \rightarrow 0} = k \ln \Omega_0 = k \ln 2^N = Nk \ln 2 = 5.76 \text{ J mol}^{-1} \text{ K}^{-1}.$$

The measured value of the entropy of CO as $T \rightarrow 0$, turns out to be equal to $4.6 \text{ J mol}^{-1} \text{ K}^{-1}$. We see that the entropy of the system is indeed different from zero, its value being close to the theoretical one.

The third law of thermodynamics is of very great importance for finding the values of thermodynamic functions. In practical use it should, however, always be borne in mind that it refers only to systems in an equilibrium state, and that it is inapplicable to metastable systems. The example presented is not the only one. In § 54 we shall return to the problem of the behaviour of systems at low temperatures and shall present other examples of apparent deviations from the third law of thermodynamics. In any case, the possibility of applying the third law of thermodynamics is often not obvious and calls for great care. Before the appearance of the statistical derivation of the third law, when the limits of its applicability were still not understood, an inconsiderate application of the third law to metastable systems led to the contradictions mentioned above.

It should be noted in addition that, although the third law of thermodynamics is a very important proposition, the degree of its importance for science can scarcely be compared with that of the second law. In this sense the term "the third law" appears to be not quite apt.

§ 36. The statistical character of the second law of thermodynamics

In the preceding paragraphs we have established that the law of increase of entropy which in thermodynamics represents a direct generalization of experimental results, assumes a new, more profound, and at the same time clearer meaning in the light of the arguments of statistical physics. From the point of view of statistical physics the law of increase of entropy represents an expression of statistical laws shown in systems consisting of a very large number of molecules. In these systems, owing to the forces of intermolecular interaction, transitions from less probable states into more probable ones always take place until the system comes into the most probable state, i.e.

the state of total statistical equilibrium. This transition from a non-equilibrium state into an equilibrium state proceeds via complex processes in which an enormous number of molecules take part. The mechanism of the establishment of equilibrium and the character of the processes involved in it depend in many respects on the actual properties of the system.

The establishment of equilibrium (i.e. molecular disorder) in an ideal gas serves as the simplest example. Molecular disorder is established as a result of the collisions of molecules with the wall of the container and with one another.

It is not the way in which equilibrium is established in a system that will interest us now, but only the fact that equilibrium will, without fail, be established eventually. We have seen that the statistical formulation of the second law of thermodynamics differs from the thermodynamic one in a very important respect: in the former the following words are employed: "the most probable trend of processes", whereas in thermodynamics one speaks simply of the trend of processes. The formulation of statistical physics has a considerably less categorical character. It does not exclude at all, but, on the contrary, envisages the possibility of processes in the course of which the system passes over from a more probable state into a less probable one, and in which its entropy decreases. The existence of such processes, called fluctuations, is completely denied in the thermodynamic formulation of the second law.

For instance, imagine that a gas occupies one half of a free volume. According to the laws of thermodynamics the gas must expand and occupy the entire volume, the expansion being accompanied by an increase in the entropy. From the point of view of statistical physics such a behaviour of the gas is the most probable one. However, the possibility that the gas will not expand but compress is not excluded. In a macroscopic system the latter process has a probability which is negligibly small in comparison with that of the process of expansion. Hence in practice in macroscopic systems the first process will always occur.

Fluctuations occurring in a system which is already in an equilibrium state are of great importance. Imagine the gas occupying the entire volume with a uniform density and in an equilibrium state. If this gas is not subjected to an external action, then from the point of view of thermodynamics it will remain in this state for an indefinitely long time. Statistical physics states that, although for an overwhelmingly large part of the time the gas will occupy the entire volume and be in the equilibrium state, the possibility of fluctuations in the course of which the gas will spontaneously go out of the equilibrium state is not excluded. In particular, the gas can pass over spon-

taneously into a state in which it occupies only a part of the entire volume. The probability of such a transition is determined by the Boltzmann formula.

We shall not dwell now on the analysis of concrete examples of fluctuations, since ch. 8 is devoted to this important phenomenon. We stress only that experiment has completely confirmed the predictions of statistics as to the existence in nature of such spontaneous processes accompanied by a decrease in entropy. But the question naturally arises as to whether or not the statistical formulation of the second law contradicts the purely thermodynamic one. Does it follow from the statistical formulation of the second law that the construction of a perpetual motion machine of the second kind is a difficult but in principle soluble problem? For its solution can use be made of fluctuation processes accompanied by a decrease in the entropy? This problem was a subject of discussion over the course of a number of years, and its solution turned out to be very fruitful for the development of the basic propositions of statistical physics. But before giving an answer to this question it is necessary to discuss another, no less complicated question, logically preceding the former: in fact, how could it happen that, in considering molecular processes, we arrived at the idea of irreversibility?

It is well known that the laws of mechanics are strictly reversible. This is seen if only from the fact that the equation of classical mechanics

$$m \frac{d^2 r}{dt^2} = F$$

remains unchanged when the sign of the time is changed. A total reversibility reigns also in the realm of intra-atomic processes: from the laws of quantum mechanics there follows the principle of microscopic reversibility, stating that for all microscopic atomic or molecular processes the probability of direct processes is equal to that of reverse processes. Thus, there is no irreversibility in the basic laws of molecular processes. All the processes are strictly symmetric with respect to the future and past. On the other hand, statistical physics, based on molecular laws, leads to the appearance of irreversibility. At first sight it may seem that the laws of statistical physics contradict those of molecular motion, on the basis of which they were derived. In reality, however, this is not so. An increase in the entropy takes place when the system was initially in a certain non-equilibrium state. Then the most probable behaviour of the system in the course of time will be its transition into an equilibrium state. In fig. III.14 the time is plotted on the x -axis, and the entropy is plotted on the y -axis; the solid curve represents this most probable transition, while the dotted line represents the improbable

Fig. III.14

Fig. III.15

transition into a state with lower entropy *. Here the direction of time, the difference between the initial and final instants of time, appears completely obvious. However, if one thinks more carefully over this reasoning, then it can be seen that we always begin the consideration deliberately with a non-equilibrium state of the system. A certain asymmetry is concealed in the very statement of the problem. We say: in the beginning a non-equilibrium state is given; what will happen afterwards with the system left to itself? Let us try, however, to imagine how this initial non-equilibrium state could arise. It could arise either by an intervention in the system from without, or spontaneously in a closed system. In the first case it is clear that the absence of symmetry in the behaviour of the system with respect to the past in no way contradicts the reversibility of the laws of molecular processes. It is associated with the asymmetry of the conditions of the problem; in the past the system underwent actions from without, while in the future it is left to itself. A more important, but less obvious case is that when the system underwent no action from without but came into a given state (the initial one in our previous consideration) spontaneously, always remaining closed. The question arises as to what was the state occupied by the system before it came into the given state. It could come into a given non-equilibrium state from an even more non-equilibrium state or, on the contrary, from an equilibrium state. But every macroscopic system spends the major part of its

* It should be noted that the drawings presented here and below should be considered as a scheme illustrating the properties of the entropy. In reality, in a system consisting of parts the value of the entropy is strictly defined in the course of a certain finite time interval, but not at every given instant. Hence the graph $S(t)$ should not be taken literally [see B.G.Levich, *Vvedenie v statisticheskuyu fiziku (Introduction to statistical physics)* (Gostekhizdat, Moscow, 1954) §35; F.Reif, *Statistical and thermal physics* (McGraw-Hill, New York, 1965) §15.18].

time in a state of statistical equilibrium. If we ask what state the system was in at $t < 0$, then from the most general considerations it is clear that with a high probability it was in an equilibrium state. Hence a system comes most often into a given non-equilibrium state from an equilibrium state. In other words, in order that a system may come into a given non-equilibrium state at $t = 0$, it must undergo a fluctuation at $t < 0$. In fig. III.15 the solid line represents the most probable process bringing the system into the state which was the initial one for the process presented in fig. III.14. Of course, it is not excluded that the non-equilibrium state given at $t = 0$ arose from another, even more non-equilibrium state, as is shown by the dotted line in fig. III.15. But, since the probability of finding a closed system in a non-equilibrium state is low, such a case is improbable. Now we match the two drawings, i.e. consider the whole process in time. Then we obtain the curves shown in fig. III.16, which are completely symmetric with respect to the future and past.

Fig. III.16

The asymmetry of the second law — the indication that the entropy will increase in the future — thus turns out to be associated with the asymmetry of the initial condition — the definition of the system in a non-equilibrium state at the initial instant.

We now imagine that the state of a closed system is defined as the equilibrium state, corresponding to the maximum value of the entropy (fig. III.17). According to the propositions of thermodynamics the system will remain in an equilibrium state, during the subsequent time, and its entropy will remain constant. Statistical physics allows the possibility of a spontaneous transition, a fluctuation, of the system from the equilibrium state. As we have seen above, the probability of a fluctuation decreases sharply with its magnitude. Therefore, in order that we may notice the fluctuation, it is necessary to observe the system for a sufficiently long time interval, in any case much longer than the relaxation time τ . Moreover, the probability of a fluctuation depends very much on the size of the system (the number of particles in it).

Fig. III.17

If we observe the behaviour of a closed system which is in an equilibrium state at the instant $t = 0$, then we shall see that the entropy of this system will decrease (the segments ab and de on the curve of fig. III.17) and increase (the segments bc and ef) equally frequently. This agrees, after all, with the aforesaid; the process shown in fig. III.16 is, in essence, a particular case of the process shown in fig. III.17, and corresponds to one of the cusps in the latter.

Thus, we see that if one renounces asymmetry in the statement of the problem, i.e. if an improbable (non-equilibrium) state of the system is not given at the initial instant, then the law of increase of entropy loses its one-sided meaning and becomes symmetric with respect to the future and past. This can also be formulated in the following way: in the course of a sufficiently long time interval the number of transitions from an equilibrium state into a non-equilibrium one in a closed system is equal to the number of reverse transitions from a non-equilibrium state into an equilibrium one. This equality arises because the number of the former is equal to a large number of initial (equilibrium) states multiplied by a low probability of the fluctuation. The number of the latter transitions is equal to a small number of initial (non-equilibrium) states multiplied by a high probability of the transition into an equilibrium state (relaxation). In a system which is always closed the entropy increases and decreases equally frequently.

In practice, however, one most often has to deal with systems which are, at the initial instant, in a given non-equilibrium state. In the case of a system which is always closed every non-equilibrium state can be considered as a fluctuation. If we observe the successive changes of state of a system during the course of a time comparable with or smaller than the relaxation time, then the most probable trend of the processes will be an increase of the entropy. In this case the apparent asymmetry arises because of the asymmetry in the statement of the problem.

It is also possible that the system came into a non-equilibrium state as a result of an external action, which thereupon ceases. In this case the system

is insulated only from a certain instant. Its entropy will henceforward increase. Here the asymmetric trend of the entropy is associated with the presence in the past of an action on the system from outside.

We see that the difference between irreversible and reversible processes becomes relative, and that there is no contradiction between the reversibility of the laws of mechanics and the existence of irreversible processes in statistics. In view of the relative character of the ideas of reversibility and irreversibility the necessity arises for a more clear criterion of irreversible and reversible molecular processes. In order to arrive at such a formulation, we shall consider one more concrete example.

Imagine a certain volume in a container occupied by a mixture of two gases. Let, the following non-equilibrium state of the gas be given at a certain initial instant: in the volume considered the composition of the gas deviates by 1% from a homogeneous composition. If the gas is left to itself, then with a probability of the order of unity after the lapse of the relaxation time the molecules will be mixed up and the system will pass over into a state with a uniform density. The entropy of the gas will increase. From the point of view of pure thermodynamics we have a classical example of an irreversible process. However, let us analyse this process more carefully from the statistical point of view. The system will indeed pass over spontaneously from the non-uniform to a uniform distribution of molecules in the mixture. But it cannot be stated that the initial state will never again repeat itself, and that the system will always remain in a state with a uniform distribution of molecules. On the contrary, fluctuations will occur in the system, as a result of which the homogeneity of the gas composition will be violated. After the lapse of a sufficiently long time, in the system left to itself, there will necessarily occur a fluctuation of such a magnitude that the deviation from uniformity in the volume singled out will reach 1%, and the system will come back into the initial state. The return of the system into the initial state shows that the process of mutual diffusion of gases cannot be considered as irreversible. The process considered can be called a reversible process.

One would think that we arrive again at a complete contradiction with pure thermodynamics. However, the practical importance of this contradiction depends on the scale of the phenomenon and the time needed for the system to come back into the initial state. This time can be assumed, roughly speaking, to be inversely proportional to the probability of a fluctuation of the corresponding magnitude. Hence it can be assumed that the time needed for the system to come back into the initial state is longer, the larger the size of the system and the greater the difference between the initial and equilib-

rium state. We shall denote this time, usually called the recovery time, by τ^* . Then it is obvious that, if the total observation time T is small in comparison with τ^* , the system will not manage to come back into the initial state during the observation time. In this case the process accompanied by an increase in entropy is irreversible. But if, on the contrary, the total observation time T is large in comparison with the recovery time τ^* , then during the observation time the system will without fail come back into the initial state. In this case the same process must be considered as reversible. Such a treatment was first developed by M. Smolukhovskii.

Thus, the relation between the times τ^* and T is a decisive factor in the criterion of reversibility and irreversibility.

To get an idea of the order of magnitude of the recovery time τ^* we shall calculate it for a simple system. At the instant $t = 0$ let an ideal gas, confined initially in the left-hand half of a container, occupy the entire container. We shall find the time needed for all N molecules of the gas to gather again, in the left-hand half of the container as a result of molecular motion with a probability close to unity, for example, equal to 0.9.

The probability, for one measurement, that one of the molecules will be found in the left-hand half of the container is equal to $w_1^{(1)} = \frac{1}{2}$. Correspondingly, the probability, for one measurement, that two molecules will be found in the left-hand half of the container is equal to $w_1^{(2)} = (\frac{1}{2})^2$, while the probability of finding in one measurement N molecules in the left-hand half of the container is $w_1^{(N)} = (\frac{1}{2})^N = 2^{-N}$.

The probability that one will not find in one measurement N molecules in the left-hand half of the container is obviously equal to $1 - 2^{-N}$. The probability that one will not find in n measurements N molecules in the left-hand half of the container is equal to $(1 - 2^{-N})^n$.

The probability that after n measurements N molecules will be found in the left-hand half of the container is equal to

$$w_n^{(N)} = 1 - (1 - 2^{-N})^n.$$

Assuming, by our condition, that $w_n^{(N)} = 0.9$, we find

$$n \ln(1 - 2^{-N}) = \ln 0.1.$$

Since N is large, $2^{-N} \ll 1$, so that $\ln(1 - 2^{-N}) \approx -2^{-N}$. Then we have $n/2^N = 1$.

If the measurements are carried out every Δt sec, then N molecules will be found with a probability 0.9 to be gathered again in the left-hand half of

the container after the lapse of a time

$$\tau^* \approx n\Delta t \approx 2^N \Delta t.$$

If, for example, the measurements are carried out every $\Delta t = 1$ sec, then $\tau^* = 2^N$ sec. The recovery time increases very rapidly with increasing number N of particles in the gas.

An idea of the numerical values of τ^* is given by the figures in table 2.

Table 2

N	5	10	100	10^5	10^{19}
τ^* , sec	32	1024	10^{32}	2^{10^5}	$2^{10^{19}}$

We see that, if the number of particles in the system is sufficiently small, the time in which the system comes back into the initial state — the recovery time — can be observed in the course of measurable time intervals.

On the contrary, when the number of particles in the system is large, the recovery time becomes immense. A system with a large number of particles cannot be expected to come back into the initial state in really observable time intervals. It should be noted that experiments have confirmed the numerical values of recovery times for the gathering of a small number of colloidal particles in small volumes (see §56).

From the above it is clear that the point of view developed regarding reversibility and irreversibility does not in practice contradict the conclusions of thermodynamics at all. Recovery times for processes on the macroscopic scale turn out to be so large that for any practical observation time the inequality $\tau^* \gg T$ is always satisfied. Hence processes which are irreversible from the thermodynamic point of view can be considered as irreversible also from the statistical point of view.

We now can pass on to the discussion of the second question put at the beginning of this section: can a perpetual motion machine of the second kind be realized by making use of the phenomenon of fluctuations?

Imagine that we have a certain mechanism which can be used to produce useful work from a fluctuation occurring in a certain system. For concreteness we imagine that this mechanism is a piston which is set in a one-way motion by the density fluctuations occurring in the volume of the gas under the piston. If such a mechanism could be realized in practice, then useful work could be obtained systematically at the expense of the thermal energy of the

medium, i.e. a perpetual motion machine of the second kind could be constructed. However, it is easily shown that the construction of such a machine is impossible.

As a matter of fact, whatever the design of the machine, the piston and the other parts as well as the gas or another medium consist of atoms or molecules. Hence the operating mechanism, as well as the medium, will undergo fluctuations. The fluctuations of the mechanism and the medium are independent of each other and occur, generally speaking, at different instants and in different directions. Let, for example, the piston move and do work as the gas expands. But the piston itself also undergoes fluctuations and hence displacements in the direction opposite to that in which it moves as the gas expands. Owing to the independence of fluctuations in the gas and in the mechanism the displacement of the piston averaged over time turns out to be exactly equal to zero. Consequently, the mean work produced by the piston is also equal to zero.

These qualitative considerations are confirmed by the quantitative calculations for different schemes of such operating mechanisms.

Thus, a systematic production of useful work at the expense of small fluctuations occurring in a certain operating mechanism turns out to be in principle impossible. Similarly, it is impossible to obtain useful work at the expense of single large fluctuations: the probability of large fluctuations decreases incomparably more rapidly than the value of the useful effect increases.

This very fact proves that the construction of a perpetual motion machine of the second kind producing useful work systematically at the expense of fluctuations is in principle impossible. The classical formulation of the second law: "it is impossible to construct a perpetual motion machine of the second kind, i.e. a device which, in the course of a long time, would use heat at a lower temperature and thus serve as a source of a useful work" remains valid.

In conclusion we must dwell on the problem of the so-called "thermal death" of the universe.

The theory of the thermal death of the universe put forward by Clausius consists of the following: For the present the universe is not in a state of thermal equilibrium; there exist in it temperature differences, motion, and so on. However, since the universe represents a closed system to which the laws of statistics and thermodynamics are applicable, after the lapse of a sufficiently long time interval all temperature differences existing in the universe will be smoothed out, and the motion will cease. The universe will pass over into a state of total rest — thermal death.

The teaching of Clausius was subjected to criticism by many physicists, in the first place Boltzmann.

At present it is ascertained without doubt that there are no grounds for applying the laws of statistical physics to the universe changing in time. The treatment of gravitational phenomena within the framework of the general theory of relativity already shows that the thermodynamic properties of systems on a cosmic scale must differ radically from those of ordinary closed systems. In thermodynamics based on the general theory of relativity it turns out that the entropy of systems on a cosmic scale cannot tend to and reach a maximum value, and that thermal equilibrium cannot be established in them *.

A more complete study of the laws of the behaviour of the universe and, in particular, its thermodynamic behaviour, is a matter for the future. But even now it is clear that they are far more complex than the properties of ordinary macroscopic molecular systems, and that the application of the laws of ordinary thermodynamics to the universe is inadmissible.

Ideal Gases

§37. The distribution function for ideal gases

In this and following chapters we shall consider the application of the general theory to concrete systems. In the first place ideal gases will be considered.

The partition function of an ideal monatomic gas has the form

$$Z = \sum e^{-\epsilon_n/kT} \Omega(\epsilon_n), \quad (37.1)$$

where ϵ_n is the energy of the gas as a whole, and the summation is carried out over the energy levels of the system.

Since the spacings between the energy levels of the gas as a whole are very small in comparison with kT , the summation over the energy levels can be replaced by integration. Thus,

$$Z = \int e^{-\epsilon/kT} d\Omega. \quad (37.2)$$

Let us find the number of states, $d\Omega$, of a system with given energy. Since all particles of an ideal gas are independent, one can write that

$$d\Omega = \prod_i' d\Omega_i = \prod_i' \frac{dp_i dq_i}{h^{3N}},$$

where the product is taken over all coordinates and momenta of the particles. The prime in the product denotes that in its formation one has to include only those terms which correspond to different states of the system as a whole.

Substituting $d\Omega$ into (37.1) we find

$$Z = \frac{\int e^{-\epsilon/kT} \prod_i' dp_i dq_i}{h^{3N}}. \quad (37.3)$$

In order to find the integration range in (37.3), we shall consider the case of two uniformly moving particles. Let p_1 denote the momentum of the first particle and p_2 the momentum of the second particle. The integration in (37.3) is carried out over all values of the momenta which each of the molecules can have. We shall consider the two states of the system shown in fig. III.18 by dotted lines. In the first state the first molecule has a momen-

Fig. III.18

tum equal to a , and the second molecule has a momentum equal to b . In the second state, on the contrary, the second molecule has momentum a , and the first molecule has momentum b . It can be said that the second state differs from the first by the fact that the momentum of the first particle is replaced by that of the second particle, and vice versa. In other words, the representative points of the two molecules, or for brevity, the molecules, are mutually exchanged in phase space.

In carrying out the integration in (37.3) we take into account separately each of these and similar states of the system of two molecules. Integrating with respect to p_1 at a fixed value of p_2 , and thereupon with respect to p_2 at a fixed value of p_1 , we pass through a sequence of values of the momenta (p_1, p_2) and (p_2, p_1) , differing from each other by the mutual exchange of the particles in phase space. In other words, we assume that the states "the first molecule has a momentum p_1 , and the second molecule has a momentum p_2 " and "the first molecule has a momentum p_2 and the second molecule has a momentum p_1 " are two different states. However, if the two molecules are identical, then these states are equivalent. But from the proposition of quantum theory on the complete identity of elementary particles it follows that the two states correspond to one and the same physical state of the system. A physical state of the system is characterized by the fact that one particle has a momentum p_1 , and the second particle has a momentum p_2 . It does not matter which of the particles has the momentum p_1 or p_2 , since the two particles are completely identical. The states (p_1, p_2) and (p_2, p_1) are not two equivalent states, but one and the same state of the system. Hence we would make a mistake by taking the two states (p_1, p_2) and (p_2, p_1) as independent states in the integration in (37.3). In reality both of these correspond to only one physical state of the system. In order to avoid this mistake one should take into account only one of the states: either (p_1, p_2) or (p_2, p_1) . The integration with respect to p_1 and p_2 in (37.3) should be carried out not over all their possible values but only over the values corresponding to physically different states of the system. For this one can, for example, integrate not over the entire phase area (p_1, p_2) but over one half of it, cut by the bisector drawn in fig. III.18. However, it is simpler to proceed differently. One can, as before, carry out the integration over all values of p_1 and p_2 , and reduce by a factor of two the result obtained. This will compensate for the incorrect doubling of the number of states as they are calculated. One has to proceed completely analogously also in calculating that part of the partition function which includes the integration with respect to the coordinates of the two molecules. States differing from each other only by the mutual exchange of the molecules in space should be considered not as different states, but as one and the same state.

In general, in calculating the integral over all states of the system consisting of two particles one has to carry out the integration over all states — the coordinates and momenta (p_1, q_1) of the first particle and (p_2, q_2) of the second particle, but the result obtained should be reduced by a factor of two. In this case it will be automatically taken into account that the "exchange" in phase space of the representative points characterizing the state of each of the particles does not lead to different states of the entire system.

The result obtained can be generalized to arbitrary states of a gas containing N molecules. All states of the gas which differ from each other only by the fact that the values of the coordinates and momenta of one molecule are exchanged with those of another molecule are identical physical states. It can be said that the set of all states which are obtained by the mutual permutation of N representative points in the phase space corresponds to only one physical state. In calculating the total partition function of the gas each of these must be taken into account in the integration only once. Hence in carrying out the integration over all possible values of the coordinates and momenta of gas molecules the result must be divided by the number of the mutual permutations of representative points in the phase space. This number is, obviously, equal to $N!$.

It should be noted that the necessity of dividing the phase integral by $N!$ was taken into account in classical statistics. Otherwise the additivity of the thermodynamic functions obtained would be violated. However, the full meaning of this procedure is seen in quantum statistics after taking into consideration the principle of the identity of atomic particles.

Thus, we can write that

$$d\Omega = \prod_i' d\Omega_i = \frac{\prod_i d\Omega_i}{N!} = \frac{1}{N!} \prod_i \frac{dp_i dq_i}{h^{3N}}. \quad (37.4)$$

The Gibbs distribution for an ideal gas has the form

$$dw = \frac{1}{Z} e^{-\epsilon/kT} d\Omega = \frac{1}{Z} e^{-\epsilon/kT} \frac{dp_1 \dots dp_{3N} dq_1 \dots dq_{3N}}{h^{3N} N!}.$$

Correspondingly, for the partition function we obtain

$$Z = \frac{1}{N!} \int e^{-\epsilon/kT} \prod_i d\Omega_i,$$

where the integration is carried out over the entire phase space. Writing the energy of the gas as follows:

$$\epsilon = \sum_i \epsilon_i,$$

we obtain

$$Z = \frac{1}{N!} \frac{1}{h^{3N}} \prod_i \int e^{-\epsilon_i/kT} dp_i dq_i = \frac{z^N}{N!},$$

where z is the partition integral for one molecule calculated earlier [formula (19.7)]. Substituting its value, we find that

$$Z = \frac{1}{N!} \left(\frac{2\pi mkT}{h^2} \right)^{\frac{3}{2}N} V^N. \quad (37.5)$$

We pass on to the calculation of the thermodynamic functions of an ideal monatomic gas.

For the energy of the gas one can write

$$E = kT^2 \frac{\partial}{\partial T} \ln Z = \frac{3}{2} NkT. \quad (37.6)$$

The energy of the gas is proportional to the temperature and does not depend on the volume of the gas, in correspondence with formula (20.14).

The heat capacity of a monatomic gas turns out to be equal to

$$C_V = \left(\frac{\partial E}{\partial T} \right)_V = \frac{3}{2} Nk \approx 12 \text{ J mol}^{-1} \text{ K}^{-1}.$$

For the free energy of an ideal monatomic gas we find, according to (32.1),

$$F = -kT \ln Z = -NkT \ln V \left(\frac{2\pi mkT}{h^2} \right)^{\frac{3}{2}} + kT \ln N!$$

In order to calculate $N!$ for a large N one can make use of Stirling's formula (see Appendix IV). We then have

$$F = -NkT \ln \left[\frac{eV}{N} \left(\frac{2\pi mkT}{h^2} \right)^{\frac{3}{2}} \right]. \quad (37.7)$$

From the free energy one can find the equation of state of the gas. In correspondence with (32.6) we obtain

$$p = - \left(\frac{\partial F}{\partial V} \right)_T = \frac{NkT}{V}. \quad (37.8)$$

Thus, we arrive at the well-known equation of state of an ideal gas. It should be noted that we have found this equation in a purely theoretical way, without any reference to experimental data. Only the numerical value of the constant k is determined experimentally.

We shall now calculate the entropy of the gas. According to (29.7) it is equal to

$$\begin{aligned} S &= - \left(\frac{\partial F}{\partial T} \right)_V = Nk \ln \left[\frac{eV}{N} \left(\frac{2\pi mkT}{h^2} \right)^{\frac{3}{2}} \right] + \frac{3}{2}Nk = \\ &= Nk \ln(V/N) + C_V \ln kT + \frac{5}{2}Nk + Nkj. \end{aligned} \quad (37.9)$$

For reasons which will be explained later the quantity

$$j = \ln(2\pi m/h^2)^{\frac{3}{2}}$$

is called the chemical constant.

The entropy defined by formula (37.9) is expressed as a function of the number of particles and the volume of the gas.

The entropy is proportional to the number of particles of the gas as it should be, by virtue of its additivity. As the volume and number of particles of the gas are simultaneously increased by an arbitrary factor, the entropy increases or decreases by the same factor.

It may seem strange that the entropy which we have calculated does not contain any arbitrary constant, while, according to what was said in §24, the entropy is determined only to within an indefinite constant. In fact, the formula does not contain any arbitrary constant because we based the calculation of F and S on formulae (29.7) and (32.1), in which the arbitrary constant of the entropy was chosen as the conditional zero entropy.

The expression (37.9) for entropy loses its applicability as $T \rightarrow 0$. In deriving (37.9) we have not taken into account the phenomenon of quantum degeneration of the gas, which plays a basic role in its behaviour at very low temperatures. This phenomenon will be considered in ch. 10.

One cannot obtain a correct expression for the entropy, satisfying the third law of thermodynamics, without taking into account the phenomenon of degeneration. However, it should be noted that there are no ordinary gases at such low temperatures as those at which degeneration occurs. Long

before these temperatures are reached the liquefaction of gases takes place for all practical values of the density.

At very high temperatures formula (37.9) is again inapplicable, since it does not take into account the thermal ionization of atoms. Nevertheless, the interval of applicability of formula (37.9) is very large: from the liquefaction point to several thousand degrees.

In practice it is often more convenient to express entropy in terms of the pressure and temperature. Substituting into (37.9) the value of V expressed in terms of the pressure, we find

$$\begin{aligned} S &= \frac{5}{2}Nk \ln kT - Nk \ln p + \frac{5}{2}Nk + Nkj = \\ &= C_p \ln kT - Nk \ln p + \frac{5}{2}Nk + Nkj. \end{aligned} \quad (37.10)$$

In addition we calculate the Gibbs thermodynamic potential G . On the basis of (28.11) and (37.7), we have for G :

$$\begin{aligned} G = F + pV &= -\frac{5}{2}NkT \ln kT + NkT \ln p - NkTj = \\ &= NkT \ln p - C_p T \ln kT - NkTj. \end{aligned} \quad (37.11)$$

The expression for the heat capacity obtained above can be compared with experimental data. The number of monatomic gases is not very large. Noble gases and metal vapours are examples.

Table 3 gives measured values of the heat capacity.

Table 3
Heat capacity (at a constant volume) of monatomic gases

Substance	Temperature (°C)	C_V (J mol ⁻¹ K ⁻¹)
He {	291	12.59
	93	12.26
	26	12.56
	18	12.64
Ar	288	12.85
Na (vapour)	750–920	12.35
Hg (vapour)	548–629	12.43

From the table it is seen that the predictions of theory are well justified experimentally: the heat capacity of monatomic gases is constant over a large temperature interval and has a value which is almost the same as the theoretical value:

$$C_V \approx 12 \text{ J mol}^{-1} \text{ K}^{-1}.$$

In conclusion we shall consider the important problem of gas mixing.

For simplicity we assume that gas is put into two chambers with volumes V_1 and V_2 , which are separated in the beginning by an impenetrable membrane. Then the membrane is removed, and the molecules of both portions of the gas begin to interdiffuse. As a result of this process gas mixing takes place. We assume that the temperature and pressure of the gases were equal before mixing.

Let us find the change in the entropy as the two portions of the gas mix with each other. Here two cases should be distinguished: the mixing of gases of a different kind, and the mixing of gases of the same kind.

We shall begin with the treatment of the first case.

According to (37.9), the entropies of the different gases before mixing are given by the expressions

$$S_1^{(0)} = N_1 k \ln \frac{V_1}{N_1} + N_1 f(T),$$

$$S_2^{(0)} = N_2 k \ln \frac{V_2}{N_2} + N_2 f(T),$$

where $f(T)$ are the terms of the formula for the entropy which do not depend on the volume. The total entropy of the system before mixing is equal to

$$S^{(0)} = S_1^{(0)} + S_2^{(0)}.$$

After mixing, each of the ideal gases will behave as though there were no second gas, and will occupy the entire volume $V_1 + V_2$. The temperature of the mixture will be equal to the initial temperature of the gas. Hence after the mixing the entropy of each of the gases will be equal to

$$S_1 = N_1 k \ln \frac{V_1 + V_2}{N_1} + N_1 f(T),$$

$$S_2 = N_2 k \ln \frac{V_1 + V_2}{N_2} + N_2 f(T).$$

The entropy of a mixture consisting of two non-interacting ideal gases is equal to the sum of their entropies, i.e.

$$S = S_1 + S_2.$$

The change in the total entropy of the entire system in mixing is equal to $\Delta S = S - S^{(0)} =$

$$\begin{aligned} N_1 k \ln \frac{V_1 + V_2}{N_1} + N_2 k \ln \frac{V_1 + V_2}{N_2} - N_1 k \ln \frac{V_1}{N_1} - N_2 k \ln \frac{V_2}{N_2} = \\ = N_1 k \ln \frac{V_1 + V_2}{V_1} + N_2 k \ln \frac{V_1 + V_2}{V_2}. \end{aligned}$$

At given temperature and pressure

$$\frac{V_1 + V_2}{V_1} = \frac{(N_1 + N_2)kT/p}{N_1 kT/p} = \frac{N_1 + N_2}{N_1},$$

and analogously for $(V_1 + V_2)/V_2$, so that the change in the entropy is equal to

$$\Delta S = N_1 k \ln \frac{N_1 + N_2}{N_1} + N_2 k \ln \frac{N_1 + N_2}{N_2}.$$

Thus, the entropy of the mixture is higher than that of the initial gases.

The process of mixing of two different gases is an irreversible process. The origin of this irreversibility is quite understandable. When the membrane separating the gases is removed the interdiffusion of the gases takes place. Before mixing there existed a "regularity" in the position of molecules: the molecules of one gas were in one part of the container, and those of the second gas were in the other part of the container.

When the diffusion completely mixed the two gases, a uniform completely random distribution of the molecules occurs, and the probability of the state increases. In order to separate the gases it is necessary to do a certain amount of work, which in principle can be calculated.

Now consider the process of mixing two identical gases. Gases can be considered as identical in the case where they behave identically in all possible external fields.

The entropy of two portions of one gas before mixing is equal to

$$S_1 = N_1 k \ln \frac{V_1}{N_1} + N_2 k \ln \frac{V_2}{N_2} + (N_1 + N_2) f(T).$$

The entropy of the entire gas after mixing is equal to

$$S_2 = (N_1 + N_2) k \ln \frac{V_1 + V_2}{N_1 + N_2} + (N_1 + N_2) f(T).$$

Then for the change in the entropy we obtain

$$\Delta S = S_2 - S_1 = (N_1 + N_2) k \ln \frac{V_1 + V_2}{N_1 + N_2} - N_1 k \ln \frac{V_1}{N_1} - N_2 k \ln \frac{V_2}{N_2}.$$

However, from the equation of state of the gas it follows that, at a constant pressure and temperature,

$$\frac{V_1 + V_2}{N_1 + N_2} = \frac{V_1}{N_1} = \frac{V_2}{N_2},$$

Hence

$$\Delta S \equiv 0.$$

Thus, the change in the entropy in mixing two portions of one gas is indeed identically equal to zero. This result, which is in complete agreement with experiment, is closely connected with the assumption of the mutual identity of all particles of the given gas. Owing to this identity their mutual mixing is not a physical event. In mixing two portions of one gas at a constant pressure and temperature the distribution of molecules in the overall volume turns out to be uniform and random, and no interdiffusion takes place. It should be stressed that molecules or atoms can be considered as belonging to one kind and, hence, as identical, only in the case where they have the identical chemical structure, mass, and all other characteristics. This means that even different isotopes of one element, or atoms in different energy states, cannot be considered as identical. Thus, for example, the mixing of two different isotopes of a gas, or two portions of a gas consisting of normal and excited molecules, represents an irreversible process. This is particularly clear from the fact that a spontaneous separation of mixed gases does not occur, and that a certain amount of work must be done for their separation.

§38. The Maxwell–Boltzmann distribution and the Boltzmann distribution in a uniform field of force

In practice one often has to deal with a gas in a uniform external field of force. The most important example of such a field is the gravitational field. Up to now we have not considered the action of the gravitational field on the behaviour of a gas. We shall now consider an ideal gas in a uniform field of force. In such a field every molecule has a total energy

$$\epsilon = \epsilon_{\text{transl}} + u(x, y, z),$$

where ϵ_{transl} is the kinetic energy of its translational motion, and u is the potential energy in the external field, depending on the position of the particle.

Substituting this expression for the energy into the Gibbs distribution (19.6) for a molecule of an ideal gas, we have

$$dw = \frac{1}{zh^3} \exp\left[\frac{\epsilon_{\text{transl}} + u}{kT}\right] dp_x dp_y dp_z dV, \quad (38.1)$$

where the integral over states is, obviously, equal to

$$z = \int \exp\left[\frac{\epsilon_{\text{transl}} + u}{kT}\right] \frac{dp_x dp_y dp_z dV}{h^3}. \quad (38.2)$$

The integration is carried out over all possible values of the variables. Noting that the integral over states can be written in the form

$$\begin{aligned} z &= \int e^{-\epsilon_{\text{transl}}/kT} \frac{dp_x dp_y dp_z}{h^3} \int e^{-u/kT} dV = \\ &= \left(\frac{2\pi mkT}{h^2}\right)^{\frac{3}{2}} \int e^{-u/kT} dV, \end{aligned} \quad (38.3)$$

we find that the Gibbs distribution, normalized to unity, for a molecule of an ideal gas in the presence of an external field has the form

$$dw = \left[\frac{1}{(2\pi mkT)^{\frac{3}{2}}} e^{-p^2/2mkT} dp_x dp_y dp_z \right] \left[\frac{e^{-u/kT} dV}{\int e^{-u/kT} dV} \right]. \quad (38.4)$$

The probability distribution obtained, characterizing the probability for a molecule to have a given momentum and to be in a given volume element is called the Maxwell-Boltzmann distribution.

The first of the factors in (38.4) is the Maxwell distribution, with which we are familiar. It characterizes the probability distribution over the components of the momentum. The second factor depends only on the coordinates of the molecule and is determined by the form of its potential energy $u(x, y, z)$ in an external field of force. It expresses the probability for a molecule to be found in a given volume dV . In the particular case where there is no external field the distribution of molecules over the entire volume of the container is uniform and the second factor reduces to the value $V^{-1}dV$.

On the basis of the theorem of multiplication of probabilities the Maxwell-Boltzmann distribution can be considered as the product of the probabilities of two independent events: the probability of a given value of the momentum and the probability of a given position of the molecule. The first probability represents the Maxwell distribution, while the second probability represents the Boltzmann distribution. Each of the distribution is normalized to unity.

The fact that the two distributions are independent expresses an important, and at first not obvious physical proposition: the probability of a given value of momentum does not depend on the position of the molecule and, conversely, the probability of a given position of the molecule does not depend on its momentum.

Now consider in more detail the Boltzmann distribution for the particular case where the gas is in the field of terrestrial gravitation. We direct the z -axis vertically up. Then the potential energy of a gas molecule can be written in the form

$$u = mgz .$$

Since the potential energy depends only on the height, molecules are distributed uniformly in the plane $z = \text{const}$. Hence only the dependence of the probability distribution on the coordinate z is of interest. It has the form

$$dw_B = \frac{e^{-mgz/kT} dz}{\int e^{-mgz/kT} dz} , \quad (38.5)$$

where the integral is taken over all possible values of z .

Introducing the mean number of particles per cm^3 at a given height instead of the probability distribution, one can rewrite (38.5) in the form

$$dn = n_0 e^{-mgz/kT} dz, \quad (38.6)$$

where n_0 is the number of particles per cm^3 in the plane $z = 0$.

Formula (38.6) shows that the density of a gas in the gravitational field decreases according to an exponential law. It decreases by a factor e as the height increases to $\delta = kT/mg$. This quantity can be called the characteristic length of the distribution of particles in the gravitational field. For hydrogen δ amounts to about 3×10^5 m at room temperature while for air δ is correspondingly equal to 10^4 m. The Maxwell velocity distribution of molecules with a constant temperature T holds at all heights. However, the number of molecules at different heights decreases according to the exponential law (38.6). At first sight the constancy of the temperature at all heights may seem to contradict the following simple reasoning: if a molecule, which at a height z_0 has a kinetic energy $\frac{1}{2}mv_0^2$ moves to a height z , then its kinetic energy must decrease to a value $\frac{1}{2}mv_0^2 - mg(z - z_0)$, where $mg(z - z_0)$ is the work done against the force of gravity. Hence at a great height a molecule will have smaller velocity and kinetic energy. But, on the other hand, the temperature is connected with the mean square velocity by the relation (10.6). Consequently, the temperature of the gas must decrease with height. The fallacy of this reasoning lies in the consideration of only one molecule, without taking into account its collisions with other gas molecules. The Maxwell velocity distribution is established owing to collisions between molecules. In the foregoing reasoning the establishment of the Maxwell distribution is ignored and the "temperature of a molecule", which has no meaning, is considered. In fact, those molecules which have a large velocity will preferentially go up. Hence the Maxwell distribution will be established automatically at all heights.

Let us consider certain conclusions which can be derived from the density distribution of the gas with height. First of all, we shall dwell on the idea of the weight of a gas. Imagine a container of a height h , confining a gas. This gas has a certain weight. It is often said that the weight of a gas is the weight of all the molecules constituting it. In reality, however, this is not strictly true. The weight of a gas is measured by the difference between the pressures exerted by the gas on the bottom and the top of the container. All molecules of the gas, which are in permanent motion and which in the greater part of the container do not collide directly either with the bottom or the top of the container, take part in the production of this pressure difference. In this lies the difference between the weight of a gas and the weight of a body lying on the pan of a balance.

Let us find the weight of a gas column of height h . We can proceed in two

ways. First, it can be determined purely formally, by writing that the weight of the gas column is equal to the weight of all the molecules constituting it. Second, it can be found by taking the difference between the pressures exerted by the gas on the bottom ($z=0$) and the top ($z=h$) of the container.

In the first case we have:

$$\begin{aligned} P &= mg \int dN = mgn_0 \int_0^h e^{-mgz/kT} dz \int dx dy = \\ &= Smgn_0 \frac{kT}{mg} (1 - e^{-mgh/kT}) = SkT(n_0 - n_h), \end{aligned}$$

where S is the area of the cross section of the container, and n_0 and n_h are the densities of the gas at the heights $z = 0$ and $z = h$.

In the second case we can write that

$$P = S(p_0 - p_h) = S(n_0 - n_h)kT,$$

where p_0 and p_h are the pressures at the heights $z = 0$ and $z = h$ respectively. Thus, the calculation confirms the validity of the concept of the weight of a gas as measured by the difference between the pressures on the bottom and top of the container.

The molecules of a gas which are in a gravitational field possess a certain mean potential energy which exceeds the mean energy of the gas outside the field of force. Hence the mean energy of a gas in a gravitational field and, consequently, also its heat capacity must be higher than the values which we have calculated earlier. Let us find the extra heat capacity of the gas in a gravitational field. For this we shall calculate the mean potential energy of a gas molecule in a gravitational field. By definition it is equal to

$$\bar{u} = mg\bar{z} = mg \int z dw_B, \quad (38.7)$$

where dw_B is the probability that the molecule will be found at a height between z and $z + dz$, given by formula (38.5). Substituting the expression for dw_B into (38.7), we have

$$\bar{u} = mg\bar{z} = mg \frac{\int z e^{-mhz/kT} dz}{\int e^{-mgz/kT} dz}. \quad (38.8)$$

In calculating the integrals contained in (38.8) it is essential to know the

height of the gas column. Consider first of all the case of an infinitely high gas column or, more precisely, a column confined in a container whose height is considerably larger than the characteristic height δ . Then the range of integration with respect to z extends from $z = 0$ to $z \rightarrow \infty$. The calculation of the simple integrals (see Appendix IV) gives

$$\bar{u} = kT.$$

The mean potential energy of one molecule in the infinitely high gas column turns out to be proportional to the absolute temperature. The mean potential energy of a gram-mole of the gas in the infinitely high column is equal to

$$\bar{U} = N_0 \bar{u} = N_0 kT.$$

Whence we find for the extra heat capacity at a constant volume per gram-mole due to the potential energy

$$C_V^{\text{pot}} = N_0 k.$$

The heat capacity obtained is thus comparable with that due to the kinetic energy of the molecules.

We come to a completely different conclusion in the case of a gas column confined in a container of a height $h \ll \delta$. In this case the mean potential energy of the molecules is equal to

$$\bar{u} = mg \frac{\int_0^h e^{-mgz/kT} z dz}{\int_0^h e^{-mgz/kT} dz}.$$

Since in the integration range $mgz/kT = z/\delta \ll 1$, one can expand the integrand in a series and confine oneself to the first term of the expansion. This gives

$$\bar{u} = \frac{1}{2} mgh, \quad \bar{U} = N\bar{u} = \frac{1}{2} Nmgh.$$

In this approximation the mean potential energy of the gas column does not depend on the temperature at all. The corresponding contribution to the heat capacity is zero. In the next higher order approximation one can obtain a heat capacity which is very small in comparison with that due to the presence of kinetic energy. Thus, in practical cases of interest the contribution of the potential energy to the heat capacity of a gas can be disregarded.

Finally, consider the height distribution of molecules possessing different masses. From the form of the distribution (38.5) it is clear that the larger the mass of the molecule the more rapidly the number of corresponding molecules decreases with height. If there are equal numbers of molecules with masses m_1 and m_2 at the height $z = 0$, then the ratio of the numbers of the molecules of the two kinds at a height h is equal to

$$\frac{n_1}{n_2} = \exp \left[- \frac{(m_1 - m_2)gh}{kT} \right].$$

If the simple laws of the equilibrium distribution of density were applicable to the Earth atmosphere, then a sharp change of the composition of the atmosphere with height would be observed. In reality, however, measurements performed on the composition do not confirm this conclusion. It is also well known that the temperature decreases with height, which is also in complete contradiction with the requirement of the constancy of the temperature in an equilibrium gas column. These, and also a number of other facts show that the atmosphere is not in a state of statistical equilibrium.

§39. The calculation of the heat capacity of diatomic molecules by means of classical statistics. The law of equipartition of energy over degrees of freedom

Most substances in the gaseous state exist in the form of molecules. One very often has to deal with diatomic gases. Examples of such gases are H_2 , O_2 , N_2 , HCl and CO . Our immediate problem is the generalization of the results previously obtained to the cases of polyatomic gases and, in particular, to diatomic gases.

The basic difference between diatomic and polyatomic gases and monatomic gases is the presence of rotational and vibrational degrees of freedom in the former. We shall begin the treatment with the simplest case, diatomic gases. We shall assume at first that the molecule represents a system obeying the laws of classical mechanics. Since we shall not be interested in the internal motion of electrons in the atom, we shall replace each atom by a material point having no extension. Two material points bound into a molecule can be likened to a miniature dumb-bell at the ends of which there are two infinitely small spheres with masses m_1 and m_2 (different atomic masses). Since the link between the atoms in the molecule is not absolutely rigid, the following forms of motion are possible: translational motion (three degrees of freedom),

rotation about two axes perpendicular to the axis connecting the two atoms (two degrees of freedom), and vibration of the atoms along the line connecting them. We consider molecules as material points having infinitesimal dimensions, so that it makes no sense to speak of the rotation about the axis of the molecule.

The energy of the molecule can be written in the form

$$\epsilon = \epsilon_{\text{transl}} + \epsilon_{\text{rot}} + \epsilon_{\text{vib}}, \quad (39.1)$$

where ϵ_{transl} , ϵ_{rot} and ϵ_{vib} are respectively the energies of the translational, rotational and vibrational motion.

The state of a molecule formed by two atoms bound to each other is determined by defining six coordinates and six momenta. The coordinates are: the x, y, z coordinates determining the position of the centre of mass in space; θ and φ determining the position of the axis of the molecule in space; the q -coordinate determining the departure of the atoms from the equilibrium distance. The momenta corresponding to these coordinates are

$$p_x, \quad p_y, \quad p_z, \quad M_1 = I\omega_1, \quad M_2 = I\omega_2, \quad p_q.$$

Here I denotes the moment of inertia, and ω denotes the angular velocity of rotation of the molecule. The corresponding phase space has $2 \cdot (3+2) = 12$ dimensions.

We apply the Gibbs distribution to the molecule, considering it as a quasi-closed subsystem. Obviously, we have

$$dw = \frac{1}{h^{6z}} \exp \left[-\frac{\epsilon_{\text{transl}} + \epsilon_{\text{rot}} + \epsilon_{\text{vib}}}{kT} \right] d\Gamma. \quad (39.2)$$

An element of the phase space of a diatomic molecule can be written in the form

$$d\Gamma = d\Gamma_{\text{transl}} d\Gamma_{\text{rot}} d\Gamma_{\text{vib}}, \quad (39.3)$$

where the following notations are introduced:

$$\begin{aligned} d\Gamma_{\text{transl}} &= dp_x dp_y dp_z dx dy dz; \\ d\Gamma_{\text{rot}} &= dM_1 dM_2 \sin \theta d\theta d\varphi; \\ d\Gamma_{\text{vib}} &= dp_q dq. \end{aligned} \quad (39.4)$$

The first factor in the expression of the phase volume corresponds to the three degrees of freedom of the translational motion, the second factor corresponds to the two degrees of freedom of the rotational motion, and the third factor corresponds to the vibrational motion of the molecule. Thus,

$$dw = \frac{1}{h^6} \exp \left[-\frac{\epsilon_{\text{transl}} + \epsilon_{\text{rot}} + \epsilon_{\text{vib}}}{kT} \right] d\Gamma_{\text{transl}} d\Gamma_{\text{rot}} d\Gamma_{\text{vib}}. \quad (39.5)$$

We see that the Gibbs distribution resolves into three independent factors, corresponding to the translational, rotational and vibrational motions. Each of these forms of motion is independent of the other two. Hence the translational motion, rotation and vibration can be considered independently of each other.

The translational motion of diatomic molecules differs in no way from that of monatomic molecules, since the translational motion reduces to the motion of the centre of mass of the system.

Now let us consider *the rotational motion of a diatomic molecule*.

The rotational energy of a diatomic molecule for a given distance between the atoms has the form

$$\epsilon_{\text{rot}} = \frac{I\omega_1^2}{2} + \frac{I\omega_2^2}{2} = \frac{M_1^2}{2I} + \frac{M_2^2}{2I}, \quad (39.6)$$

where ω_1 and ω_2 are the angular velocities of the molecule; and M_1 and M_2 are the angular momenta. The moment of inertia I of the molecule is equal to

$$I = \frac{m_1 m_2}{m_1 + m_2} a^2, \quad (39.7)$$

where a is the distance between the atoms, and m_1 and m_2 are their masses.

The probability for the molecule to have values of angular momenta lying between M_1 and $M_1 + dM_1$, M_2 and $M_2 + dM_2$, and to be oriented in space in such a way that its axis forms with the coordinate axes angles between θ , $\theta + d\theta$ and φ , $\varphi + d\varphi$, has the form

$$dw_{\text{rot}} = \text{const} \cdot \exp \left[-\frac{M_1^2 + M_2^2}{2IkT} \right] dM_1 dM_2 \sin \theta d\theta d\varphi. \quad (39.8)$$

Since we are not interested in the orientation of the molecule in space, it is more convenient to pass over from the expression (39.8) to the expression

for the probability that the angular momentum has a given value for any orientation of the axis of the molecule in space. Integrating expression (39.8) with respect to the angles θ and φ , we obtain

$$dw_{\text{rot}} = \text{const} \cdot \exp \left[-\frac{M_1^2 + M_2^2}{2IkT} \right] dM_1 dM_2. \quad (39.9)$$

The constant in the expression (39.9) can be found from the normalization condition.

Instead of the angular momenta with respect to the axes, one can introduce the more customary quantities, the angular velocities. Then the probability for the molecule to have angular velocity components lying between ω_1 , $\omega_1 + d\omega_1$, ω_2 , $\omega_2 + d\omega_2$ is given by

$$dw_{\text{rot}} = \text{const} \cdot \exp \left[-\frac{I(\omega_1^2 + \omega_2^2)}{2kT} \right] d\omega_1 d\omega_2, \quad (39.10)$$

where the constant is again determined from the normalization condition.

Integrating formula (39.10) over all values of the angular velocity components (the integration range can be extended up to $\pm \infty$ on the same grounds as for the translational velocity components), we have

$$1 = \text{const} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \exp \left[-\frac{I(\omega_1^2 + \omega_2^2)}{2kT} \right] d\omega_1 d\omega_2, \quad (39.11)$$

whence

$$\text{const} = \frac{I}{2\pi kT}. \quad (39.12)$$

Hence we have finally

$$dw_{\text{rot}} = \frac{I}{2\pi kT} \exp \left[-\frac{I(\omega_1^2 + \omega_2^2)}{2kT} \right] d\omega_1 d\omega_2. \quad (39.13)$$

Proceeding from the condition (39.10), we find the mean rotational energy

$$\overline{\epsilon}_{\text{rot}} = \frac{1}{2} I (\overline{\omega_1^2} + \overline{\omega_2^2}). \quad (39.14)$$

For the mean value of the square of the angular velocity component we have

$$\overline{\omega_1^2} = \frac{I}{2\pi kT} \int_{-\infty}^{\infty} \omega_1^2 e^{-I\omega_1^2/2kT} d\omega_1 \int_{-\infty}^{\infty} e^{-I\omega_2^2/2kT} d\omega_2 = \frac{kT}{I}. \quad (39.15)$$

From consideration of the symmetry it is clear that

$$\overline{\omega_1^2} = \overline{\omega_2^2}, \quad (39.16)$$

hence the mean value of the rotational energy is equal to

$$\overline{\epsilon}_{\text{rot}} = kT. \quad (39.17)$$

To each degree of freedom of the rotational motion there corresponds an energy equal to $\frac{1}{2}kT$.

Passing on to the *vibrational motion of a diatomic molecule*, we note first of all that in the first approximation one can confine oneself to small vibrations about the equilibrium position, i.e. the equilibrium distance between the two atoms. In this case the vibrational energy of a diatomic molecule can be written in the form

$$\epsilon_{\text{vib}} = \frac{\mu \dot{q}^2}{2} + \frac{\mu \omega^2 q^2}{2} = \frac{p_q^2}{2\mu} + \frac{\mu \omega^2 q^2}{2}, \quad (39.18)$$

where q is the departure of the atoms from the equilibrium position, μ is the reduced mass, and ω is the vibrational frequency connected with the constant of the quasi-elastic force κ by the relation $\omega = (\kappa/\mu)^{\frac{1}{2}}$. The momentum of the vibrating system is $p_q = \mu \dot{q}$.

The probability for the atoms in the vibrating molecule to be in a position q and to have a momentum p_q has the form

$$dw_{\text{vib}} = \frac{1}{z} \exp \left[-\frac{p_q^2}{2\mu kT} \right] \exp \left[-\frac{\mu \omega^2 q^2}{2kT} \right] \frac{dp_q dq}{h}. \quad (39.19)$$

The partition function z in the expression (39.19) is found from the normalization condition:

$$z = \frac{1}{h} \int_{-\infty}^{\infty} \exp \left[-\frac{p_q^2}{2\mu kT} \right] dp_q \int_{-\infty}^{\infty} \exp \left[-\frac{\mu \omega^2 q^2}{2kT} \right] dq. \quad (39.20)$$

Since the integrands decrease very rapidly with increasing arguments and the integrals converge rapidly, we have extended the integration range to infinity.

A simple calculation gives

$$z = \frac{2\pi kT}{h\omega} . \quad (39.21)$$

Thus, we have finally

$$dw_{\text{vib}} = \left(\frac{\omega}{2\pi kT} \right) \exp \left[-\frac{p_q^2}{2\mu kT} \right] \exp \left[-\frac{\mu\omega^2 q^2}{2kT} \right] dp_q dq . \quad (39.22)$$

We find the mean energy of the vibrational motion:

$$\bar{\epsilon}_{\text{vib}} = \frac{\overline{p_q^2}}{2\mu} + \frac{\mu\omega^2 \overline{q^2}}{2} . \quad (39.23)$$

Calculating the means, we have

$$\overline{p_q^2} = \mu kT , \quad \overline{q^2} = \frac{kT}{\mu\omega^2} . \quad (39.24)$$

Substituting the mean values from (39.24) into (39.23), we find

$$\bar{\epsilon}_{\text{vib}} = kT . \quad (39.25)$$

To one vibrational degree of freedom there corresponds on the average an energy two times larger than that corresponding to one degree of freedom of the translational or rotational motion. The meaning of this will become clear if one recalls that for the vibrational motion the mean (over one period) kinetic energy of the system is equal to the mean potential energy. The energy of vibrational motion consists of two components having the same structure: quadratic expressions with respect to the independent variables p_q and q . For other degrees of freedom the energy is expressed by one quadratic term with respect to the independent variable for each degree of freedom. The averaging of each quadratic term in the energy leads to the mean energy $\frac{1}{2}kT + \frac{1}{2}kT = kT$.

In the general case it can be said that each quadratic term entering into the energy of the system has a mean value equal to $\frac{1}{2}kT$. We have convinced ourselves of this by the example of monatomic and diatomic molecules. All our reasoning can be applied without any special difficulty to the case of polyatomic molecules.

Consider, for instance, triatomic molecules. A triatomic molecule can have a structure similar to that of the CO_2 molecule, or the H_2O and SO_2 molecules (fig. III.19). In the first case all the atoms are distributed along a line, and the molecule is called a linear molecule. Molecules of the second type are called non-linear molecules. In the case of a linear triatomic molecule, having nine degrees of freedom, the following forms of motion are possible: the translational motion of the molecule as a whole (three degrees of freedom), the rotation about two axes perpendicular to the axis of the molecule (two degrees of freedom), and the vibrational motion (four degrees of freedom). Possible types of vibrational motion for a linear molecule are shown in fig. III.19. The directions of motion in a given phase of normal vibrations are shown by arrows, while ν_1 , ν_2 and ν_3 denote vibrational frequencies. Two vibrations with frequency ν_2 taking place independently of each other in two perpendicular planes are possible. The mean energy of a linear molecule is made up of the mean energy of the translational, rotational and vibrational motions. Each of these forms of motion, as well as different normal vibrations, are independent of each other. Hence to each of these forms of motion taken separately we can apply the reasoning of the preceding paragraphs. To each degree of freedom of the translational and rotational motion there corresponds a mean energy $\frac{1}{2}kT$, while to each vibrational degree of freedom there corresponds an energy kT . Thus, the mean energy of a linear triatomic molecule is equal to

$$\bar{\epsilon} = 3 \frac{kT}{2} + 2 \frac{kT}{2} + 4kT = 6.5kT.$$

For a non-linear molecule the mean energy turns out to be different. For such a molecule the following forms of motion are possible: the translational motion of the molecule as a whole (three degrees of freedom), the rotation

Fig. III.19

about three mutually perpendicular axes (three degrees of freedom), and the vibrations (three degrees of freedom). Possible normal vibrations are shown in fig. III.19. Everything else said about linear molecules holds also for non-linear triatomic molecules. Thus, the mean energy of a non-linear triatomic molecule is equal to

$$\bar{\epsilon} = 3 \frac{kT}{2} + 3 \frac{kT}{2} + 3kT = 6kT.$$

The problem of the mean energy of a polyatomic molecule can be considered in an analogous way. If the molecule contains n atoms, then out of $3n$ degrees of freedom there are always three translational degrees of freedom, three or two (in the case of a linear molecule) rotational degrees of freedom and respectively $3n - 6$ or $3n - 5$ vibrational degrees of freedom. Each of the degrees of freedom gives the corresponding contribution to the mean energy, the same as in the case of diatomic or triatomic molecules. Thus, the mean energy of a non-linear n -atomic molecule is equal to

$$\bar{\epsilon} = 3 \frac{kT}{2} + 3 \frac{kT}{2} + (3n-6) kT,$$

and that of a linear n -atomic molecule is

$$\bar{\epsilon} = 3 \frac{kT}{2} + 2 \frac{kT}{2} + (3n-5) kT.$$

In the general case one can write

$$\bar{\epsilon} = r \cdot \frac{1}{2} kT,$$

where r is the number of quadratic terms entering into the expression for the energy. Thus it turns out that all degrees of freedom of a molecule are equivalent: each quadratic term in the energy gives a contribution of $\frac{1}{2}kT$ to the mean energy of the molecule (the law of equipartition over degrees of freedom). The law of equipartition is a very general law. In deriving it we have not made any special assumptions, but have only assumed that the laws of statistical physics are valid and that the motion of the molecule obeys the laws of classical mechanics.

It should in addition be noted that the formulation of this important law is rather inappropriate, since it underlines the difference between vibrational and other degrees of freedom.

Since, however, the formulation presented is generally adopted, we shall make use of it in what follows. Moreover, we shall often for brevity call the number of quadratic terms in the energy the number of degrees of freedom.

Knowing the mean energy of a gas molecule, and taking into account that all molecules in an ideal gas are completely identical and equivalent, we can easily find the mean energy of the gas as a whole. If the gas has N molecules then the mean energy of the gas is equal to

$$E = N\bar{\epsilon} = N \cdot \frac{1}{2}rkT. \quad (39.26)$$

The heat capacity of a gas at constant volume C_V is equal to

$$C_V = \left(\frac{\partial E}{\partial T} \right)_V = \frac{1}{2}Nkr. \quad (39.27)$$

In particular, for one gram-mole of a gas the heat capacity at constant volume is equal to

$$C_V = \frac{1}{2}rR. \quad (39.28)$$

Correspondingly, the heat capacity at constant pressure is equal to

$$C_p = C_V + R = \frac{1}{2}(r+2)R. \quad (39.29)$$

Thus, the heat capacity of ideal gases turns out to be independent of the temperature, and is determined solely by the structure of the molecule. For monatomic gases the heat capacity at constant volume, calculated according to formula (39.29), is equal to $C_V = \frac{3}{2}R = 12.48 \text{ J mol}^{-1} \text{ K}^{-1}$.

For comparison with experiment, table 3 in §37 presents the measured values of the heat capacities of certain monatomic gases at constant volume and different temperatures. From table 3 it is seen that the theoretical predictions are well justified experimentally: the heat capacity of monatomic gases is constant over a wide temperature interval and has almost exactly the theoretical value.

For diatomic gases the situation is quite different. According to theoretical predictions, the heat capacity of diatomic gases should be equal to

$$C_V = \frac{7}{2}R \approx 29.11 \text{ J mol}^{-1} \text{ K}^{-1}. \quad (39.30)$$

However, experiment shows that diatomic gases do not in reality possess

such a large heat capacity. Moreover, it turns out that the heat capacity of diatomic gases depends on the temperature. This dependence is illustrated by fig. III.20. The general character of the dependence of the heat capacity on the temperature can be defined in the following way. Although at very high temperatures the heat capacity does not reach the theoretical value (39.30), it tends to it. As the temperature decreases the heat capacity also decreases and tends to the value

$$C_V = \frac{5}{2}R = 20.8 \text{ J mol}^{-1} \text{ K}^{-1} . \quad (39.31)$$

This value would be possessed by a diatomic molecule with an absolutely rigid link between the atoms, for which any vibrational motion is impossible. This vanishing of vibrational motion is completely inexplicable from the point of view of classical mechanics. From this standpoint, as we have stressed more than once, all degrees of freedom are completely equivalent. The vanishing of small vibrations as the temperature drops is in sharp contradiction with the basic propositions of classical mechanics. An even more striking example of such a contradiction is provided by the behaviour of hydrogen at

Fig. III.20

Fig. III.21

low temperatures. Namely, as is seen from fig. III.21, as the temperature decreases so does the heat capacity of hydrogen down to the value $\frac{3}{2}R$, equal to the value of the heat capacity of a monatomic gas. Thus, at low temperatures not only the vibrational motion but also the rotational motion vanishes in hydrogen molecules. A diatomic molecule can then perform only a translational motion.

From the point of view of our usual notions it is quite incomprehensible why an extended body, such as a diatomic molecule, can lose the ability to rotate. The contradiction between this fact and obvious ideas based on the laws of classical mechanics is even more evident than in the case of the vanishing of vibrations.

All that has been said about diatomic molecules holds also for polyatomic molecules. The part of the energy corresponding to vibrational degrees of freedom is always considerably smaller than that to be expected from the law of equipartition. For example, in the case of the linear molecule CO_2 the vibrational heat capacity should be equal to $4R \approx 32 \text{ J mol}^{-1} \text{ K}^{-1}$. In fact, it amounts to about $3.2 \text{ J mol}^{-1} \text{ K}^{-1}$ at room temperature, and increases up to a value of $24 \text{ J mol}^{-1} \text{ K}^{-1}$ at very high temperatures. Analogously, CH_4 molecules, possessing nine vibrational degrees of freedom to which, according to the law of equipartition, there should correspond a heat capacity of $72 \text{ J mol}^{-1} \text{ K}^{-1}$, have a vibrational heat capacity which does not exceed $13.8 \text{ J mol}^{-1} \text{ K}^{-1}$.

Thus, experiment points to the inapplicability of the law of equipartition

over degrees of freedom. But, as we have stressed, this law is based on only two assumptions: the assumption of the applicability of general statistical laws to simple molecular systems and the assumption of the applicability of the laws of classical mechanics to the description of the motion of individual molecules. Since the validity of the first assumption is beyond any doubt, the disagreement with experiment to which the law of equipartition leads shows that the second assumption is incorrect. In reality the motions of individual molecules obey the laws of quantum mechanics. The statistics of molecular systems moving according to the laws of quantum mechanics will be discussed below.

§40. The thermodynamic functions of a system which can be in two quantum states

Before going on to the consideration of more complex diatomic and polyatomic molecules, we have to consider the general aspect of the properties of a system which can be in two quantum states. We shall not specify the nature of these quantum levels. In the following paragraphs we shall see that these can be the quantum levels of the energy of rotational or vibrational motion. Sometimes they may also have a different nature.

Let us find the partition function of such a system. By definition,

$$z = \sum e^{-\epsilon_i/kT} g(\epsilon_i), \quad (40.1)$$

where ϵ_i are the quantum energy levels and $g(\epsilon_i)$ is the number of states of the particle whose energy is equal to ϵ_i . If g is different from unity, so that to one value of the energy of the system there correspond several different states, then the latter are called degenerate states, and their number is called the statistical weight of the energy level ϵ_i . In our case, where, for simplicity, we confine ourselves to two energy levels, the index i runs over the values 0, 1. We denote $g(\epsilon_0)$ by g_0 , and $g(\epsilon_1)$ by g_1 . Then

$$z = g_0 e^{-\epsilon_0/kT} + g_1 e^{-\epsilon_1/kT} = g_0 e^{-\epsilon_0/kT} \left(1 + \frac{g_1}{g_0} e^{-(\epsilon_1 - \epsilon_0)/kT} \right). \quad (40.2)$$

If the energy is expressed in thermal units of kT , then one can write that

$$\epsilon_1 - \epsilon_0 = kT_c, \quad (40.3)$$

where T_c is a certain temperature corresponding to the difference $\epsilon_1 - \epsilon_0$. By means of (40.3) the expression (40.2) can be written in the form

$$z = g_0 e^{-\epsilon_0/kT} \left(1 + \frac{g_1}{g_0} e^{-T_c/T} \right). \quad (40.4)$$

From the expressions (40.2) and (40.4) we see that, if the energy difference between the excited and ground state is so large that at a temperature T the inequality $\epsilon_1 - \epsilon_0 \gg kT$ or $T_c \gg T$ holds, then the second term in (40.4) can be disregarded, so that

$$z = g_0 e^{-\epsilon_0/kT}. \quad (40.5)$$

Physically this means that at a given temperature the probability for the system to get into an excited state with energy ϵ_1 is very small. The temperature is too low for thermal excitation to bring the system into an upper energy state with an appreciable probability. If, however, only one term enters into the partition function, so that the system is, with a probability equal to unity, in a state with an energy ϵ_0 , then its energy is exactly equal to ϵ_0 . This is confirmed by a direct calculation.

The partition function of a system consisting of N independent equal particles is

$$Z = \frac{1}{N!} (g_0 e^{-\epsilon_0/kT})^N.$$

According to (21.3), the energy of the system is equal to

$$E = kT^2 \frac{\partial \ln Z}{\partial T} = N\epsilon_0.$$

The heat capacity of the system at constant volume is

$$C_V = \left(\frac{\partial E}{\partial T} \right)_V = 0. \quad (40.6)$$

Thus, we see that at $T \ll T_c$ the presence of the second level does not affect the thermodynamic properties of the system at all, and it behaves as a system with constant energy. The heat capacity of the system at a sufficiently low temperature is equal to zero.

The behaviour, as the temperature rises, of the heat capacity of the system with two energy levels is of interest. If the inequality $T_c \gg T$ is not fulfilled, then one has to retain two terms in the partition function, writing

$$z = g_0 e^{-\epsilon_0/kT} \left(1 + \frac{g_1}{g_0} e^{-\Delta\epsilon/kT} \right).$$

In this case

$$Z = \frac{1}{N!} (g_0 e^{-\epsilon_0/kT})^N \left(1 + \frac{g_1}{g_0} e^{-\Delta\epsilon/kT} \right)^N.$$

The energy of the system is

$$E = kT^2 \frac{\partial \ln Z}{\partial T} = N\epsilon_0 + \frac{Ng_1 \Delta\epsilon e^{-\Delta\epsilon/kT}}{g_0 [1 + (g_1/g_0) e^{-\Delta\epsilon/kT}]}. \quad (40.7)$$

Finally, the heat capacity at a constant volume is

Fig. III.22

$$\begin{aligned}
 C_V &= \left(\frac{\partial E}{\partial T} \right)_V = N \left(\frac{g_1}{g_0} \right) \left(\frac{\Delta \epsilon}{kT} \right)^2 \frac{e^{-\Delta \epsilon/kT}}{[1 + (g_1/g_0) e^{-\Delta \epsilon/kT}]^2} = \\
 &= Nk \left(\frac{g_1}{g_0} \right) \left(\frac{T_c}{T} \right)^2 \frac{e^{-T_c/T}}{[1 + (g_1/g_0) e^{-T_c/T}]^2}. \quad (40.8)
 \end{aligned}$$

The form of the heat capacity is shown in fig. III.22. From fig. III.22 it is seen that this form is unusual: at $T = 0$ the heat capacity is zero, in agreement with what was said earlier. At higher temperatures the heat capacity increases and has a characteristic maximum. As the temperature rises further the heat capacity again reduces to zero. This latter fact represents a characteristic feature of a system with two levels. The reason why C_V reduces to zero is understandable from formula (40.7). At a very high temperature the energy of the system is equal to

$$E \approx N\epsilon_0 + \frac{Ng_1}{g_0} \frac{\epsilon_1 - \epsilon_0}{1 + g_1/g_0} = \text{const} \quad (40.9)$$

and does not depend on temperature. Physically this means that at $T \gg T_c$ the thermal excitation is so large that the system may with equal ease be in the ground state or in an excited state. The probability for the system to be in an excited state is comparable to the probability of being in the ground state.

If the system had other excited levels, ranging up to very large energies, this would not hold. Even at a high temperature there would be energy levels which the system would only have a small probability of occupying. Hence the mean energy of such a system would not be expressed by a formula of the type of (40.9) and, at a high temperature, would vary with temperature.

Correspondingly, the heat capacity of the system would not reduce to zero at a high temperature.

The form of the heat capacity, with a maximum and the reduction to zero on the low and high temperatures sides, is typical of a system with levels lying in a finite energy interval. The presence of two levels simplifies the calculation, but it is not essential. A similar form of the heat capacity also occurs in systems with several levels. It is of importance only that they lie sufficiently close to each other, so that the temperature at which the condition $kT \gg \epsilon_0 - \epsilon_n$ is fulfilled may be reached. A typical example of atoms with two closely lying levels are atoms of the halogens and the alkali metals. In the case of halogens the lowest level is four-fold degenerate, $g_0 = 4$, and the excited level lying closest to it is two-fold degenerate, $g_1 = 2$. The

distance between the levels is $T_c = 582.7$ K for fluorine, $T_c = 1299$ K for chlorine, and $T_c = 5275$ K for bromine. The next energy level lies much higher: the corresponding temperature amounts to several tens of thousands of degrees (for example, for bromine it amounts to about 88×10^3 K) and gives practically no contribution to the heat capacity.

§41. Diatomic molecules

The simplest molecules are diatomic molecules, representing a stable combination of two identical or dissimilar atoms. We cannot here discuss in detail the problem of the nature of the forces leading to the formation of molecules from free atoms nor describe in detail the motion of atoms in molecules. We shall confine ourselves to the most superficial characteristics of molecules, presenting only those data which we shall need in what follows. (Ch. 10 of Part V is devoted to the theory of molecules.)

Fig. III.23 shows a typical curve representing the energy of interaction of the electron shells of atoms as a function of the distance between them. The potential energy of interaction has a minimum at a certain point denoted by r_0 . To the right of it at large distances the tangent to the curve and, consequently, the force of interaction also is positive. This means that the atoms

Fig. III.23

attract each other. To the left of the point r_0 , in the region where the electron shells are overlapping, a strong repulsion between the atoms arises.

Thus there corresponds to the position of stable equilibrium in a molecule a definite distance between the nuclei of the atoms, which can be called the diameter of the molecule (see table 4 below). The energy $U(r_0)$ of the electron shells has a minimum value. If the distance between the nuclei changes by a small value x , then the energy of the molecule becomes equal to $U(r_0+x)$. For small values of x it can be expanded in a series in powers of x and one can restrict oneself to the first terms of the expansion:

$$\begin{aligned} U(r_0+x) &\approx U(r_0) + \left(\frac{\partial U}{\partial r}\right)_{r=r_0} x + \left(\frac{\partial^2 U}{\partial r^2}\right)_{r=r_0} \frac{1}{2}x^2 = \\ &= U(r_0) + \frac{1}{2}\kappa x^2 \end{aligned} \quad (41.1)$$

(at the point of the minimum the first derivative is equal to zero, and the second derivative is positive). Formula (41.1) shows that when the atoms depart from the equilibrium position they are acted upon by a quasi-elastic force bringing them back into the equilibrium position. From this it is clear that in a molecule, in addition to the motion of electrons in atomic shells, the vibration of the atoms about the equilibrium position is also possible. Moreover, a molecule as a whole can rotate about two axes perpendicular to the straight line connecting the nuclei.

Thus, the energy of a molecule can be considered as made up of the energy of translational motion of the molecule as a whole in space, the energy of motion of the electrons, the vibrational energy and the energy of rotation of the molecule. The translational motion of a diatomic molecule differs in no way from that of a monatomic molecule. Hence we shall be interested only in the internal motion of a diatomic molecule. Its internal energy can be written in the form

$$\epsilon_{\text{int}} = \epsilon_{\text{el}} + \epsilon_{\text{vib}} + \epsilon_{\text{rot}}, \quad (41.2)$$

where ϵ_{el} is the energy of motion of the electrons, ϵ_{vib} is the energy of vibrations, and ϵ_{rot} is the energy of rotation. The internal motion of the molecule turns out to be quantized. The energies ϵ_{el} , ϵ_{vib} and ϵ_{rot} take on a discrete series of values. The spacing $\Delta\epsilon_{\text{el}}$ between neighbouring energy levels of the electrons in the molecule turns out to be much larger than the spacing $\Delta\epsilon_{\text{vib}}$ between neighbouring energy levels of the vibrational motion. In its turn the spacing $\Delta\epsilon_{\text{vib}}$ between neighbouring energy levels of the vibrational motion is very large in comparison with the spacing $\Delta\epsilon_{\text{rot}}$ between neighbouring energy levels of the rotational motion. Thus,

Fig. III.24

$$\Delta\epsilon_{el} \gg \Delta\epsilon_{vib} \gg \Delta\epsilon_{rot} \quad (41.3)$$

Hence the energy levels of a molecule are distributed in the way shown schematically in fig. III.24. In this drawing the vibrational and rotational levels pertaining to two electron levels, l and l' , are presented schematically. The spacing between the latter is large and is represented by dashed-dotted lines to show that there is not sufficient room for it in the scale of the drawing. Bold lines correspond to vibrational states with quantum numbers $\nu = 0, 1, 2$. Fine lines correspond to different rotational levels with quantum numbers $J = 1, 2, 3, 4$. Since the motion of electrons is much faster than that of heavy nuclei (for the vibrations and rotation of the molecule as a whole), it can be assumed in the first approximation that the motion of the nuclei does not affect that of the electrons.

Further, if the amplitude of vibration of the nuclei of the molecule is sufficiently small, the effect of the vibrational motion on the rotation can be disregarded. For a small vibrational amplitude the change in the distances between the nuclei is so small that the corresponding change in the moment

of inertia of the molecule is very small and can be ignored. The rotation will proceed with a constant moment of inertia, as though there were no vibrations. Thus, to a first approximation all three forms of motion in a molecule can be considered to be independent of each other.

It should be noted that the accuracy of contemporary methods of measurement is such that for many purposes the calculations based on the concept of the independent rotational and vibrational motion turn out to be insufficiently accurate. In contemporary theory one has to take into account the change in the moment of inertia of the molecule due to its vibration.

The spacing between neighbouring energy levels of the electron motion, as between energy levels in atoms, is of the order of several electron-volts, which corresponds to a temperature of several thousand degrees. In order to bring a molecule from one electronic level to another the corresponding energy must be imparted to it. This is only possible at very high temperatures (or for non-thermal effects on the molecule, for example, when it is irradiated by light, bombarded by fast electrons, etc.). As a rule, however, it can be assumed that these sources of excitation of the electronic motion are absent and that molecules are in the lowest electron energy level. In what follows we shall confine ourselves to the study of this case. Thus, in considering the thermal motion of molecules it is possible to disregard electron energy levels.

We shall consider now the vibrational motion of a diatomic molecule. The oscillations of the two nuclei about the equilibrium distance can be reduced to the oscillatory motion of one material point with a reduced mass $\mu = m_1 m_2 / (m_1 + m_2)$. Such a material point represents a linear oscillator, considered in §1. For a sufficiently small vibration amplitude it can be considered to be a harmonic oscillator. The energy of a harmonic oscillator takes on a discrete series of values given by formula (1.18):

$$\epsilon_{\text{vib}} = h\nu(n + \frac{1}{2}),$$

where the quantum number n takes on a series of integer values: $n = 0, 1, 2, \dots$; ν is the classical frequency connected with the constant of the quasi-elastic force κ and the mass of the oscillator by the usual relation

$$\nu = (\kappa\mu^{-1})^{\frac{1}{2}}/2\pi.$$

All levels of the oscillator are non-degenerate, so that to each value of the quantum number n there corresponds a definite energy ϵ_{vib} . The energy difference between neighbouring levels of the vibrational motion is equal to

$$\Delta\epsilon_{\text{vib}} = h\nu(n+\frac{1}{2}) - h\nu(n-1+\frac{1}{2}) = h\nu$$

and does not depend on the quantum number n ; the energy levels are distributed at equal distances from each other.

According to the Bohr frequency rule, when a system passes over from one energy level to another a photon with energy $h\nu$ is emitted or absorbed. In quantum mechanics it turns out that the change in the quantum number n obeys the so-called selection rule:

$$\Delta n = \pm 1.$$

Measuring the frequencies of the light absorbed or emitted by the molecules, one can determine the natural frequency ν of the molecule and find the constant of the quasi-elastic force κ and the energy difference $\Delta\epsilon_{\text{vib}}$. The values of these quantities for several molecules are presented in table 4. The radiation emitted or absorbed by molecules as their vibrational state is changed (for a fixed value of the electron energy) lies in the infrared spectral region *, as a rule between 100 and 4000 cm^{-1} .

Table 4
Basic quantities characterizing the properties of diatomic molecules

Molecule	Distance between the atoms r_0 (10^{-8} cm)	Moment of inertia I (10^{-40} g cm^2)	Vibrational frequency ν/c (cm^{-1})	Rotational constant $\frac{B}{c} = \frac{h}{8\pi^2 Ic}$ (cm^{-1})	Constant of the quasi- elastic force (10^{-5} dyne cm)	Dissociation energy D (eV)
H ₂	0.74	0.46	4276	59.35	5.1	4.48
N ₂	1.10	13.84	2360	2.00	22.2	7.38
O ₂	1.21	19.13	1580	1.45	11.3	5.08
Cl ₂	1.99	113.5	565	0.24	3.21	2.47
HCl	1.27	2.67	2989	10.6	8.65	4.40
CO	1.13	14.37	2169	1.92	18.6	9.61
NO	1.15	16.43	1906	1.68	15.4	5.29

The formulae given for the energy of a vibrating molecule are valid only in the approximation of small vibrations. For a high excitation (for example,

* It should be noted that this does not refer to symmetric molecules of the type of H₂ and O₂, for which there are no such transitions. For these molecules $\Delta\epsilon_{\text{vib}}$ is determined from transitions with a simultaneous change of electron states.

at a high temperature) their amplitude becomes large, and one must take into account anharmonic terms in the potential energy.

We shall now consider the rotational motion of a diatomic molecule. If the change in the moment of inertia of the molecule due to vibrations is disregarded, then the molecule can be considered as a rigid rotator with a moment of inertia $I = m_1 m_2 r_0^2 / (m_1 + m_2)$ rotating about the centre of mass. As is shown in quantum mechanics (Part V, §81), the energy of a rotating body is expressed by the formula

$$\epsilon_{\text{rot}} = \frac{h^2}{8\pi^2 I} J(J+1) = hBJ(J+1), \quad (41.4)$$

where J is a quantum number taking on integer values: $J = 0, 1, 2, \dots$, and $B = h^2/8\pi^2 I$ is a constant called the rotational constant. It turns out that the states of a rotator corresponding to given rotational energy are $(2J+1)$ -fold degenerate (see §30 and §81 of Part V).

When the quantum states of the molecule change, the quantum number changes by an amount $\Delta J = \pm 1$. The spacing between neighbouring rotational energy levels is equal to

$$\Delta\epsilon_{\text{rot}} = \frac{2h^2}{8\pi^2 I} (J+1).$$

By observing the radiation in the transition between rotational levels, one can determine the value of $\Delta\epsilon_{\text{rot}}$ and, consequently, the moment of inertia I of the molecule. The value of these quantities for some molecules can be calculated by means of table 4. Substituting into the expressions for ϵ_{rot} and ϵ_{vib} the values of the constants given in the fourth and fifth columns of the table, we verify the validity of the assumption that $\Delta\epsilon_{\text{vib}} \gg \Delta\epsilon_{\text{rot}}$ ($\Delta\epsilon_{\text{rot}}$ is smaller than $\Delta\epsilon_{\text{vib}}$ by a factor of 800–1000). It should be noted that in practice one seldom manages to observe the transitions of a molecule between different rotational levels for an unchanged electron state and an unchanged vibrational state, since $\Delta\epsilon_{\text{rot}}$ is so small that the corresponding frequencies $\nu = \Delta\epsilon_{\text{rot}}/h$ lie in the far infrared spectral region, where the accuracy of measurements is poor. The emission spectra and absorption spectra of molecules in the visible spectra region are those most often observed. These spectra arise when the vibrational, rotational and electronic state of a molecule are changed simultaneously. The emission (or absorption) spectrum has in this case the character of a group of close spectral lines merging in a low-resolution spectroscopy into continuous bands (molecular

band spectrum). The origin of the bands is easily understood from fig. III.24. Let, for example, a transition take place from upper levels to the lowest level. The fundamental frequency is emitted in the transition from the level 2, $\nu = 0$, $J = 1$. Frequencies close to the fundamental frequency are emitted in the transition from the levels 2, $\nu = 1$, $J = 0$; $\nu = 2$, $J = 0$ and so on. Thus, when the vibrational, rotational and electronic states of a molecule are changed simultaneously a number of frequencies lying close to each other are emitted (since the inequality (41.3) is fulfilled). The totality of spectroscopic data has made it possible to establish the position of energy levels for a very large number of diatomic molecules.

§42. Thermodynamic functions of diatomic gases

We can now pass on to the consideration of the heat capacities and thermodynamic functions of diatomic gases, the calculation of which was insuperably difficult for classical statistics. The method of calculation of the thermodynamic functions for diatomic gases in no way differs from that which we have already considered for monatomic gases. Since the molecules are identical, independent particles, the partition function for an entire gas containing N molecules can be written in the form

$$Z = \frac{1}{N!} (z)^N. \quad (42.1)$$

We have to find the partition function for one molecule. The energy of a molecule can be divided into the energy of its motion as a whole in space and the energy of its internal motion:

$$\epsilon = \epsilon_{\text{transl}} + \epsilon_{\text{int}}.$$

Since these two forms of motion are independent, the number of states of the system corresponding to an energy ϵ is resolved into the number of states corresponding to the energy of translational motion and the number corresponding to the internal motion:

$$\Omega = \Omega(\epsilon_{\text{transl}}) \Omega(\epsilon_{\text{int}}).$$

Accordingly, the partition function can be resolved into the product of two factors:

$$\begin{aligned}
 z &= \sum \exp(-\epsilon_{\text{transl}}/kT) \Omega(\epsilon_{\text{transl}}) \cdot \sum \exp(-\epsilon_{\text{int}}/kT) \Omega(\epsilon_{\text{int}}) = \\
 &= z_{\text{transl}} z_{\text{int}},
 \end{aligned}
 \quad (42.2)$$

where z_{transl} is the partition function associated with the translational motion of the molecule as a whole, and z_{int} is the partition function for the internal motion.

The partition function for the translational motion of a diatomic molecule is no different from that of a monatomic molecule, since it moves in space as a material point with a mass $m = m_1 + m_2$ located at the centre of mass of the molecule. Hence for the partition function of translational motion one can write that

$$z_{\text{transl}} = \left(\frac{2\pi mkT}{h^2} \right)^{\frac{3}{2}} V. \quad (42.3)$$

The calculation of z_{int} is more complicated. The internal motion of a diatomic molecule reduces to its rotation with respect to two mutually perpendicular axes and the vibrations of the atoms about the equilibrium position. In the first approximation one can neglect the effect of small vibrations on the value of the moment of inertia of the molecule and assume the vibrational and rotational motions to be independent of each other (see §41). One can disregard the electron energy since it remains unchanged. Hence, according to (41.2), the energy of internal motion of the molecule can be written in the form

$$\epsilon_{\text{int}} = \epsilon_{\text{vib}} + \epsilon_{\text{rot}}.$$

Accordingly the partition function for the internal motion resolves into the product of two factors:

$$\begin{aligned}
 z_{\text{int}} &= \sum \exp [-(\epsilon_{\text{vib}} + \epsilon_{\text{rot}})/kT] \Omega(\epsilon_{\text{vib}}) \Omega(\epsilon_{\text{rot}}) = \\
 &= \sum \exp(-\epsilon_{\text{vib}}/kT) \Omega(\epsilon_{\text{vib}}) \cdot \sum \exp(-\epsilon_{\text{rot}}/kT) \Omega(\epsilon_{\text{rot}}) = \\
 &= z_{\text{vib}} z_{\text{rot}}.
 \end{aligned}
 \quad (42.4)$$

Substituting the expressions for z from (42.2) and (42.4) into (42.1), we obtain

$$Z = \frac{1}{N!} (z_{\text{transl}})^N (z_{\text{vib}})^N (z_{\text{rot}})^N. \quad (42.5)$$

From this the expressions for the thermodynamic functions can be found:

$$\begin{aligned} F &= -kT \ln Z = \\ &= -kT \ln \frac{z_{\text{transl}}^N}{N!} - kT \ln z_{\text{rot}}^N - kT \ln z_{\text{vib}}^N = \\ &= F_{\text{transl}} + F_{\text{vib}} + F_{\text{rot}}, \end{aligned} \quad (42.6)$$

where F_{transl} , F_{vib} and F_{rot} denote the individual components of the free energy due to the translational, vibrational and rotational motions of the gas molecules. The expression for F_{transl} is the same as the free energy of a monatomic gas [formula (37.7)] if in the latter the mass of one atom is replaced by the total mass of the diatomic molecule. Analogously,

$$E = kT^2 \frac{\partial \ln Z}{\partial T} = E_{\text{transl}} + E_{\text{vib}} + E_{\text{rot}}, \quad (42.7)$$

$$S = - \left(\frac{\partial F}{\partial T} \right)_V = S_{\text{transl}} + S_{\text{vib}} + S_{\text{rot}}, \quad (42.8)$$

$$C_V = \left(\frac{\partial E}{\partial T} \right)_V = C_{V_{\text{transl}}} + C_{V_{\text{vib}}} + C_{V_{\text{rot}}}. \quad (42.9)$$

Thus, all the thermodynamic functions are resolved into individual components. Each component corresponds to one of the independent forms of motions of the diatomic molecule: the translational, vibrational or rotational motion. In order to calculate the thermodynamic functions of a diatomic gas it is necessary to find the corresponding partition functions of the internal motion. In the following sections we shall consider the partition functions for the vibrational and rotational motions.

§43. The vibrational partition function and the contribution of vibrations to the energy and heat capacity

In the first approximation a vibrating diatomic molecule can be considered as a quantum harmonic oscillator the energy of which is expressed by formula

(1.18). All energy levels of the oscillator are non-degenerate, i.e. with a weight $\Omega = 1$. Substituting the expression for the energy (1.18) into the partition function, we have

$$z_{\text{vib}} = \sum_{n=0}^{\infty} \exp \left[-h\nu \left(n + \frac{1}{2} \right) / kT \right] = e^{-h\nu/2kT} \sum_{n=0}^{\infty} e^{-h\nu n/kT}. \quad (43.1)$$

Making use of the well-known formula for the sum of an infinitely decreasing geometric series, we obtain

$$z_{\text{vib}} = e^{-h\nu/2kT} \sum_{n=0}^{\infty} (e^{-h\nu/kT})^n = \frac{e^{-h\nu/2kT}}{1 - e^{-h\nu/kT}}. \quad (43.2)$$

From formula (43.2) we see that the partition function and, consequently, the thermodynamic quantities also are determined by the value of the variable $h\nu/kT$. In the notation of §40 we can, expressing $h\nu$ in energy units, write $h\nu = kT_c$, where T_c is the so-called characteristic temperature. Formula (43.2) can be rewritten in the form

$$z_{\text{vib}} = \frac{e^{-T_c/2T}}{1 - e^{-T_c/T}}.$$

Now we calculate the thermodynamic functions of a diatomic molecule corresponding to its vibrational motion. We first of all find the mean vibrational energy:

$$\begin{aligned} E_{\text{vib}} &= N\bar{\epsilon}_{\text{vib}} = NkT^2 \frac{\partial}{\partial T} \ln z_{\text{vib}} = \\ &= NkT^2 \frac{\partial}{\partial T} \ln \frac{e^{-T_c/2T}}{1 - e^{-T_c/T}} = \\ &= \frac{NkT_c}{2} \coth \frac{T_c}{2T} = \frac{Nh\nu}{2} \coth \left(\frac{h\nu}{2kT} \right). \end{aligned} \quad (43.3)$$

For the vibrational heat capacity we find

$$\begin{aligned}
 C_{V_{\text{vib}}} &= \frac{\partial E_{\text{vib}}}{\partial T} = \\
 &= \frac{Nk}{4} \left(\frac{h\nu}{kT} \right)^2 \frac{1}{\sinh^2(h\nu/2kT)} = \\
 &= \frac{Nk}{4} \left(\frac{T_c}{T} \right)^2 \frac{1}{\sinh^2(T_c/2T)}. \quad (43.4)
 \end{aligned}$$

We see that the mean vibrational energy and heat capacity turn out to be complicated functions of the temperature T and the characteristic temperature T_c (or the natural frequency ν). Consider the limiting form of these functions at high temperatures ($T \gg T_c$) and low temperatures ($T \ll T_c$). In the first case the exponential function can be expanded in a series, and one can restrict oneself to the first terms of the expansion. This gives

$$E_{\text{vib}} \approx NkT, \quad (43.5)$$

$$C_{V_{\text{vib}}} \approx Nk. \quad (43.6)$$

At low temperatures $e^{T_c/T} \gg 1$, so that

$$E_{\text{vib}} \approx \frac{1}{2}NkT_c + NkT_c e^{-T_c/T}, \quad (43.7)$$

$$C_{V_{\text{vib}}} \approx Nk (T_c/T)^2 e^{-T_c/T}. \quad (43.8)$$

Formulae (43.5) and (43.6) agree with the classical formulae of §39. On the contrary, at low temperatures the expressions for the energy and heat capacity differ fundamentally from the classical ones. As the temperature decreases the vibrational energy tends to a constant limit $E_0 = \frac{1}{2}NkT_c = \frac{1}{2}Nh\nu$. The latter quantity, representing the vibrational energy of the molecules at absolute zero, is called the zero point energy. The existence of the zero point energy is a characteristic feature of quantum motion. It is an expression of the fact that in quantum theory the concept of a particle at rest is devoid of any physical meaning.

The numerical value of E_0 can be found from spectroscopic data. For this it is only necessary to find the value of the natural vibrational frequency ν of the molecule. The heat capacity at low temperatures turns out to be a small quantity decreasing according to an exponential law, i.e. tending to zero as $T \rightarrow 0$. Thus, the general scheme of the variation of the energy and heat

capacity with the temperature reduces to the fact that at high temperatures, when the thermal energy kT is large in comparison with the spacing $\Delta\epsilon = h\nu = kT_c$ between the energy levels, the heat capacity and the energy are given by the classical expressions; at low temperatures the energy tends to a limiting value — to the zero point energy of the quantum oscillator, while the heat capacity tends to zero. Such behaviour of these quantities is in agreement with general considerations. At high temperatures the magnitude of the quantum steps $\Delta\epsilon$ is small in comparison with the thermal energy, so that the oscillator can be in a large number of excited quantum states, and its energy can be assumed to vary continuously, as in the case of a classical oscillator. On the contrary, at low temperatures the oscillator is always in the ground state and thermal excitation is insufficient to bring it into upper excited states.

The curve showing the dependence of the mean energy of the oscillator on the ratio T/T_c , given by formula (43.3), is shown in fig. III.25. From fig. III.25 it is seen that, when T approaches T_c , a smooth transition takes place between the limiting values (43.5) and (43.7). The basic difference between the classical expression for the mean energy of the oscillator (43.5) and the quantum expression (43.3) lies in the fact that in the latter case the energy depends on the frequency. Because of this the temperature still does not completely characterize the energy of the oscillator. For the same temperature two oscillators with different natural oscillation frequencies will have different energies. Fig. III.26 shows the dependence of the energy of the oscillator on the frequency for a fixed temperature T .

The heat capacity decreases smoothly with decreasing temperature from its classical value (43.6) down to zero. Thus, the vanishing of the vibrational

Fig. III.25

Fig. III.26

heat capacity (the “freezing” of oscillations mentioned in §39) appears in the most direct and natural way in considering the properties of a molecule as a quantum oscillator.

At low temperatures the vibrational frequency ν turns out to be relatively very large in comparison with kT/h . There corresponds to a high frequency a great rigidity of the bond between the two atoms. With decreasing temperature the increase of the relative rigidity leads to a progressive damping of oscillations.

So that one may have an idea of the order of magnitude of the quantities and, in particular, that of the characteristic temperatures of different molecules, we give in table 5 the corresponding values for a number of molecules. The values of the natural vibrational frequencies of the molecules are found from spectroscopic data.

Table 5

Molecule	Characteristic temperature (10^3 K)	Molecule	Characteristic temperature (10^3 K)
H ₂	6.0	HCl	4.14
N ₂	3.34	HBr	3.7
O ₂	2.23	HI	3.2
CO	3.07		

From table 5 the following conclusion, important from the practical point of view, can be drawn directly: since the characteristic temperatures of vibrational motion for all the molecules are of the order of several thousand degrees, a temperature of the order of 300 K corresponds to the limiting case $T \ll T_c$. Hence the vibrational heat capacity is very small for most molecules at room temperature. For example, in the case of HI at 640 K a calculation according to the general formula (43.4) shows that the vibrational heat capacity amounts to about $0.33 \text{ J mol}^{-1} \text{ K}^{-1}$. In most cases of practical importance at not very high temperatures it can be assumed that the vibrational motion is damped and that its contribution to the heat capacity is zero. In any case it is substantially smaller than that to be expected from the law of equipartition. The vibrational part of the heat capacity depends on the temperature and is different for molecules of different substances.

We now consider the calculation of other thermodynamic quantities. The free energy due to the vibrational motion has the form

$$\begin{aligned} F_{\text{vib}} &= -NkT \ln z_{\text{vib}} = \frac{1}{2}Nh\nu + NkT \ln(1 - e^{-h\nu/kT}) = \\ &= \frac{1}{2}NkT_c + NkT \ln(1 - e^{-T_c/T}). \end{aligned} \quad (43.9)$$

Correspondingly, the entropy is

$$\begin{aligned} S_{\text{vib}} &= -\frac{\partial F_{\text{vib}}}{\partial T} = -Nk \ln(1 - e^{-h\nu/kT}) + \frac{Nh\nu}{T} \frac{1}{e^{h\nu/kT} - 1} = \\ &= Nk \left(\frac{T_c}{T} \right) \frac{1}{e^{T_c/T} - 1} - Nk \ln(1 - e^{-T_c/T}). \end{aligned} \quad (43.10)$$

At high temperatures one can carry out the expansion in powers of the ratio T_c/T and confine oneself to the first terms of the expansion. This gives

$$F_{\text{vib}} \approx E_0 + NkT \ln(T_c/T),$$

$$S \approx Nk - Nk \ln(T_c/T).$$

On the contrary, at low temperatures $e^{-T_c/T} \ll 1$, so that

$$F_{\text{vib}} \approx E_0, \quad S_{\text{vib}} \approx 0.$$

For the practical calculation of the partition function of the vibrational

Fig. III.27

motion and the thermodynamic quantities it is necessary to know a characteristic molecular constant: the natural vibrational frequency ν of the molecule. Its value for most diatomic molecules is known from spectroscopic data, in particular from infrared vibrational spectra.

The values of the functions involved in formulae (43.3), (43.4), (43.9) and (43.10) are tabulated and are found directly from tables. Their dependence on the ratio $h\nu/kT$ is shown in fig. III.27.

§44. The rotational partition function and the contribution of rotation to thermodynamic functions

We shall consider now the partition function for the rotational motion of a diatomic molecule.

The energy of the rotator takes on a discrete series of values

$$\epsilon_{\text{rot}} = \frac{h^2}{8\pi^2 I} J(J+1), \quad (44.1)$$

where $J = 0, 1, 2, 3, \dots$

Each state with a definite rotation energy, i.e. with a definite value of the rotation quantum number, turns out to be $(2J+1)$ -fold degenerate. Hence the partition function of the rotational motion has the form

$$z_{\text{rot}} = \sum_{J=0}^{\infty} (2J+1) \exp\left(-\frac{h^2 J(J+1)}{8\pi^2 I k T}\right) \quad (44.2)$$

The partition function z_{rot} depends on the ratio $h^2/8\pi^2 I k T = T_c/T$, where $T_c = h^2/8\pi^2 I k$ is the characteristic temperature for the rotation. Thus,

$$z_{\text{rot}} = \sum_{J=0}^{\infty} (2J+1) \exp\left(-\frac{T_c J(J+1)}{T}\right). \quad (44.3)$$

Table 6 gives the values of the characteristic temperatures for the rotation of different diatomic molecules.

Table 6

Molecule	Characteristic temperature (K)	Molecule	Characteristic temperature (K)
H ₂	85.4	O ₂	2.07
D ₂	43	HCl	15.1
N ₂	2.85	HI	9.0

From table 6 it is seen that, in contrast to the characteristic temperatures for the vibrational motion, the characteristic temperatures for the rotational motion are extremely small and lie considerably below the condensation point of a gas at normal pressure. Exceptions to the rule are the molecules H₂ and D₂, for which the characteristic temperatures are relatively large and lie above the condensation temperatures. The high characteristic temperatures of H₂ and D₂ are due to the smallness of their moments of inertia ($I(\text{H}_2) = \frac{1}{2}m_{\text{H}}a^2$ and $I(\text{D}_2) = \frac{1}{2}m_{\text{D}}a^2$, where m_{H} and m_{D} are the masses of the proton and deuteron, and a is the distance between them in the molecules). Hence for all molecules, except H₂ and D₂, it can be assumed that the spacing between two successive rotational energy levels is small in comparison with the thermal energy. In other words, the temperature is always high with respect to the rotation of heavy molecules.

For high temperatures the summation over individual energy levels in (44.3) can be replaced by integration over the almost continuous levels:

$$\begin{aligned}
 z_{\text{rot}} &= \sum (2J+1) \exp\left(-\frac{T_c J(J+1)}{T}\right) \approx \\
 &\approx \int_0^{\infty} (2J+1) \exp\left(-\frac{T_c J(J+1)}{T}\right) dJ.
 \end{aligned}
 \quad (44.4)$$

Introducing a new integration variable, $y = J(J+1)$, we find

$$z_{\text{rot}} = \int_0^{\infty} \exp\left(-\frac{T_c y}{T}\right) dy = \frac{T}{T_c} = \frac{8\pi^2 I k T}{h^2}. \quad (44.5)$$

We thus arrive at the classical expression for z_{rot} .

In the next approximation the partition function can be calculated by means of the well-known Euler summation formula*:

$$\sum_{J=0}^{\infty} f(J) \approx \int_0^{\infty} f(x) dx + \frac{1}{2}f(0) - \frac{1}{12}f'(0) + \frac{1}{720}f'''(0).$$

In the given case $f(J) = (2J+1) \exp[-T_c J(J+1)/T]$, so that

$$f(0) = 1; \quad f'(0) = 2 - (T_c/T); \quad f'''(0) \approx -12 T_c/T$$

and for z_{rot} we obtain

$$z_{\text{rot}} \approx \frac{8\pi^2 I k T}{h^2} + \left(\frac{1}{3} + \frac{h^2}{15 \times 8\pi^2 I k T} \right). \quad (44.6)$$

The second and third terms represent the quantum correction to the classical value of z_{rot} . From formula (44.6) it is seen that this correction is small at a temperature T higher than T_c , and that it decreases rapidly with increasing T .

Taking into account the quoted values of the characteristic temperatures, it can be said that the entire range of realistic temperatures lies much higher

* See, for example, A. Gelfond, *Ischislenie konechnykh raznostei (Calculation of finite differences)*, (Gostekhizdat, Moscow, 1952) p. 343. H. Margenau and G. M. Murphy, *Mathematics of physics and chemistry* (D. Van Nostrand, New York, 1948).

than T_c . Hence the quantum corrections to z_{rot} for all except the lightest molecules, play a negligible role.

For low temperatures ($T \ll T_c$) in the general expression for z_{rot} only the first, that is the largest terms should be retained. This gives

$$z_{\text{rot}} \approx 1 + 3 \exp(-2T_c/T). \quad (44.7)$$

Now we find the terms of the thermodynamic functions associated with the rotational motion. Obviously, we have

$$\begin{aligned} E_{\text{rot}} &= NkT^2 \frac{\partial \ln z_{\text{rot}}}{\partial T} = \\ &= NkT^2 \frac{\partial}{\partial T} \ln \sum_{J=0}^{\infty} (2J+1) \exp\left(-\frac{T_c J(J+1)}{T}\right). \end{aligned} \quad (44.8)$$

For high temperatures we have

$$E_{\text{rot}} \approx NkT \left(1 - \frac{h^2}{24\pi^2 I k T}\right). \quad (44.9)$$

Correspondingly, the rotational heat capacity at high temperatures has the classical value:

$$C_{V_{\text{rot}}} \approx Nk. \quad (44.10)$$

At low temperatures

$$\begin{aligned} E_{\text{rot}} &= NkT^2 \frac{\partial}{\partial T} \ln \left[1 + 3 \exp\left(-\frac{h^2}{4\pi^2 I k T}\right) \right] \approx \\ &\approx \frac{3h^2 N}{4\pi^2 I} \exp\left(-\frac{h^2}{4\pi^2 I k T}\right) \end{aligned} \quad (44.11)$$

and the heat capacity is

$$C_{V_{\text{rot}}} \approx 3 \left(\frac{h^2}{4\pi^2 I} \right)^2 \frac{N}{kT^2} \exp\left(-\frac{h^2}{4\pi^2 I k T}\right). \quad (44.12)$$

Thus, at very low temperatures the rotation energy and heat capacity turn out to decrease exponentially with the temperature. As we have stressed before, the decrease of the heat capacity with the temperature according to the exponential law can be observed only for the lightest molecules.

We write, in addition, the expressions for the free energy and entropy. At high temperatures

$$F_{\text{rot}} = -NkT \ln z_{\text{rot}} = -NkT \ln \left[\sum_{J=0}^{\infty} (2J+1) \exp \left(-\frac{T_c J(J+1)}{T} \right) \right] \approx \\ \approx NkT \left(\ln \frac{T_c}{T} - \frac{T_c}{3T} \right) \quad (44.13)$$

and

$$S_{\text{rot}} \approx -Nk \ln \frac{T_c}{T} + Nk. \quad (44.14)$$

At low temperatures, taking into account (44.7), we obtain

$$F_{\text{rot}} \approx -3NkT \exp(-2T_c/T) \quad (44.15)$$

and

$$S_{\text{rot}} \approx 3Nk \exp(-2T_c/T) + \frac{6NkT_c}{T} \exp(-2T_c/T). \quad (44.16)$$

Thus, the rotational energy and entropy decrease exponentially at very low temperatures. The general form of the heat capacity associated with rotation has the same character as that of the heat capacity associated with the vibrations of the molecules: at high temperatures the heat capacity tends to the classical value, while at low temperatures, in accordance with the requirements of the third law of thermodynamics, the heat capacity tends to zero. However, the notions of high and low temperature for rotations and vibrations turn out to be fundamentally different: for vibrations room temperature, as a rule, should be considered low, whereas for rotations it should be considered high.

As is seen from formulae (44.8), (44.12) and the subsequent formulae, it is necessary to know only one molecular constant, the moment of inertia I of the molecule, for the actual calculation of the partition function and thermodynamic quantities. The value of this quantity is known for most diatomic

molecules from spectroscopic data, in particular from infrared rotational spectra. If the rotational-vibrational spectrum of the molecule, i.e. the energy levels of its rotational and vibrational motions are known, then the calculation of the partition functions can be carried out by means of a direct summation *.

In conclusion we note that in the case of hydrogen and deuterium it is necessary to take into account the effect of the nuclear spin on the rotational motion. It turns out that the nuclear spin fundamentally affects the character of the rotational states of molecules consisting of identical atoms. In particular, depending on the value of the nuclear spin the molecules of hydrogen can be in rotational states of two types.

In states of the first type, corresponding to the total spin of the two nuclei being equal to zero, the rotational quantum number J runs over a series of even values $J = 0, 2, 4, 6, \dots$. In states of the second type, corresponding to the total spin of the two nuclei being equal to unity, the quantum number runs over a series of odd values $J = 1, 3, 5, \dots$.

Molecules of the first type are called *parahydrogen*, and those of the second type are called *orthohydrogen*. In normal conditions there are no transitions between orthohydrogen and parahydrogen, so that the gas as a whole must be considered as a mixture of the two different types.

This fact affects the form of the calculated thermodynamic functions ** in an essential way.

§45. Polyatomic molecules

The consideration of polyatomic molecules differs little in principle from that of diatomic molecules. The partition function of a polyatomic molecule, like that of a diatomic molecule, can be written in the form

$$Z = Z_{\text{transl}} Z_{\text{vib}} Z_{\text{rot}}, \quad (45.1)$$

provided the effect of the vibrations on the rotation of the molecule (in connection with the change in the size of the latter) is disregarded. The parti-

* For more detail see I.N.Godnev, *Vychislenie termodinamicheskikh funktsii po molekularnym dannym* (Calculation of thermodynamic functions from molecular data) (Gostekhizdat, Moscow, 1956). A.H.Wilson, *Thermodynamics and statistical mechanics* (Cambridge University Press, Cambridge, 1957).

** See, for example, L.D.Landau and E.M.Lifshitz, *Course in theoretical physics*, Volume 5, *Statistical physics* (Pergamon Press, London, 1958).

tion function of the translational motion differs in no way from that calculated before. However, the calculation of the partition function of the internal motion of polyatomic molecules is incomparably more complicated than for diatomic molecules.

In considering the rotational motion of a molecule it is necessary to distinguish between three cases: the linear molecule, the symmetric top, and the asymmetric top. The rotational motion of a linear polyatomic molecule does not differ from that of a diatomic molecule. For a symmetric top two major moments of inertia are equal to each other ($I_1 = I_2 \neq I_3$), whereas for an asymmetric top all moments of inertia differ from each other ($I_1 \neq I_2 \neq I_3$). In the first case quantum-mechanical considerations allow one to calculate the rotational energy levels of the molecule, which are expressed by a formula similar to that for the energy levels of a simple top. However, there is no explicit expression for the energy levels of an asymmetric top. In the case of molecules of the type of asymmetric tops use is usually made of certain approximate expressions for the energy levels, the accuracy of which is not very great. However, the situation is made substantially simpler by the fact that the characteristic temperatures for the rotation of polyatomic molecules are, as a rule, even lower than those for diatomic molecules. Hence the ordinary temperatures at which one can work with non-condensed polyatomic gases are relatively high, and for the partition function of the rotational motion use can be made, without any appreciable error, of the classical expression for z_{rot} . Thus, for example, the difference between the quantum and classical expression for the rotational state function for the HCN molecule at a temperature of 100 K amounts to about 0.5%, and for the CH_3Cl molecule it amounts to about 1%. At a temperature of 300 K this difference becomes quite negligible, and lies beyond the limits of accuracy of the measurements. In most calculations of the partition function of polyatomic molecules use is made of the classical approximation.

A characteristic feature of a large number of polyatomic molecules, in particular the molecules of organic compounds, is the presence of a certain number of identical atoms in them. The symmetry of a molecule is closely associated with the presence of identical atoms in the molecule. Because of the presence of symmetry the molecule can be matched with itself in definite rotations, just as a diatomic molecule containing two identical atoms matches with itself when rotated through 180° . The presence of symmetry in the molecule requires the introduction of a symmetry factor γ into the rotational partition function. A symmetry factor $\gamma = 2$ should also be introduced for diatomic molecules with identical nuclei. It represents the number of physically indistinguishable positions of the molecule when it rotates as a

rigid body. To obtain a correct expression for the rotational partition function, in which each physical state would be taken into account only once, the partition function obtained in integrating over all values of the angle of rotation (in the classical approximation) must be divided by the symmetry factor γ . With the introduction of the symmetry factor the rotational partition function of a polyatomic molecule with three different moments of inertia in the classical approximation can be written in the following form:

$$z_{\text{rot}} = \frac{\pi^{\frac{1}{2}}}{\gamma h^3} [8\pi^2(kT)^3 I_1 I_2 I_3]^{\frac{1}{2}}, \quad (45.2)$$

where the moments of inertia are expressed in $\text{g}\cdot\text{cm}^2$, and the temperature is measured on the absolute scale. If the structure of the molecule is known, then the values of the factor γ are found from simple considerations of the symmetry. In the case of the linear molecule CO_2 (see fig. III.19) the factor of symmetry is $\gamma = 2$, so that the molecule is matched with itself when rotated through the angle π . The non-linear molecule SO_2 (fig. III.19) is also matched with itself when rotated through the angle π , and so for it $\gamma = 2$. The methane molecule CH_4 represents a regular tetrahedron with the carbon atom in the centre. It is matched with itself when rotated through an angle of 120° about the vertical axis and when each of the four vertices of the tetrahedron are matched, all together in 12 rotations, so that $\gamma = 12$. The ammonia molecule NH_3 represents a pyramid with the nitrogen atom at the vertex. It is matched with itself when rotated through an angle of 120° about the vertical axis, so that $\gamma = 3$.

The vibrational motion of polyatomic molecules is also incomparably more complex than that of diatomic molecules. The number of vibrational degrees of freedom amounts to $3n - 6$ for non-linear polyatomic molecules and to $3n - 5$ for linear ones, and can be rather large for complex molecules. For example, the molecule SO_2 has three vibrational degrees of freedom, the molecule NH_3 already has six, and for the molecule C_6H_6 the number of vibrational degrees of freedom is equal to 30. The study of the vibrations of such systems is a complex problem. Nevertheless, the vibrational motion of a very large number of molecules has been investigated. If the departures of the atoms from the equilibrium position are assumed to be small (which is not always possible in the case of polyatomic molecules; see below), then the motion of the system will represent small vibrations and the vibrational motion of the molecule can be resolved into a set of independent normal

vibrations *. To each degree of freedom there corresponds one normal vibration with its natural frequency. The frequencies of the normal vibrations (the natural frequencies of the system) are connected with the masses of the nuclei and the constants of the quasi-elastic forces by the usual relations. In the general case the frequencies of all the normal vibrations are different. However, the frequencies of certain normal vibrations are often the same. In this case the vibrations are degenerate.

The values of the natural frequencies can be found from an analysis of infrared spectra as well as the dispersion spectra of the molecules, although this is not at all a simple problem. The spectra of a number of simpler molecules have been investigated in sufficient detail, and their natural frequencies have been determined with a high degree of accuracy. Fig. III.19 presents the normal vibrations of certain typical molecules (H_2O , SO_2 and CO_2). Each normal vibration with a natural frequency ν_l gives its contribution to the partition function z_{vib} which, by virtue of the independence of normal vibrations can be written in the form of the product of the corresponding factors:

$$z_{\text{vib}} = \prod_{l=1}^{3n-6} \frac{\exp(-h\nu_l/2kT)}{1 - \exp(-h\nu_l/kT)} = \prod_{l=1}^{3n-6} \frac{\exp(-T_c^{(l)}/2T)}{1 - \exp(-T_c^{(l)}/T)}, \quad (45.3)$$

where $T_c^{(l)}$ is the characteristic temperature of the l th normal vibration. The values of $T_c^{(l)}$ for different normal vibrations can differ considerably from each other. Thus, for example, the six normal oscillations of the ammonia molecule have the following characteristic temperatures $T_c^{(l)}$ (in 10^2 K): 13.6, 23.3, 23.3, 47.8, 48.8, 48.8. We see that characteristic temperatures can differ from each other by a factor of three. The difference between characteristic frequencies is associated with the difference between the constants of quasi-elastic forces (the difference in the rigidity of the atomic bonds in the molecules). The characteristic temperatures of polyatomic molecules, as well

* In arbitrary coordinates the potential energy of a system of vibrating points has the form

$$U = \frac{1}{2} \sum a_{ik} \xi_i \xi_k,$$

where ξ are the displacements. To find the normal vibrations it is necessary to find the coordinates ξ_i such that the potential energy of the system has the orthogonal quadratic form $U = \frac{1}{2} \sum a_j \xi_j^2$. The choice of new variables can be made in a purely algebraic way, but is simplified essentially if use is made of the symmetry properties of the system (see, for example, L.D. Landau and E.M. Lifshitz, *Mechanics* (Pergamon Press, Oxford, 1960).

as those of diatomic molecules, amount to several hundred or thousand degrees. Hence the contribution of vibrations to the heat capacity at moderate temperatures is relatively small. In any case, the vibrational part of the heat capacity is many times smaller than that to be expected from the law of equipartition.

As an example one can consider the ammonia molecule. The total heat capacity of the molecule NH_3 amounts to

$$C_V = C_{V_{\text{transl}}} + C_{V_{\text{rot}}} + C_{V_{\text{vib}}} = \\ = \frac{3}{2} + \frac{3}{2} + C_{V_{\text{vib}}} \quad (\text{in units of } Nk).$$

Table 7 gives the values (in $\text{J mol}^{-1} \text{ deg}^{-1}$) of the vibrational heat capacity $C_{V_{\text{vib}}}$ calculated according to (45.3) and observed experimentally.

Table 7

T (K)	$C_{V_{\text{vib}}}$ (calc.)	$C_{V_{\text{vib}}}$ (exper.)	T (K)	$C_{V_{\text{vib}}}$ (calc.)	$C_{V_{\text{vib}}}$ (exper.)
243	0.50	0.59	423	2.93	3.14
273	0.80	0.92	582	5.48	5.02
303	1.21	1.30	655	7.20	6.28
334	1.55	1.88	796	8.62	7.95
383	2.34	2.51			

For $T > 240 \text{ K}$ the rotational heat capacity can be assumed to have the classical value $\frac{3}{2}$. Thus, at a temperature of about 800 K the vibrational heat capacity amounts to about $\frac{2}{3}$ of the total heat capacity of the molecule and can in no way be disregarded. Even at room temperature $C_{V_{\text{vib}}}$ amounts to about 7% of the total heat capacity. Nevertheless, it is considerably smaller than that to be expected from the law of equipartition ($6Nk$). Such a situation is characteristic of most polyatomic molecules.

The contribution of different forms of motion to the value of the entropy of the ammonia molecule is shown in fig. III.28.

The vibrational motion of polyatomic molecules has a remarkable feature which has no analogue for diatomic molecules. Namely, very often the amplitude of zero-point vibrations of definite groups contained in the molecule turns out to be so large that the corresponding motion ceases to be harmonic or loses completely its vibrational character. This is seen most clearly by concrete examples. A large number of polyatomic molecules, in particular

Fig. III.28

Fig. III.29

organic ones, contain individual groups or radicals having the character of independent groups; for example, the ethylene molecule C_2H_4 represents a combination of two CH_2 groups. Similarly the ethane molecule C_2H_6 consists of two CH_3 groups. The dimethylacetylene molecule $CH_3-C\equiv C-CH_3$ contains two CH_3 groups and a carbon core. Owing to the existence of interaction between the hydrogen atoms the potential energy of each of the CH_2 or CH_3 groups has a minimum for a definite orientation of one group with respect to the other. That is, to the minimum of the potential energy there corresponds a value of the angle of rotation (measured from the median line) of one CH_3 group with respect to the other equal to 60° or 180° . In other words, the potential energy has a minimum when the two groups are situated as an object and its mirror image (fig. III.29). When a displacement from the equilibrium position occurs (a rotation of one of the groups with respect to the other) the potential energy increases and there arises a force tending to bring the molecule back to the equilibrium arrangement. Then rotational oscillations about the axis of the molecule arise. If, however, the zero-point energy of these oscillations is so large that it exceeds the potential barrier hindering the group from rotation, the rotational oscillations turn over into a free rotation of the group with respect to the axis of the molecule. The latter case is encountered relatively seldom. The dimethylacetylene molecule quoted above serves as an example of it. In this molecule the two CH_3 groups are a relatively large distance apart, and their interaction is not very large. Hence the height of the barrier preventing a rotation turns out to be relatively small, and the CH_3 groups rotate freely. However, in most cases the rotation of individual groups is hindered. At low temperatures rotational oscillations

of a large amplitude take place, which turn over into a rotation at very high temperatures, when the thermal energy kT proves to be higher than the barrier height U_0 . The existence of free rotation changes the value of the heat capacity and other thermodynamic quantities in comparison with that for molecules without rotations: a part of the vibrational degrees of freedom is replaced by rotational ones. If the rotation is assumed to be free, then the calculation of the heat capacity and other thermodynamic quantities presents no difficulty, since the rotation of a relatively heavy group can be assumed to be classical. But if the rotation is hindered, then it is necessary to know for the calculation the height of the barrier hindering the rotation. Finding this height from spectroscopic data is very difficult. Hence one proceeds in the reverse order: one calculates thermodynamic quantities, most often the entropy, by assuming different values of the height of the barrier, and compares the calculated and measured values. The matching of the theoretical and experimental curve of the dependence of the entropy on the temperature allows one to find the height of the barrier. For different molecules the height of the barrier varies within a rather wide range. Thus, for the rotation of the CH_3 group in the ethane molecule $\text{H}_3\text{C}-\text{CH}_3$ the height of the barrier amounts to about 1570 K, so that the rotation at a temperature $T > 1570$ K is free. For the ethylene molecule C_2H_4 the barrier hindering the CH_2 groups from rotation has a height of about 6000 K, so that the rotation at room temperature is strongly hindered and there take place rotational oscillations of a relatively small amplitude.

Systems of Interacting Particles

§46. Interaction between molecules in non-ideal gases

Up to now we have restricted ourselves to the study of the properties of gases so rarefied that the interaction between the molecules may be disregarded. We now pass on to the consideration of the statistical behaviour of systems of interacting particles.

In §6 we have touched already upon the problem of the character of the intermolecular interaction. At large distances between molecules this interaction reduces to a weak attractive force which decreases rapidly with increasing distance between the centres of the molecules. At small distances, when molecules approach each other closely, so that a mutual penetration of their electron shells takes place, a very strong repulsion arises. Owing to this repulsion the molecules cannot penetrate very much into each other, and they cannot get deformed in collisions. In what follows we shall confine ourselves to a monatomic gas, and shall assume that the interaction depends only on the distance between the atoms.

The form of the potential energy of the interaction between two molecules is shown in fig. III.30. We shall assume that the attractive forces are so weak that the largest value of the potential energy of attraction occurs when the molecules approach closely (the distance between the centres is

equal to the diameter d). But $|u(d)|$ is nevertheless small in comparison with the thermal energy kT ,

$$|u(d)| \ll kT. \quad (46.1)$$

The potential energy decreases so rapidly with increasing distance that it is practically reduced to zero at distances between the centres of the molecules amounting to only a few diameters. We formally introduce a certain distance ρ such that beyond it the interaction can be completely disregarded. We shall call this distance the radius of interaction. This means that we replace the true potential energy curve by the simplified curve shown by a dotted line in fig. III.30 and expressed by the formulae

$$u = \begin{cases} 0, & r \geq \rho, \\ -u(r), & \rho > r > d, \\ \infty, & d \geq r. \end{cases} \quad (46.2)$$

Here r denotes the distance between the centres of the i th and k th molecules. This means that the interaction is absent when the distance between the centres of the molecules exceeds ρ , represents an attraction [negative value of $u(r)$] when the distance between the centres is smaller than ρ but larger than d , so that the molecules do not directly touch each other, and turns into a very strong repulsion (infinitely strong in our approximation)

Fig. III.30

when the molecules come into direct contact. The value of ρ is as a rule equal to three or four molecular diameters.

If the gas is not very dense, then the mean distance between the molecules is very large in comparison with their dimensions. Hence it can as a rule be assumed that not more than two molecules approach each other to within the distance of interaction at once. In other words, it can be assumed that the molecules interact only in pairs. Configurations in which a "cluster" of three, four, or more particles are found simultaneously in the sphere of interaction are seldom encountered, and we shall disregard them.

We calculate the partition function of the gas in this condition. The energy ϵ of the entire gas can be written in the form

$$\epsilon = \epsilon_{\text{kin}} + U. \quad (46.3)$$

The first term in (46.3) expresses the sum of the kinetic energies of the molecules. It is the same as the energy of an ideal gas. The second term represents the potential energy of interaction of the molecules, depending only on their mutual distances. Making use of this expression for ϵ , one can write the partition function of the gas in the form

$$Z = \frac{1}{N!h^{3N}} \left(\int e^{-p^2/2mkT} dp_x dp_y dp_z \right)^N \left(\int e^{-U/kT} dV_1 \dots dV_N \right), \quad (46.4)$$

where $dV_1 \dots dV_N$ is the product of the differentials of the space coordinates $dx dy dz$ for every one of the molecules. The first factor does not differ from the corresponding quantity for an ideal gas. By virtue of the results of §37 it can be written in the form

$$\int e^{-p^2/2mkT} dp_x dp_y dp_z = (2\pi mkT)^{\frac{3}{2}},$$

so that

$$Z = \frac{1}{N!h^{3N}} (2\pi mkT)^{\frac{3}{2}N} \left(\int e^{-U/kT} dV_1 \dots dV_N \right). \quad (46.5)$$

Here we have to calculate the second factor, called the configuration integral:

$$I = \int e^{-U/kT} dV_1 dV_2 \dots dV_N. \quad (46.6)$$

To do this we make use of the assumption that the molecules interact with one another only in pairs. Hence the energy of interaction can be written in the form of the sum of the energies of interaction of the molecular pairs

$$U = \sum u(r_{ik}), \quad (46.7)$$

where a pair is understood to be two molecules which are at a distance smaller than the radius of interaction ρ . The energy of interaction of each pair is denoted by u . It is determined by formula (46.2). The number of terms in the sum (46.7) is equal to the number of pairs formed in a gas of N molecules. It is equal to the number of combinations of N elements in twos, i.e. to $\frac{1}{2}N(N-1)$. For large N this number can be assumed to be equal to $\frac{1}{2}N^2$. Then

$$\exp\left(-\frac{U}{kT}\right) = \exp\left(-\frac{\sum u(r_{ik})}{kT}\right) = \prod_i \exp\left(-\frac{u(r_{ik})}{kT}\right),$$

where the product is taken over all the pairs, i.e.

$$\exp\left(-\frac{U}{kT}\right) = \exp\left(-\frac{u(r_{12})}{kT}\right) \exp\left(-\frac{u(r_{13})}{kT}\right) \dots \quad (46.8)$$

This product contains $\frac{1}{2}N^2$ factors. Each term in this product tends to unity when $r_{ik} > \rho$, since $u(r_{ik}) \rightarrow 0$. It is more convenient to introduce a function f_{ik} defined by

$$f_{ik} = \exp\left(-\frac{u(r_{ik})}{kT}\right) - 1, \quad (46.9)$$

which tends to zero when $r_{ik} > \rho$ and differs from zero only when $r_{ik} < \rho$. Then, obviously, $e^{-u(r_{ik})/kT} = 1 + f_{ik}$, and

$$\begin{aligned} e^{-U/kT} &= \prod (1+f_{ik}) = \\ &= (1+f_{12})(1+f_{13})(1+f_{14}) \dots = \\ &= 1 + (f_{12}+f_{13}+f_{14}+\dots) \\ &\quad + (f_{12}f_{13}+f_{12}f_{14}+\dots) + \dots \end{aligned} \quad (46.10)$$

Indeed, the double, triple and so on products of the function f_{ik} are, by definition of this function and by virtue of the assumption of the absence of clusters, always very small. Thus, for example, in order that $f_{12}f_{13}$ may differ substantially from zero it is necessary that f_{12} and f_{13} should at the same time be different from zero, i.e. that the distances r_{12} and r_{13} should at the same time be small (smaller than ρ). This means that the first, second and third molecules simultaneously come into the range of interaction ρ , forming not a pair but a triplet of molecules. Similarly $f_{12}f_{13}f_{14}$ differs from zero only if f_{12} , f_{13} and f_{14} are not at the same time equal to zero. This happens only when the first, second, third and fourth molecules simultaneously get into a region of the order of ρ . Hence with a sufficient degree of accuracy it can be written that

$$e^{-U/kT} \approx 1 + (f_{12} + f_{13} + \dots) = 1 + \sum f_{ik}. \quad (46.11)$$

The number of terms in $\sum f_{ik}$ is equal to the number of pairs, i.e. to $\frac{1}{2}N^2$. Since all the molecules are identical, it can be assumed that all f_{ik} are the same, so that

$$e^{-U/kT} \approx 1 + \frac{1}{2}N^2 f(r_{ik}). \quad (46.12)$$

Substituting the expression $e^{-U/kT}$ from (46.12) into (46.6), we have

$$\begin{aligned} I &= \int e^{-U/kT} dV_1 \dots dV_N = \int (1 + \frac{1}{2}N^2 f_{ik}) dV_1 \dots dV_N = \\ &= \int dV_1 \dots dV_N + \frac{1}{2}N^2 \int f_{ik} dV_1 \dots dV_N. \end{aligned} \quad (46.13)$$

The first integral in (46.13) is obviously equal to V^N . In the second integral the integration over all volume elements except the i th and k th gives

$$\begin{aligned} \int dV_1 \dots dV_{i-1} dV_{i+1} \dots dV_{k-1} dV_{k+1} \dots dV_N \int f_{ik} dV_i dV_k = \\ = V^{N-2} \int f_{ik} dV_i dV_k. \end{aligned}$$

Thus,

$$I = V^N + \frac{1}{2}N^2 V^{N-2} \int f_{ik} dV_i dV_k.$$

To carry out the last integration we introduce spherical coordinates with the centre located at one of the molecules. Then $r_{ik} = r$, and

$$\begin{aligned}\int f_{ik} dV_i dV_k &= \int \left[\exp \left(-\frac{u(r_{ik})}{kT} \right) - 1 \right] dV_i dV_k = \\ &= \int dV \int \left[\exp \left(\frac{u(r)}{kT} \right) - 1 \right] 4\pi r^2 dr ,\end{aligned}$$

where 4π is the result of integration with respect to the angles. Hence, writing

$$4\pi \int \left[\exp \left(-\frac{u(r)}{kT} \right) - 1 \right] r^2 dr = \beta , \quad (46.14)$$

we obtain

$$\int f_{ik} dV_i dV_k = V\beta .$$

For I the final expression is the following:

$$I = V^N \left(1 + \frac{N^2}{2V} \beta \right) . \quad (46.15)$$

Substituting the expression (46.15) for I into (46.5), we have

$$Z = \frac{(2\pi mkT)^{\frac{3}{2}N} V^N}{N! h^{3N}} \left(1 + \frac{N^2 \beta}{2V} \right) = Z_{\text{id}} \left(1 + \frac{N^2 \beta}{2V} \right) , \quad (46.16)$$

where Z_{id} denotes the partition function of the ideal monatomic gas. It should be noted that the value of $N^2 \beta / 2V = NV^{-1} \cdot \frac{1}{2} N \beta$ is small for a small gas density NV^{-1} .

By means of the partition function (46.16) one can calculate the thermodynamic functions of a gas which departs slightly from an ideal gas. We shall restrict ourselves to the calculation of the pressure, since the equation of state of a gas is of very great interest.

The departure of a gas from an ideal gas is taken into account by means of the van der Waals equation, which for small gas densities can be written in the form

$$p = \frac{NkT}{V - Nb} - \frac{N^2 a}{V^2} \approx \frac{NkT}{V} + \frac{N^2 kTb}{V^2} - \frac{N^2 a}{V^2} . \quad (46.17)$$

Since in the course of the calculations of the preceding paragraph we have not taken into account "clusters", the results obtained hold for small gas densities. A simple calculation of the pressure, based on the partition function (46.16), leads to an expression which is exactly the same as (46.17). Indeed, according to (32.5) the pressure p is equal to

$$\begin{aligned} p &= kT \frac{\partial \ln Z}{\partial V} = kT \frac{\partial \ln Z_{id}}{\partial V} + kT \frac{\partial}{\partial V} \ln \left(1 + \frac{N^2 \beta}{2V} \right) \approx \\ &\approx p_{id} + kT \frac{\partial}{\partial V} \left(\frac{N^2 \beta}{2V} \right) = \frac{NkT}{V} - \frac{N^2 kT \beta}{2V^2}. \end{aligned} \quad (46.18)$$

Here, assuming the density to be small, we have expanded the logarithm in a series in powers of the quantity $N^2 \beta / 2V$ which is very small in comparison with unity, and have confined ourselves to the first term of the expansion.

Comparing formula (46.18) with (46.17) we convince ourselves of their complete identity provided we assume

$$\frac{1}{2} \beta = \frac{a}{kT} - b. \quad (46.19)$$

Thus, formula (46.18) represents the van der Waals equation, derived theoretically for small gas densities. The foregoing calculation refers to the case of monatomic gases. It can, however, also be shown that in the case of complex polyatomic gases the qualitative aspect of the derivation is not changed, although the explicit form of the quantity β will be more complicated.

To explain the meaning of the constants a and b occurring in the van der Waals equation, we shall consider in detail the quantity β .

By definition,

$$\beta = 4\pi \int_0^\infty f(r) r^2 dr. \quad (46.20)$$

Substituting the expression for $f(r)$ into (46.20), we have

$$\beta = 4\pi \int_0^\infty \left[\exp \left(-\frac{u(r)}{kT} \right) - 1 \right] r^2 dr. \quad (46.21)$$

We divide the integral (46.21) into two parts: the integral in the interval $0 \leq r \leq d$ and the integral in the interval $d \leq r \leq \infty$, i.e.

$$\beta = 4\pi \int_0^d \left[\exp\left(-\frac{u(r)}{kT}\right) - 1 \right] r^2 dr + 4\pi \int_d^\infty \left[\exp\left(-\frac{u(r)}{kT}\right) - 1 \right] r^2 dr.$$

In the first interval, by virtue of (46.2), $e^{-u(r)/kT} \approx 0$, and thus in the first integral the exponential term can be dropped. In the second integral the potential energy of interaction of the molecules is, by virtue of (46.1), small in comparison with the thermal energy kT , so that it can be written approximately that

$$\exp\left(-\frac{u(r)}{kT}\right) \approx 1 - \frac{u(r)}{kT} = 1 + \frac{|u(r)|}{kT}.$$

We then have

$$\beta = -4\pi \int_0^d r^2 dr + \frac{4\pi}{kT} \int_d^\infty |u(r)| r^2 dr = -\frac{4\pi}{3} d^3 + \frac{4\pi}{kT} \int_d^\infty |u(r)| r^2 dr.$$

Substituting β into (46.19), we obtain

$$-\frac{2\pi d^3}{3} + \frac{2\pi}{kT} \int_d^\infty |u(r)| r^2 dr = \frac{a}{kT} - b. \quad (46.22)$$

Equating in (46.22) the coefficients of T^{-1} and the constant terms, we find

$$b = \frac{2}{3}\pi d^3 = 4v_0, \quad (46.23)$$

where v_0 is the volume occupied by the molecule. Thus, the constant b in the van der Waals equation turns out to be equal to the volume of the molecule multiplied by four. Further,

$$a = \frac{1}{2} \cdot 4\pi \int_d^\infty |u(r)| r^2 dr.$$

The constant a is expressed in terms of the integral of the potential energy of interaction of two molecules. Since the function $u(r)$ rapidly decreases with increasing distance between the molecules, this integral converges rapidly. Thus,

$$\beta = \frac{2a}{kT} - 8v_0. \quad (46.24)$$

Depending on the temperature, β can be positive or negative. At a sufficiently low temperature $\beta > 0$, while at a high temperature $\beta < 0$.

If the expressions which we have found for the constants a and b are substituted into the van der Waals equation, we then obtain

$$p = \frac{NkT}{V} \left(1 + \frac{4v_0N}{V} - \frac{2\pi N}{VkT} \int_d^\infty |u(r)|r^2 dr \right). \quad (46.25)$$

In the first approximation, when the gas density is so low that the probability of the simultaneous presence of three or more molecules in the sphere of interaction may be disregarded, the pressure in a non-ideal gas differs from that in an ideal gas by two terms. The first of these represents the ratio of four times the volume of all the molecules to the entire volume of the gas. The meaning of this (positive) correction to the pressure lies in the fact that it takes into account the volume of real molecules. In this approximation we cannot consider molecules as material points having no spatial extension.

The second correction to the pressure is negative and is in absolute value equal to the ratio

$$\frac{N^2}{2V} \left(\frac{4\pi}{V} \int_d^\infty |u(r)|r^2 dr \right).$$

This ratio also has a simple physical meaning. The quantity

$$\frac{1}{V} 4\pi \int_d^\infty |u(r)|r^2 dr = \bar{u}$$

represents the mean value of the potential energy of interaction of a pair of molecules. This mean value is taken over all possible distances between the molecules, i.e. over the entire volume available for the motion of the molecules. Then, obviously, $N^2\bar{u}/2V$ is the mean value of the energy of interaction of all pairs of molecules existing in a unit volume of the gas. The second correction thus characterizes the decrease in the pressure of gas molecules on the walls of the container due to their mutual attraction. This fact can be expressed in another way as follows: in the gas there exists an internal pressure due to the attraction of molecules.

As is well known, the van der Waals equation describes not only the properties of gases with a relatively low density but also those of very dense gases and even liquids. However, in this case it cannot be derived theoretically, and represents a purely empirical equation which should be considered as a

more or less successful extrapolation from the region of low densities. How this extrapolation is to be made is seen from eq. (46.17), if it is rewritten in the form

$$p = \frac{NkT}{V} \left(1 + \frac{Nb}{V} \right) - \frac{N^2a}{V^2}. \quad (46.26)$$

The equation is valid for $Nb/V \ll 1$, i.e. when the volume $4Nv_0$ occupied by all the molecules is very small in comparison with the volume of the gas.

If, however, the density of the gas increases, which can be characterized by a decrease in the volume V for a fixed N , then formula (46.26) loses its validity. It is physically clear that, if the gas is compressed to the limit of close packing of the molecules with the minimum gap between them, a correct formula for the pressure should point to an infinite increase in it. A further compression, associated with a deformation of the atoms, would be associated with enormous pressures which would be infinitely large in comparison with ordinary pressures in gases or liquids. From geometrical considerations it is clear that to the close packing of spherical molecules there corresponds a volume of the system equal to $4v_0N = Nb$. Consequently, a correct formula for the pressure should lead to indefinitely increasing values of p as $V \rightarrow Nb$. However, formula (46.26) does not have such a character. But if the factor $1 + NbV^{-1}$ is considered as a result of the expansion in a series of the quantity $(1 - NbV^{-1})^{-1}$, then we obtain immediately the following formula for the pressure:

$$p = \frac{NkT}{V(1 - NbV^{-1})} - \frac{N^2a}{V^2}, \quad (46.27)$$

which satisfies the required conditions:

- 1) p increases to infinity as $V \rightarrow Nb$,
- 2) for $V \gg Nb$ formula (46.27) goes over into the theoretical formula (46.17).

Formula (46.27) is the complete van der Waals equation which describes the state of gases over a wide range of densities. From the very character of the derivation it is clear, however, that this equation cannot have the important theoretical meaning which is possessed by eq. (46.17). For large gas densities the constants a and b no longer have an exact meaning, and can only approximately be considered as the characteristics of the volume of the molecules and their interaction. This is seen, in particular, from the fact that in order to obtain quantitative agreement of eq. (46.27) with experimental data one has to renounce the constancy of the quantities a and b and con-

sider them as functions of temperature. The inconvenience of this led many investigators to propose other empirical equations of state. Nevertheless, a great merit of the van der Waals equation is the fact that it gives qualitatively, in a very correct way, the behaviour of gases, and it contains indications about the transition of a gas into the liquid state and critical phenomena.

§47. The correlation function method and its application to the theory of dense gases and liquids

We have seen that a direct calculation of the configuration integral for a system of interacting particles turns out to be a rather complex procedure.

In connection with the attempt to create a statistical theory of liquids, different methods of approach to the consideration of the statistical properties of systems of interacting particles have recently been developed. The correlation function method developed by N.N. Bugoliubov and independently by Kirkwood and by Born and Green has proved to be one of the most effective.

In the correlation function method, the calculation of the configuration integral is replaced by finding a certain set of integro-differential equations interrelating a system of functions which characterize the mutual correlation in the spatial disposition of the particles.

We stress from the very beginning that the correlation function method is a direct consequence of Gibbs statistics. In what follows we shall be interested in the spatial distribution of a system of interacting particles.

Integrating the Gibbs distribution over all momenta, we find the expression for the probability of a given configuration of a system of particles:

$$dw_{\mathbf{r}} = \int_{\mathbf{p}} dw = I^{-1} e^{-U/kT} d\mathbf{r}_1 d\mathbf{r}_2 \dots d\mathbf{r}_N, \quad (47.1)$$

where I is the configuration integral:

$$I = \int e^{-U/kT} d\mathbf{r}_1 d\mathbf{r}_2 \dots d\mathbf{r}_N. \quad (47.2)$$

If $dw_{\mathbf{r}}$ is integrated over the coordinates of all the particles except one, then we obtain

$$dw_{\mathbf{r}}^{(1)} = \frac{d\mathbf{r}_1}{I} \int e^{-U/kT} d\mathbf{r}_2 \dots d\mathbf{r}_N. \quad (47.3)$$

It is obvious that $dw_{\mathbf{r}}^{(1)}$ represents the probability that particle no. 1 be in the volume element $d\mathbf{r}_1$ for any positions of all the other $N-1$ particles. This probability can be written in the form

$$dw_{\mathbf{r}}^{(1)} = \frac{\rho_1(\mathbf{r}_1)d\mathbf{r}_1}{V}, \quad (47.4)$$

where $\rho_1(\mathbf{r}_1)$ is the density of the probability that the particle be found in the volume element $d\mathbf{r}_1$ normalized to the volume of the system:

$$\frac{\rho_1(\mathbf{r}_1)}{V} = \frac{1}{I} \int e^{-U/kT} d\mathbf{r}_2 \dots d\mathbf{r}_N. \quad (47.5)$$

We shall call the function $\rho_1(\mathbf{r}_1)$ the ordinary distribution function.

Analogously, integrating the Gibbs distribution (47.1) over the coordinates of all the particles except the first and second, we obtain

$$dw_{\mathbf{r}}^{(1,2)} = \frac{d\mathbf{r}_1 d\mathbf{r}_2}{I} \int e^{-U/kT} d\mathbf{r}_3 \dots d\mathbf{r}_N = \frac{\rho_{12}(\mathbf{r}_1, \mathbf{r}_2) d\mathbf{r}_1 d\mathbf{r}_2}{V^2}, \quad (47.6)$$

so that

$$\frac{\rho_{12}(\mathbf{r}_1, \mathbf{r}_2)}{V^2} = \frac{\rho_{12}}{V^2} = \frac{1}{I} \int e^{-U/kT} d\mathbf{r}_3 \dots d\mathbf{r}_N. \quad (47.7)$$

The function ρ_{12} represents the density of the probability that the first particle is in the volume element $d\mathbf{r}_1$ and that the second particle is simultaneously in the volume element $d\mathbf{r}_2$ normalized to the volume of the system.

We shall call ρ_{12} the binary distribution function. Distribution functions of any order can be determined in an analogous way. For example, the distribution function of the m th order characterizes the probability that the first particle be in the volume element $d\mathbf{r}_1$, the second particle in the volume element $d\mathbf{r}_2$, the m th particle in the volume element $d\mathbf{r}_m$ for any positions of the other $N-m$ particles:

$$\frac{\rho_{12\dots m}(\mathbf{r}_1, \dots, \mathbf{r}_m)}{V^m} = \frac{1}{I} \int e^{-U/kT} d\mathbf{r}_{m+1} \dots d\mathbf{r}_N. \quad (47.8)$$

If we are interested in the properties of a system which depend on the position not of all but only several particles constituting the system, the distribu-

tion functions $\rho_{12\dots m}$ play the same role as the Gibbs distribution function for the system as a whole.

By means of distribution functions one can find the mean values of quantities which depend on the coordinates of the corresponding particles. For example

$$L(\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_n) = \int L(\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_n) \rho_{12\dots m}(\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_n) \frac{d\mathbf{r}_1 d\mathbf{r}_2 \dots d\mathbf{r}_n}{V^m}.$$

§48. Equations for correlation functions

At first sight it may seem that finding the distribution function of m th order which characterizes the spatial distribution of certain particles of a system must be simpler than finding the Gibbs distribution, the distribution function of N th order characterizing the configuration of all the particles of the system.

However, it is clear that a direct determination of the distribution functions $\rho_1, \rho_2, \dots, \rho_m, \dots$ is associated with the calculation of the configuration integral and hence their application in no way simplifies the problem and is no step forward.

The application of the distribution functions would be of no interest if there were not another method of calculating them which is not associated with the determination of I .

It turns out to be possible to obtain a differential equation which must be satisfied by the distribution functions ρ_m . To find an equation which must be satisfied by an ordinary function, we differentiate formula (47.5) with respect to the coordinates \mathbf{r}_1 . Obviously, we have

$$\frac{\partial \rho_1(\mathbf{r}_1)}{\partial \mathbf{r}_1} = - \frac{V}{IkT} \int e^{-U/kT} \frac{\partial U}{\partial \mathbf{r}_1} d\mathbf{r}_2 \dots d\mathbf{r}_N. \quad (48.1)$$

Consider in more detail the derivative

$$\frac{\partial U}{\partial \mathbf{r}_1} = \frac{\partial}{\partial \mathbf{r}_1} \sum_{1 \leq i < j \leq N} u(|\mathbf{r}_i - \mathbf{r}_j|) = \frac{\partial}{\partial \mathbf{r}_1} \sum_{j=2}^N u(|\mathbf{r}_1 - \mathbf{r}_j|), \quad (48.2)$$

[cf. eq. (46.7)]. Here we have made use of the fact that all terms of the sum over i except the one referring to particle no. 1 do not depend on \mathbf{r}_1 and reduce to zero in differentiating.

Substituting (48.2) into (48.1), we obtain on the right-hand side the integral

$$\begin{aligned}
 -\frac{V}{IkT} \int e^{-U/kT} \frac{\partial}{\partial \mathbf{r}_1} \sum_j u(|\mathbf{r}_1 - \mathbf{r}_j|) d\mathbf{r}_2 \dots d\mathbf{r}_N = \\
 = -\frac{V}{IkT} \sum_j \int e^{-U/kT} \frac{\partial u(|\mathbf{r}_1 - \mathbf{r}_j|)}{\partial \mathbf{r}_1} d\mathbf{r}_2 \dots d\mathbf{r}_N.
 \end{aligned}$$

But, by the definition (47.8),

$$\frac{1}{I} \int e^{-U/kT} d\mathbf{r}_2 \dots d\mathbf{r}_{j-1} d\mathbf{r}_{j+1} \dots d\mathbf{r}_N = \frac{\rho_{1j}(\mathbf{r}_1, \mathbf{r}_j)}{V^2}.$$

Hence the right-hand side can be written in the form

$$\frac{1}{VkT} \sum_{j=2}^N \int \frac{\partial u(|\mathbf{r}_1 - \mathbf{r}_j|)}{\partial \mathbf{r}_1} \rho_{1j}(\mathbf{r}_1, \mathbf{r}_j) d\mathbf{r}_j.$$

The sum over j contains $N - 1$ terms each of which represents an integral of the form

$$\int \frac{\partial u(|\mathbf{r}_1 - \mathbf{r}_j|)}{\partial \mathbf{r}_1} \rho_{1j}(\mathbf{r}_1, \mathbf{r}_j) d\mathbf{r}_j.$$

Since the system consists of identical particles, so that $u(|\mathbf{r}_1 - \mathbf{r}_j|)$ for given $|\mathbf{r}_1 - \mathbf{r}_j|$ has one and the same value and the integration is carried out over all $|\mathbf{r}_1 - \mathbf{r}_j|$, one can write

$$\begin{aligned}
 \frac{1}{V} \sum_{j=2}^N \int \frac{\partial u(|\mathbf{r}_1 - \mathbf{r}_j|)}{\partial \mathbf{r}_1} \rho_{1j}(\mathbf{r}_1, \mathbf{r}_j) d\mathbf{r}_j = \\
 = \frac{N-1}{V} \int \frac{\partial u(|\mathbf{r}_1 - \mathbf{r}_j|)}{\partial \mathbf{r}_1} \rho_{1j} d\mathbf{r}_j \approx \\
 \approx \frac{N}{V} \int \frac{\partial u(|\mathbf{r}_1 - \mathbf{r}_j|)}{\partial \mathbf{r}_1} \rho_{1j} d\mathbf{r}_j.
 \end{aligned}$$

Substituting this expression into formula (48.1), we obtain

$$\frac{\partial \rho_1(\mathbf{r}_1)}{\partial \mathbf{r}_1} = -\frac{N}{VkT} \int \frac{\partial u(|\mathbf{r}_1 - \mathbf{r}_j|)}{\partial \mathbf{r}_1} \rho_{1j} d\mathbf{r}_j. \quad (48.3)$$

Formula (48.3) relates the ordinary distribution function ρ_1 to the binary distribution function ρ_{1j} .

Let us find the equation satisfied by the binary function ρ_{1j} . Differentiating (47.7), we obtain

$$\begin{aligned} \frac{\partial \rho_{12}(\mathbf{r}_1, \mathbf{r}_2)}{\partial \mathbf{r}_1} &= -\frac{V^2}{IkT} \int e^{-U/kT} \frac{\partial}{\partial \mathbf{r}_1} \left[\sum u(|\mathbf{r}_1 - \mathbf{r}_j|) \right] d\mathbf{r}_3 \dots d\mathbf{r}_N = \\ &= -\frac{V^2}{IkT} \int e^{-U/kT} \frac{\partial u(|\mathbf{r}_1 - \mathbf{r}_2|)}{\partial \mathbf{r}_1} d\mathbf{r}_3 \dots d\mathbf{r}_N \\ &\quad - \frac{V^2}{IkT} \sum_{j=3}^N \int \frac{\partial u(|\mathbf{r}_1 - \mathbf{r}_j|)}{\partial \mathbf{r}_1} d\mathbf{r}_j \int e^{-U/kT} d\mathbf{r}_3 \dots d\mathbf{r}_{j-1} d\mathbf{r}_{j+1} \dots d\mathbf{r}_N \approx \\ &\approx -\frac{N}{VkT} \int \frac{\partial u(|\mathbf{r}_1 - \mathbf{r}_j|)}{\partial \mathbf{r}_1} \rho_{12j} d\mathbf{r}_j - \frac{1}{kT} \rho_{12}(\mathbf{r}_1, \mathbf{r}_2) \frac{\partial u(|\mathbf{r}_1 - \mathbf{r}_2|)}{\partial \mathbf{r}_1}. \end{aligned}$$

Consequently, we have finally

$$\frac{\partial \rho_{12}}{\partial \mathbf{r}_1} = -\frac{1}{kT} \rho_{12} \frac{\partial u(|\mathbf{r}_1 - \mathbf{r}_2|)}{\partial \mathbf{r}_1} - \frac{N}{VkT} \int \frac{\partial u(|\mathbf{r}_1 - \mathbf{r}_j|)}{\partial \mathbf{r}_1} \rho_{12j} d\mathbf{r}_j. \quad (48.4)$$

Eq. (48.4) connects the binary distribution function with the threefold distribution function. In the same way, one can obtain an equation connecting the threefold distribution function with the fourfold, the m th distribution function with the $(m+1)$ th, and so on. As a result one obtains an unclosed system of equations each of which expresses the derivative of the distribution function of a given order in terms of the distribution function of the next order:

$$\begin{aligned} \frac{\partial \rho_{12\dots m}(\mathbf{r}_1, \dots, \mathbf{r}_m)}{\partial \mathbf{r}_1} &= -\frac{1}{kT} \rho_{12\dots m} \frac{\partial}{\partial \mathbf{r}_1} \left[\sum u(|\mathbf{r}_1 - \mathbf{r}_m|) \right] \\ &\quad - \frac{N}{VkT} \int \sum_{j=m+1}^N \frac{\partial u}{\partial \mathbf{r}_1} \rho_{12\dots m, m+1} d\mathbf{r}_{m+1}. \end{aligned} \quad (48.5)$$

Continuing this procedure we shall arrive at an equation connecting the distribution function of the $(N-1)$ th order with the distribution function

of the N th order, i.e. with the Gibbs distribution. Hence the problem of finding distribution functions of a lower order again turns out to be associated with the Gibbs distribution for the entire system. However, in this fact lies the most important feature of the equations obtained: functions of a higher order always enter under the integral sign with a coefficient $\sim (N/kT)(\partial u/\partial \mathbf{r}_1)$. In the case where the potential energy of interaction between two particles, $u(|\mathbf{r}_1 - \mathbf{r}_j|)$, decreases rapidly with increasing distance and becomes small at distances which exceed molecular dimensions the quantity $\partial u/\partial \mathbf{r}_1$ is very small for $|\mathbf{r}_1 - \mathbf{r}_j| \gg d$, where d is the diameter of the molecule. Hence, for example, the expression for the integral in the right-hand side of eq. (48.4) can be estimated to order of magnitude in the following way:

$$\frac{N}{V} \int \frac{\partial u}{\partial \mathbf{r}_1} \rho_{12j} d\mathbf{r}_j \approx \frac{d^3}{V/N} \left[\frac{\partial u}{\partial \mathbf{r}_1} \rho_{12j} \right]_d,$$

where $[(\partial u/\partial \mathbf{r}_1) \rho_{12j}]_d$ is taken for distances between the particles of the order of d .

If the volume per particle, V/N , is large in comparison with the volume d^3 of the particle, then the coefficient $d^3/(VN^{-1})$ is small. Hence use can be made of approximate expressions for the value of the integrand, in particular the distribution function of the third order. This conclusion refers not only to the equation for the binary function, but has a general character.

§49. The equation of state and the energy of a system of interacting particles

The binary distribution function $\rho_{12}(\mathbf{r}_1, \mathbf{r}_2)$, in terms of which the equation of state can be expressed is of great importance.

The pressure in a system is determined by formula (32.5):

$$p = \frac{kT}{Z} \frac{\partial Z}{\partial V}.$$

Since, as we have seen before, Z resolves into two factors, one of which, Z_{kin} , depends only on the kinetic energy but not on the configuration of the particles and, consequently, not on the volume, and the second of which, I , depends only on the configuration, we have

$$p = \frac{kT}{Z_{\text{kin}} I} \frac{\partial Z_{\text{kin}} I}{\partial V} = \frac{kT}{I} \frac{\partial I}{\partial V}. \quad (49.1)$$

We shall find the derivative of I with respect to the volume of the system. For this we change all linear dimensions by a factor λ :

$$\mathbf{r}^* \rightarrow \lambda \mathbf{r}. \quad (49.2)$$

In consequence of (49.2) we obtain

$$V^* \rightarrow \lambda^3 V. \quad (49.3)$$

Then

$$I = \lambda^{3N} \int e^{-U/kT} d\mathbf{r}_1 \dots d\mathbf{r}_N. \quad (49.4)$$

According to (49.3)

$$\frac{\partial Z}{\partial V^*} = \frac{\partial I}{\partial V^*} = \frac{\partial I}{\partial \lambda} \frac{\partial \lambda}{\partial V^*} = \frac{\partial I}{\partial \lambda} \frac{1}{3\lambda^2 V}$$

and, consequently,

$$\frac{\partial I}{\partial V^*} = \frac{1}{3V} \left. \frac{\partial I}{\partial \lambda} \right|_{\lambda=1}. \quad (49.5)$$

Differentiating (49.4) with respect to λ , we obtain

$$\frac{\partial I}{\partial \lambda} = \frac{3NI}{\lambda} - \frac{\lambda^{3N}}{kT} \int e^{-U/kT} \frac{\partial U}{\partial \lambda} d\mathbf{r}_1 \dots d\mathbf{r}_N. \quad (49.6)$$

According to the definition (46.7)

$$\frac{\partial U}{\partial \lambda} = \frac{\partial}{\partial \lambda} \sum \sum u(\lambda |\mathbf{r}_i - \mathbf{r}_j|) = \sum \sum (|\mathbf{r}_i - \mathbf{r}_j|) u'.$$

Substituting $\partial U / \partial \lambda$ into (49.6), we find

$$\left. \frac{\partial I}{\partial \lambda} \right|_{\lambda=1} = 3NI - \frac{1}{kT} \sum \sum \int (|\mathbf{r}_i - \mathbf{r}_j|) u' e^{-U/kT} d\mathbf{r}_1 \dots d\mathbf{r}_N,$$

or

$$\left. \frac{\partial I}{\partial \lambda} \right|_{\lambda=1} \approx 3NI - \frac{N^2}{2kT} \int (|\mathbf{r}_1 - \mathbf{r}_2|) u' e^{-U/kT} d\mathbf{r}_1 \dots d\mathbf{r}_N.$$

Here we have made use of the fact that all $\frac{1}{2}N(N-1)$ terms (the number of interacting pairs) in the double sum are identical with one another. By means of (49.5) and (49.1) we obtain

$$p = \frac{NkT}{V} - \frac{N^2}{6V} \int u'(|\mathbf{r}_1 - \mathbf{r}_2|) d\mathbf{r}_1 d\mathbf{r}_2 \int e^{-U/kT} d\mathbf{r}_3 \dots d\mathbf{r}_N.$$

Making use of (47.7), we finally find

$$p = \frac{NkT}{V} - \frac{N^2}{6V^3} \int \rho_{12}(\mathbf{r}_1, \mathbf{r}_2) (|\mathbf{r}_1 - \mathbf{r}_2|) u' d\mathbf{r}_1 d\mathbf{r}_2. \quad (49.7)$$

Formula (49.7) connects the equation of state with the binary distribution function.

The binary distribution function $\rho_{12}(\mathbf{r}_1, \mathbf{r}_2)$ characterizes the probability of a given mutual disposition of two arbitrarily chosen particles in a system. In isotropic phases (gases and liquids) one more simplification of eq. (49.7) can be made.

Since in isotropic phases the binary function cannot depend on directions but only on the distance between the particles, it can be written in the form

$$\rho_{12}(\mathbf{r}_1, \mathbf{r}_2) = \mu(|\mathbf{r}_1 - \mathbf{r}_2|).$$

Hence

$$p = \frac{NkT}{V} - \frac{N^2}{6V^3} \int \mu(|\mathbf{r}_1 - \mathbf{r}_2|) (|\mathbf{r}_1 - \mathbf{r}_2|) u'(|\mathbf{r}_1 - \mathbf{r}_2|) d\mathbf{r}_1 d\mathbf{r}_2.$$

Introducing a new variable

$$r = |\mathbf{r}_1 - \mathbf{r}_2|$$

one can write

$$\int \mu(|\mathbf{r}_1 - \mathbf{r}_2|) (|\mathbf{r}_1 - \mathbf{r}_2|) u'(|\mathbf{r}_1 - \mathbf{r}_2|) d\mathbf{r}_1 d\mathbf{r}_2 = 4\pi V \int_0^\infty \mu(r) u'(r) r^3 dr,$$

so that finally

$$p = \frac{NkT}{V} - \frac{2\pi N^2}{3V^2} \int_0^\infty \mu(r)u'(r)r^3 dr. \quad (49.8)$$

In an analogous way one can find an expression for the energy of the system:

$$E = kT^2 \frac{\partial \ln Z}{\partial T} = kT^2 \frac{1}{Z_{\text{kin}}} \frac{\partial Z_{\text{kin}}}{\partial T} + \frac{kT^2}{I} \frac{\partial I}{\partial T} = \frac{3NkT}{2} + \frac{kT^2}{I} \frac{\partial I}{\partial T}, \quad (49.9)$$

where $\frac{3}{2}NkT$ is the energy of a system of non-interacting particles.

Substituting the value of I from (47.2) and using (47.7), we calculate $\partial I / \partial T$ to be

$$\frac{\partial I}{\partial T} = \frac{N^2 I}{2V^2 kT^2} \int u(|\mathbf{r}_1 - \mathbf{r}_2|) \rho_{12}(\mathbf{r}_1, \mathbf{r}_2) d\mathbf{r}_1 d\mathbf{r}_2.$$

Hence

$$E = \frac{3NkT}{2} + \frac{2\pi N^2}{V} \int_0^\infty \mu(r)u(r)r^2 dr. \quad (49.10)$$

Thus the energy as well as the pressure are expressed in terms of the binary distribution function $\mu(r)$.

The binary distribution function $\mu(r)$ can be calculated for gases when the density of particles in the system is small.

That is, in the case of such gases the equation for the binary function (48.4) can be solved by a method of successive approximations.

Indeed, in gases with a density which is not too large the mean distance between particles is large in comparison with their size. The estimations made at the end of §48 show that the coefficient of the threefold distribution function on the right-hand side of (48.4) is proportional to $d^3/(VN^{-1})$ and, consequently, is very small for a sufficiently rarefied gas. This allows one to substitute the approximate value of ρ_{12j} into the integral on the right-hand side of (48.4) without committing any appreciable error.

To obtain an approximate expression for ρ_{12} we expand all distribution functions in a series in powers of the small quantity NV^{-1} — in reality this expansion is carried out in powers of the ratio $[d/(VN^{-1})]^3$ — and we confine ourselves in this expansion to terms of the lowest order, writing

$$\rho_{12} = \rho_{12}^{(0)} + \frac{N}{V} \rho_{12}^{(1)} + \dots, \quad (49.11)$$

$$\rho_{123} = \rho_{123}^{(0)} + \frac{N}{V} \rho_{123}^{(1)} + \dots. \quad (49.12)$$

Substituting these series into the equation for the correlation functions and retaining only low powers of small quantities, one can successively determine the correlation functions, in particular ρ_{12} . Then the pressure, according to (49.8), will appear as a series in powers of NV^{-1} .

$$pV = NkT - \frac{N^2 kT}{2V} \beta - \frac{2}{3} \frac{N^2}{V^2} \beta_2, \quad (49.13)$$

$$\beta = \int (e^{-U/kT} - 1) dV, \quad (49.14)$$

$$\beta_2 = \frac{1}{2} \int (e^{-u(r-r')/kT} - 1)(e^{-u(r)/kT} - 1)(e^{-u(r')/kT} - 1) dV dV'. \quad (49.15)$$

The second term in (49.13) is obviously the same as (46.18), while the third term gives a correction to the pressure to the next smaller order of magnitude (in powers of the density NV^{-1}). In the case of rarefied gases the correlation function method has no special advantages over other methods of calculating corrections for the interaction.

Of greater importance is the application of this method to the construction of a statistical theory of liquids.

Up to now the statistical theory of liquids has been very much in the initial state of its development. The cause of this lies in the very character of thermal motion in liquids.

Thermal motion in liquids differs from that in gases and crystals by the fact that for liquids the energy of the interaction of a molecule with its neighbours cannot be considered to be small (as in gases) or large (as in crystals) in comparison with the energy of thermal motion. For liquids these quantities are of the same order of magnitude.

In a liquid neighbouring molecules oscillate about certain equilibrium positions with a relatively large amplitude. The mutual configuration of molecules is approximately the same as that in an elementary cell of the corresponding crystal.

However, in contrast to crystals, the amplitude of these oscillations is so large that neighbouring molecules draw away from each other relatively easily and leave their equilibrium positions. The mean lifetime τ of a molecule in a given equilibrium position is limited (it is about 10^{-8} sec).

In the course of time intervals which are small in comparison with this time τ , the oscillations of molecules in a liquid have approximately the same character as those in crystals. However, for times $t \gg \tau$ a molecule of a liquid can find itself at any point of the liquid. In this sense its motion is similar to that of a gas molecule.

The character of the jumps and the frequency of the oscillations are determined by the interaction between the molecules in the liquid. This interaction can vary for different liquids over a very wide range. Therefore the basic problem of the contemporary theory of liquids reduces to finding the qualitative characteristics. Such a qualitative characteristic is, in particular, the binary correlation function $\mu(r)$. The binary correlation function characterizes the interaction of the closest neighbours. It can be determined experimentally from the scattering of X-rays.

The correlation function $\mu(r)$ determined in such a way is shown in fig. III.31 by small circles. We see that for a fixed position of a given molecule its closest neighbours are situated with highest probability at distances corresponding to the maxima of the curve $\mu(r)$. It turns out that the positions of these maxima are similar to the corresponding positions in the crystal lattice of the same substance. It is said that short-range order is observed in the disposition of atoms in a liquid and, in this sense, one speaks of the quasi-crystalline structure of water. It is necessary, however, to stress a basic difference between a crystal and a liquid. In liquids the regularity in the disposition of the atoms extends to the closest three or four neighbouring atoms. In crystals the regular disposition of the atoms extends to distances

Fig. III.31

which are infinite from the microscopic point of view. In other words, in crystals there is long-range order extending to arbitrarily large distances. As we have already stressed, this difference is associated with the different character of the thermal motion. Hence the analogy between crystals and liquids can be used only within very restricted limits.

By means of certain simplifying assumptions one can obtain from the theory of correlation functions a form of $\mu(r)$ which agrees qualitatively correctly with the experimental data. That is, first, instead of the true energy of interaction a simplified expression is introduced,

$$u(r) = \begin{cases} \infty & \text{if } d \leq 2r \\ 0 & \text{if } d > 2r \end{cases}$$

where d is the diameter of the particles. This energy corresponds to the substitution of hard (impenetrable) spheres of diameter d for the molecules. Second, the so-called superposition approximation is made in the function ρ_{123} . It consists in the substitution

$$\rho_{123} \approx \rho_{13}\rho_{23} . \quad (49.16)$$

The meaning of formula (49.16) is that the interaction of particle 3 with particle 1 is as if particle 2 did not exist at all. In other words, the interaction of particle 3 with particles 1 and 2 is equal to the sum of the pair interactions (31) and (32).

Although the superposition approximation cannot be substantiated theoretically, it is qualitatively clear that it represents an advance over the assumption of the independence of the mutual positions of the particles in space (i.e. over the assumption that $\rho_{123} = \rho_1\rho_2\rho_3$).

In the superposition approximation, eq. (48.4) is closed. It contains only the binary function $\rho_{12} = \mu(r)$.

The solution of the equation for $\mu(r)$ in the approximation mentioned has been carried out numerically. It depends only on one parameter which includes the quantities NV^{-1} , T and d . The solutions obtained are shown in fig. III.31 (by a solid line).

We see that the general forms of the calculated and experimental curves for $\mu(r)$ are very similar. This means that in spite of its schematic character, the model of molecules as hard spheres in the superposition approximation in general correctly describes the character of the interaction of molecules in a liquid.

Crystals

§50. Crystal structure and thermal motion in the one-dimensional crystal model

The contemporary theory of the crystalline state is based on the proposition that the structural units (atoms or molecules) of a crystal are placed at the points of the crystal lattice. Numerous X-ray investigations of crystals and a number of other data have confirmed this proposition and made it possible to measure the distance between atoms in a crystal lattice. In what follows we shall proceed from this proposition as the basis of the theory of the crystalline state.

The distances between atoms in crystals are very small. They are in general of the same order of magnitude as the distances between atoms in molecules, and are sometimes exactly equal to them. For example, the distance between atoms in diamond (1.54×10^{-8} cm) is very close to that between carbon atoms in long chain hydrocarbon compounds (for aliphatic compounds the distance C—C is equal to 1.51×10^{-8} cm).

The distance between molecules in molecular crystals is only two or three times larger than intramolecular distances. Owing to the smallness of these distances the interaction between them is extremely large. In order of magnitude it corresponds to the interaction between atoms in a molecule. From

this point of view an atomic or ionic crystal can be considered as a gigantic molecule containing an enormous number of bound atoms. As in molecules, the energy of interaction between atoms in a crystal is very large in comparison with the energy of thermal motion. Particles in a crystal turn out to be so strongly bound to each other that thermal motion cannot break the bonds.

Thus, from the point of view of the interatomic interaction, crystals represent the opposite limiting case to gases. It is obvious that the only possible form of motion of bound particles in a crystal is the vibrational motion about equilibrium positions. We shall assume that the amplitude of vibrations is very small in comparison with the distances between the atoms. Below we shall discuss in more detail the validity of this assumption.

We shall calculate first of all the mean energy and heat capacity of a crystal whose atoms perform small vibrations about equilibrium positions (lattice points), proceeding from the laws of classical statistics. For this we can make use of the law of equipartition of energy over the degrees of freedom. To each degree of freedom of the motion * there corresponds an energy kT . The number of vibrational degrees of freedom for a crystal containing N atoms is equal to $3N - 6 \approx 3N$ (because N is large). Hence from classical statistics it follows that the mean energy of thermal motion in the crystal is equal to

$$E = 3NkT.$$

The corresponding molar heat capacity is equal to

$$C_V = 3Nk \approx 24.7 \text{ J mol}^{-1}.$$

The heat capacity of crystals turns out to be independent of the temperature and of the concrete properties of crystals and is the same as the well-known Dulong–Petit empirical law for the heat capacity. The Dulong–Petit law yields relatively accurately the heat capacity of many atomic crystals at high temperatures. However, it becomes completely useless on going to low temperatures.

At low temperatures the heat capacity of all crystals decreases with decreasing temperature, as was to be expected from the third law of thermodynamics. Moreover, the heat capacity of certain crystals depends on the temperature even at temperatures which considerably exceed room temper-

* It should be stressed that this holds only for vibrational motion with a small amplitude, when the potential energy is expressed by a quadratic function of the displacement.

ature. As a characteristic example of the total inapplicability of the Dulong-Petit law one can quote diamond. Thus in the case of crystals we again encounter the limited applicability of the law of equipartition, i.e. the limited applicability of classical statistics.

The simplest attempt at applying quantum laws to the treatment of the heat capacity of crystals consists in the following. We consider each atom vibrating at a crystal lattice point as a quantum oscillator which has three degrees of freedom. In a crystal made of atoms of one kind all atoms are completely equivalent and are vibrating with the same frequency ν . If it is assumed that the atoms oscillate independently of each other, then the mean energy of thermal motion E of the entire crystal can be written in the form

$$E = \sum_{n=1}^N \bar{\epsilon}_n,$$

where $\bar{\epsilon}_n$ is the mean energy of the n th oscillator, and the summation is carried out over all oscillators of the crystal. Since each atom is a three-dimensional oscillator, then $\bar{\epsilon}_n = 3\bar{\epsilon}$, where $\bar{\epsilon}$ is the mean energy of the linear quantum oscillator given by formula (43.3).

Thus, the mean energy of a crystal has the form

$$E = \frac{3N h \nu}{2} \coth \frac{h \nu}{2kT},$$

and the heat capacity

$$C_V = \frac{3Nk}{4} \left(\frac{h\nu}{kT} \right)^2 \frac{1}{\sinh^2 (h\nu/2kT)}. \quad (50.1)$$

The form of the heat capacity given by formula (50.1) was discussed in §43 in connection with the vibrational heat capacity of molecules. At high temperatures ($kT \gg h\nu$) the heat capacity tends to the limiting value

$$C_V \approx 3Nk.$$

At low temperatures, in correspondence with the requirement of the third law, C_V tends to zero according to an exponential law:

$$C_V \approx \frac{3Nk}{4} \left(\frac{h\nu}{kT} \right)^2 e^{-h\nu/kT}. \quad (50.2)$$

The simplest quantum law yields qualitatively the correct behaviour of the heat capacity of a crystal with temperature. However, a more detailed comparison of formula (50.2) with experimental data for the heat capacity shows that (50.2) does not give all the features of the behaviour of the heat capacity. The heat capacity of crystals decreases with temperature not according to the exponential law (50.2) but according to a power law of the form $C_V \sim T^3$. The disagreement of formula (50.2) with experiment is associated with the error in the assumption of the independence of the oscillations of atoms in a crystal, which was taken as the basis of the derivation of the formula. In reality, atoms in a crystal are so strongly bound with each other that the idea that the individual motion of one atom is independent of the motion of other atoms is out of the question. The vibrational motion of atoms in a crystal has a collective character, and all the atoms in the crystal simultaneously take part in it.

In order to get a clearer idea of the character of the thermal motion of atoms in a crystal, we shall make use of a fictitious crystal model in the form of a chain of atoms which are distributed along a line at equal distances from each other. Such a chain can be considered as a one-dimensional crystal. Although in nature there are no one-dimensional crystals, the consideration of the thermal motion in a one-dimensional crystal will allow us to elucidate the character of the motion in a real three-dimensional crystal.

We number the atoms in the chain in such a way that the number n may run over values from $n = 1$ up to $n = N$ (there are all together N atoms in the chain). Assume that a certain atom (ion or molecule) having, say, a number n goes out of an equilibrium position and is displaced a distance ξ_n to the right or to the left. Then it will be subject to forces from the neighbouring atoms: a repulsive force on the part of the neighbour it approached, and an attractive force on the part of the other neighbour. Since the forces of intermolecular interaction rapidly decrease with increasing distance, we can take into account only the interaction of the given atom with its two closest neighbours — the atoms with numbers $n - 1$ and $n + 1$. Even the next atoms, with numbers $n + 2$ and $n - 2$, will interact only very weakly with the atom considered, so that this interaction can be disregarded.

The force acting on the n th atom due to each of its two neighbours can be written in the form

$$F_n = - \frac{\partial u(\xi_n)}{\partial \xi_n} ,$$

where $u(\xi_n)$ is the potential energy of the n th atom at the point ξ_n . For

small displacements the potential energy $u(\xi_n)$ can be expanded in a series in powers of a small quantity ξ_n and one can restrict oneself to the first terms of the expansion, as is always done in the theory of small oscillations:

$$u(\xi_n) = u(0) + \left(\frac{\partial u}{\partial \xi_n} \right)_0 \xi_n + \left(\frac{\partial^2 u}{\partial \xi_n^2} \right)_0 \cdot \frac{\xi_n^2}{2} + \dots$$

Since at the point $\xi = 0$ the potential energy has a minimum, then at that point $\partial u / \partial \xi_n = 0$ and $\partial^2 u / \partial \xi_n^2 = \kappa > 0$. The force acting on the particle is

$$F = -\kappa \xi_n.$$

Here it has been assumed that the neighbouring atoms having numbers $n-1$ and $n+1$ remained at rest at their points of the crystal lattice. In reality, of course, this is not so. A displacement of the n th atom will lead to a displacement of the $(n-1)$ th and $(n+1)$ th atoms; the $(n+1)$ th atom will be displaced under the action of a repulsive force to the right a distance ξ_{n+1} , while the $(n-1)$ th atom under the action of an attractive force will follow the n th atom and will be displaced a distance ξ_{n-1} . Hence the distance between the n th atom and its neighbours will be changed respectively by $\xi_{n+1} - \xi_n$ and $\xi_{n-1} - \xi_n$. The n th atom will be acted upon by a force

$$F_n = \kappa(\xi_{n+1} - \xi_n) + \kappa(\xi_{n-1} - \xi_n) = \kappa(\xi_{n+1} + \xi_{n-1} - 2\xi_n). \quad (50.3)$$

The displacement of the $(n+1)$ th atom will lead to a displacement of the $(n+2)$ th, while the displacement of the $(n-1)$ th atom will lead to a displacement of the $(n-2)$ th. These atoms will in their turn act on the next neighbours, and as a result the entire chain of atoms will be set in motion. To investigate this motion it is sufficient to find the motion of an arbitrarily chosen n th atom. The equations of its motion have the form

$$m\ddot{\xi}_n = \kappa(\xi_{n+1} + \xi_{n-1} - 2\xi_n). \quad (50.4)$$

We shall assume that the first and N th atoms of the chain are fixed, so that their displacements are

$$\xi_1 = \xi_N = 0. \quad (50.5)$$

Of course, we have no special grounds for this assumption. However, from the general propositions of statistical physics it follows that the motion of a

system consisting of a very large number of particles cannot depend on the character of the initial and boundary conditions. Hence the condition which we have imposed upon two atoms of a chain containing N (for $N \gg 1$) atoms cannot have an essential effect on the motion of the entire chain. If, instead of the condition (50.5), we introduced the conditions

$$\frac{\partial u(\xi_1)}{\partial \xi_1} = \frac{\partial u(\xi_N)}{\partial \xi_N} = 0$$

which would express the fact that the first and last atoms of the chain remain free and that the force acting on them reduces to zero, the final result for $N \gg 1$ would not be changed at all.

As we have already said, the departure of any atom from an equilibrium position gives rise to a perturbation which propagates along the chain. This perturbation moves from atom to atom until it reaches the last atom which is fixed at the end of the chain. Here the perturbation will not vanish but will be reflected and will propagate in the opposite direction to the other end of the chain. At the other end it will again be reflected, and so on. In the chain of atoms there will arise waves travelling in opposite directions. The superposition of these waves will lead to the formation of standing waves similar to those arising in an elastic string with fixed ends. We shall seek the particular solution of (50.4) in the form

$$\xi_{nf} = A e^{i\omega t} e^{ifan}, \quad (50.6)$$

where A is the complex amplitude of the wave, and a is the distance between neighbouring equilibrium positions. The substitution of ξ_{nf} into (50.4) gives

$$m\omega^2 = \kappa(2 - e^{+ifa} - e^{-ifa}),$$

whence for ω we find

$$\omega = (\kappa/m)^{\frac{1}{2}} [2(1 - \cos fa)]^{\frac{1}{2}} = 2(\kappa/m)^{\frac{1}{2}} \sin \frac{1}{2}fa. \quad (50.7)$$

This formula, which connects the frequency ω and the wave number f , is the law of dispersion of waves in the chain. The wave numbers must be determined from the boundary conditions (50.5) which correspond to standing waves. The latter can be written in the form of a linear combination of the expression (50.6):

$$\xi_n = A \sin fx \sin(\omega t + \alpha) = A \sin fan \sin(\omega t + \alpha), \quad (50.8)$$

where a is the distance between equilibrium positions, A is the amplitude of the wave, and α is the phase. The conditions (50.5) at the ends of the chain will be satisfied if one sets $\sin afN = 0$, or

$$f = \frac{\pi k}{aN}, \quad (50.9)$$

where the number k runs over a series of integers: $k = 1, 2, 3, \dots, N$. Thus, the displacement ξ_n can be written in the form of a superposition of waves of the form

$$\xi_{nk} = A_k \sin \frac{\pi kn}{N} \sin(\omega_k t + \alpha). \quad (50.10)$$

It follows from formula (50.10) that the appearance of N standing waves with different frequencies ω_k ($k = 1, 2, \dots, N$) is possible in a chain of N atoms. To these N frequencies there correspond N wave numbers (50.8) or N different wavelengths:

$$\lambda_k = \frac{2\pi}{f_k} = \frac{2Na}{k}. \quad (50.11)$$

The longest of the standing wave (for $k=1$) has a wavelength $2Na$, i.e. one half-wave can be fitted into the entire chain. To the values $k = 1, 2, \dots$ there correspond ever shorter waves such that an integer number of half-waves is fitted into the length of the chain. It is remarkable that all atoms of the chain vibrate with the same frequency (i.e. ω_k depends only on k but not on the ordinal number of the atom).

The velocity of propagation of the waves is equal to

$$v_k = \frac{\omega_k}{f_k} = \frac{\omega_k \lambda_k}{2\pi} = v_k \lambda_k = 2 \left(\frac{\kappa}{m} \right)^{\frac{1}{2}} \frac{\sin \frac{1}{2} f_k a}{f_k}, \quad (50.12)$$

i.e. turns out to be different for different waves. For small wave numbers f_k , i.e. for long waves, $\sin \frac{1}{2} f_k a$ can be expanded in a series and we can write $\sin \frac{1}{2} f_k a \approx \frac{1}{2} f_k a$. In this case

$$\omega_k = \left(\frac{\kappa}{m} \right)^{\frac{1}{2}} f_k a, \quad (50.13)$$

$$v = v_0 = a \left(\frac{\kappa}{m} \right)^{\frac{1}{2}} = \text{const.} \quad (50.14)$$

In the case of very long waves, for which the inequality $f_k a \ll 1$ or $\lambda \gg a$ is fulfilled, a very large number of atoms are oscillating almost in phase; a change of the phase takes place in a half wavelength which covers a large number of atoms. Hence the atomic structure of the lattice has no effect on its properties. The lattice behaves with respect to long waves as a continuous elastic medium. Standing waves in the lattice are equivalent to those in an elastic medium. The velocity of propagation of waves in the lattice, given by (50.14), is the same as that of elastic waves (the velocity of sound) in a continuous medium.

To the shortest possible waves, $\lambda_N = 2Na/N = 2a$, there corresponds the highest frequency:

$$\omega_N = 2 \left(\frac{\kappa}{m} \right)^{\frac{1}{2}} \quad (50.15)$$

and the velocity of propagation

$$v = v_{\min} = \frac{2a}{\pi} \left(\frac{\kappa}{m} \right)^{\frac{1}{2}}. \quad (50.16)$$

Comparison of formulae (50.14) and (50.16) shows that long waves propagate with a velocity which is somewhat larger than that of short waves, i.e. the phenomenon of dispersion takes place. In the intermediate frequency range the velocity of propagation of waves, determined by formula (50.12), depends on the wave number f_k or the frequency ω_k .

In addition to the boundary condition (50.5) use is often made of the so-called conditions of periodicity. If an entire infinite chain of atoms is divided into segments of length L each containing N atoms ($L=aN$) then the motion of all the segments must be the same. This means that the following conditions must be fulfilled:

$$\xi_n = \xi_{n+N}$$

or, upon substitution of ξ_n from (50.6),

$$e^{ifaN} = 1.$$

Hence

$$f = \pm \frac{\pi k}{aN}, \quad (50.9')$$

where k takes on even integer values $k = 2, 4, \dots, N$. Here f has positive as well as negative values in the interval $-\pi/a \leq f \leq \pi/a$. The interval between the neighbouring values f_k and f_{k+1} doubles. The total number of waves remains the same.

The function $\omega(f)$ is shown in fig. III.32.

The displacement of an arbitrary n th atom in the chain is given in the form of a superposition of displacements of the form (50.10), i.e.

$$\xi_n = \sum_k \xi_{nk} = \sum_k A_k \sin(\omega_k t + \alpha) \sin f_k a n, \quad (50.17)$$

where the summation is carried out over all possible values of the wave vector f_k . Instead of an arbitrary amplitude A_k we introduce the amplitude

$$C_k = \left(\frac{N-1}{2} \right)^{\frac{1}{2}} A_k$$

and let

$$C_k \sin(\omega_k t + \alpha) = q_k. \quad (50.18)$$

Fig. III.32

Then we have

$$\xi_n = \left(\frac{2}{N-1} \right)^{\frac{1}{2}} \sum_k q_k \sin f_k a n. \quad (50.19)$$

If the values of the amplitudes q_k are given, then it follows from formula (50.19) that the displacement of an arbitrary atom in the chain will be completely determined. Hence the amplitudes q_k can be considered as the generalized coordinates of the system.

We now find the energy of the entire chain expressed in terms of the generalized coordinates q_k . The kinetic energy of the chain is obviously equal to

$$T = \frac{1}{2} m \sum_n \dot{\xi}_n^2,$$

where the summation is carried out over all atoms of the chain. We have

$$\begin{aligned} \dot{\xi}_n^2 &= \frac{2}{N-1} \left(\sum_k \dot{q}_k \sin f_k a n \right)^2 = \\ &= \frac{2}{N-1} \sum_k \sum_{k'} \dot{q}_k \dot{q}_{k'} \sin f_k a n \sin f_{k'} a n, \end{aligned}$$

hence

$$T = \frac{m}{2} \sum_n \sum_k \sum_{k'} \frac{2}{(N-1)} \dot{q}_k \dot{q}_{k'} \sin f_k a n \sin f_{k'} a n.$$

Changing the order of summation, we obtain

$$T = \frac{m}{2} \sum_k \sum_{k'} \frac{2}{N-1} \dot{q}_k \dot{q}_{k'} \sum_n \sin f_k a n \sin f_{k'} a n.$$

By virtue of the orthogonality property of sine functions, the sum $\sum_n \sin f_k a n \sin f_{k'} a n$ is equal to zero, provided $f_k \neq f_{k'}$, i.e. $k \neq k'$. If $f_k = f_{k'}$, then $k = k'$ and

$$\sum_{n=1}^{N-1} \sin f_k a n \sin f_{k'} a n = \frac{N-1}{2}.$$

Hence

$$T = \frac{1}{2} m \sum_k \dot{q}_k^2. \quad (50.20)$$

The kinetic energy of the chain is expressed by the quadratic form of the derivatives of the coordinates q_k .

We now find the potential energy of the entire chain. From formula (50.3) it follows that the potential energy of the entire crystal is equal to

$$U = \sum u_n = \frac{1}{2} \kappa \sum (\xi_{n+1} - \xi_n)^2, \quad (50.21)$$

where u_n is the potential energy of the n th atom.

We can convince ourselves of this by differentiating eq. (50.21). Indeed, if the force F_n acting on the n th atom is

$$F_n = - \frac{\partial U}{\partial \xi_n} = - \frac{\kappa}{2} \frac{\partial}{\partial \xi_n} [(\xi_2 - \xi_1)^2 + \dots + (\xi_n - \xi_{n-1})^2 + (\xi_{n+1} - \xi_n)^2 + \dots + (\xi_N - \xi_{N-1})^2] = \kappa(\xi_{n-1} + \xi_{n+1} - 2\xi_n),$$

then from formula (50.19) we find

$$\begin{aligned} \xi_{n+1} - \xi_n &= \left(\frac{2}{N-1} \right)^{\frac{1}{2}} \sum_k q_k \{ \sin [f_k a(n+1)] - \sin f_k a n \} = \\ &= \left(\frac{2}{N-1} \right)^{\frac{1}{2}} \sum_k q_k 2 \cos(f_k a n + \frac{1}{2}) \sin \frac{1}{2} f_k a. \end{aligned}$$

Proceeding in the same way as in calculating the kinetic energy, we have

$$\begin{aligned} U &= \frac{\kappa}{2} \frac{2}{N-1} 4 \sum_n \sum_k \sum_{k'} q_k q_{k'} \cos(f_k a n + \frac{1}{2}) \times \\ &\times \cos(f_{k'} a n + \frac{1}{2}) \sin \frac{1}{2} f_k a \sin \frac{1}{2} f_{k'} a = \frac{\kappa}{2} \frac{2}{N-1} 4 \times \\ &\times \sum_k \sum_{k'} q_k q_{k'} \sin \frac{1}{2} f_k a \sin \frac{1}{2} f_{k'} a \times \sum_n \cos(f_k a n + \frac{1}{2}) \cos(f_{k'} a n + \frac{1}{2}). \end{aligned}$$

But for cosines the orthogonality condition holds:

$$\sum \cos(f_k a n + \frac{1}{2}) \cos(f_{k'} a n + \frac{1}{2}) = \begin{cases} \frac{N-1}{2} & \text{for } k = k' , \\ 0 & \text{for } k \neq k' , \end{cases}$$

hence

$$U = \frac{1}{2} \kappa \sum_k q_k^2 (2 \sin \frac{1}{2} f_k a)^2 .$$

Taking into account formula (50.7), we find finally

$$U = \frac{1}{2} m \sum_k \omega_k^2 q_k^2 . \quad (50.22)$$

Thus, the total energy of the crystal is equal to

$$E = \frac{1}{2} m \sum_k (\dot{q}_k^2 + \omega_k^2 q_k^2) . \quad (50.23)$$

Formula (50.23) has an important physical meaning: the total energy of the crystal is expressed in a quadratic form containing only the squares of the quantities \dot{q}_k and q_k (but not their products of the form $\dot{q}_k q_k$). Hence the quantities q_k are the normal coordinates of the vibrating crystal. Each term in (50.23) has the form

$$\epsilon = \frac{1}{2} m (\dot{q}_k^2 + \omega_k^2 q_k^2) = \frac{1}{2} m (\dot{q}_k^2 + 4\pi^2 \nu_k^2 q_k^2) , \quad (50.24)$$

i.e. represents the energy of a linear harmonic oscillator with a mass equal to that of an atom oscillating with a frequency ν_k . The energy E is equal to the sum of the energies of such oscillators which have different frequencies ν_k . The energy of a crystal of N atoms which perform bound oscillations turns out to be equal to the energy of N independent harmonic oscillators with a set of frequencies ν_k determined by formula (50.7). In this sense a system of N atoms which perform bound oscillations is equivalent to a set of N independent oscillators with frequencies ν_k . Instead of finding the mean energy of a complex system of N bound atoms, we can seek the mean energy of a

much simpler equivalent system of N independent oscillators. It should be stressed that linear oscillators with an energy given by formula (50.24) have nothing in common with real atoms (with the exception of the same mass). Each oscillator represents one of the normal oscillations of the crystal as a whole. All atoms oscillating with one and the same frequency ν_k take part in the normal oscillation of the crystal.

The transition which we have made from displacements ξ_n to normal coordinates q_k represents a transformation which is typical for wave processes, and is not connected with the properties of the linear chain. The possibility of the transition to normal coordinates, in which the energy has the quadratic form (50.23), represents a general algebraic theorem.

Real crystals made of atoms (or molecules) of the same mass m are very seldom encountered. Usually the crystal lattice contains particles with different masses and different chemical natures. The latter leads to a change in the law of interaction between neighbouring atoms, so that the quantity κ has different values at different points of the crystal.

Without taking into account the above effect we shall consider only the effect of the difference in the masses of the atoms on the character of the motion in the case of the one-dimensional-chain model.

Let atoms with masses m_1 and m_2 having one and the same physical nature (i.e. with the same values of the quasi-elastic constant) be placed alternately at equal distances in a chain. The equations of motion of the chain will now be written in the form

$$m_1 \ddot{\xi}_n = \kappa(2\xi_n - \eta_{n+1} - \eta_{n-1}), \quad (50.25)$$

$$m_2 \ddot{\eta}_n = -\kappa(2\eta_n - \xi_{n+1} - \xi_{n-1}), \quad (50.26)$$

where ξ_n and η_n are the displacements of the atoms with masses m_1 and m_2 respectively.

Analogously to (50.6), we can seek the solution of eqs. (50.25) and (50.26) which satisfies the boundary conditions (50.5) in the form

$$\xi_{nf} = A e^{ifan} e^{i\omega t},$$

$$\eta_{nf} = B e^{ifan} e^{i\omega t}.$$

The substitution of these expressions into (50.25) and (50.26) leads to the system of algebraic equations

$$(-\omega^2 m_1 + 2\kappa)A = 2\kappa \cos(fa)B,$$

$$(-\omega^2 m_2 + 2\kappa)B = 2\kappa \cos(fa)A.$$

Eliminating the amplitudes, one can obtain the following expression for ω^2 :

$$\omega^2 = \kappa \left(\frac{1}{m_1} + \frac{1}{m_2} \right) \pm \kappa \left[\left(\frac{1}{m_1} + \frac{1}{m_2} \right)^2 - \frac{4 \sin^2 fa}{m_1 m_2} \right]^{\frac{1}{2}} \quad (50.27)$$

If ω is written as a function of f , then depending on the sign in front of the root one obtains the two branches shown in fig. III.33. For small f , expanding the square root in (50.28) in a series in powers of f , we obtain

$$\omega_- \approx \left[\frac{2\kappa}{m_1 + m_2} \right]^{\frac{1}{2}} (fa), \quad (50.28)$$

$$\omega_+ \approx \left[2\kappa \left(\frac{1}{m_1} + \frac{1}{m_2} \right) \right]^{\frac{1}{2}}. \quad (50.29)$$

The branch ω_- , called the acoustic branch, corresponds to $\omega \rightarrow 0$ as $f \rightarrow 0$. Its behaviour does not differ significantly from that of the dispersion curve (50.13) for a chain of identical atoms.

The second branch of frequencies, which is absent in a chain of identical atoms, shows a completely different behaviour (the upper curve in fig. III.33). As $f \rightarrow 0$, ω_+ tends to the constant limit (50.29). This branch of frequencies is

Fig. III.33

called the optical branch. For given f the frequency of the waves of the optical branch is much higher than that of the acoustic branch.

For small f it is easy to determine the ratio of the wave amplitudes of the optical branch:

$$\frac{A}{B} \approx -\frac{m_2}{m_1}. \quad (50.30)$$

The minus sign in the above formula shows that particles with masses m_1 and m_2 which are involved in optical waves are moving towards each other.

In acoustic waves neighbouring particles with different masses are moving in the same direction.

We see that the difference in the masses of the atoms change fundamentally the character of thermal motion in the crystal.

Consider the case when at the points of the crystal lattice there are charged ions instead of neutral atoms. The optical branch corresponds to motion of the ions towards each other. Hence optical waves give rise to variations in the polarization of the crystal, and it is optical waves that have an effect on electromagnetic processes in crystals. Their name is associated with this fact.

§51. Long waves in a three-dimensional crystal

Thermal motion in a three-dimensional crystal has, in general, the same character as in the one-dimensional model. A displacement of an arbitrary atom from the equilibrium position in the lattice is transmitted to its closest neighbours in three dimensions. Their displacements will, in their turn, give rise to displacements of other atoms, and an elastic wave propagating in three dimensions will arise in the crystal. As a result of the reflection of the elastic waves from the faces of the crystal a system of standing waves will be established in the crystal. In the same approximation as for the one-dimensional model (disregarding the third powers of displacements) the energy of a crystal can be written in normal coordinates in the form

$$E = \sum \left(\frac{m\dot{q}_k^2}{2} + \frac{4\pi^2 m \nu_k^2 q_k^2}{2} \right), \quad (51.1)$$

where the summation is carried out over all possible wave numbers. The bound oscillations of atoms in the three-dimensional crystal are equivalent to a set of $3N$ independent linear oscillators with the natural frequencies ν_k .

The determination of the natural frequencies for the three-dimensional crystal presents very great mathematical difficulties. Hence in order to find the thermodynamic functions of a crystal it is necessary to make further simplifying assumptions in addition to the proportionality of the forces to the first power of the displacements. First, in considering thermal waves in a crystal we shall confine ourselves to the case of long waves ($\lambda \gg a$). As we have seen in the preceding paragraph, in the case of long waves very large groups of atoms are oscillating in phase and one can disregard the discrete atomic structure of the crystal. Similarly in the case of long waves in a three-dimensional crystal one can digress from the discrete structure and consider the crystal as a continuous elastic medium. Second, we shall disregard the anisotropy of the crystal and shall consider it as an isotropic elastic medium. In the isotropic elastic medium the thermal perturbations of the crystal form a system of standing waves. In a three-dimensional elastic medium the wave number f is equal to

$$f = (f_1^2 + f_2^2 + f_3^2)^{\frac{1}{2}}, \quad (51.2)$$

where f_1 , f_2 and f_3 are quantities which characterize respectively the propagation of the wave in three mutually perpendicular directions.

In order that a condition of the type (50.5), i.e. the condition of reflection of elastic waves from the faces of the crystal may be fulfilled, the wave numbers must satisfy the following conditions:

$$f_1 = \frac{\pi k_1}{aN}; \quad f_2 = \frac{\pi k_2}{aN}; \quad f_3 = \frac{\pi k_3}{aN}, \quad (51.3)$$

where k_1 , k_2 and k_3 are integers (1, 2, ..., N). The frequency of long waves is connected with the wave numbers by a relation which represents a direct generalization of formula (50.13).

In contrast to the one-dimensional model, in a three-dimensional isotropic elastic medium the propagation of three elastic waves is possible: one longitudinal wave (in which displacements take place in the direction of propagation of the wave) and two transverse waves (in which displacements are perpendicular to the direction of propagation). The velocities of propagation c_l and c_t of the longitudinal and transverse waves are different. Hence, instead of (50.12), in the three-dimensional case one must write

$$2\pi\nu_l = c_l f, \quad 2\pi\nu_t = c_t f,$$

where ν_l and ν_t are the frequencies of the longitudinal and transverse elastic waves, and c_l and c_t are their velocities.

In what follows we shall need to know the number of elastic waves whose frequency lies in the interval between ν_l and $\nu_l + d\nu_l$ and ν_t and $\nu_t + d\nu_t$ respectively. The calculation of this quantity in no way differs from the calculations in §38 of Part I.

Indeed, in §38 of Part I the number of travelling waves in a cavity of volume V has been calculated. The number of standing waves in a crystal can be found in a completely analogous way. The only difference from the calculation carried out in §38 of Part I lies in the fact that in a crystal wave vectors are determined by formula (51.3) which differs from (38.11) of Part I by the absence of the factor 2. On the other hand, here the integers k_1, k_2, k_3 take on only positive values, whereas in §38 of Part I they take on negative as well as positive values.

As a result, for the number of longitudinal waves with a frequency between ν_l and $\nu_l + d\nu_l$ one obtains the formula

$$g(\nu_l) d\nu_l = \frac{4\pi V}{c_l^3} \nu_l^2 d\nu_l, \quad (51.4)$$

which is identical with formula (38.22) of Part I *.

For the number of transverse waves with a frequency between ν_t and $\nu_t + d\nu_t$ we find analogously

$$g(\nu_t) d\nu_t = 2 \frac{4\pi V}{c_t^3} \nu_t^2 d\nu_t,$$

where the factor 2 appears because in an elastic medium there are two transverse waves with one and the same frequency ν_t . The total number of elastic waves whose frequency lies between ν and $\nu + d\nu$ is obviously equal to

* It should be noted for what follows that the displacement represented in formula (50.18) in the form of a standing wave can be written in the form of a superposition of two travelling waves. Reproducing the calculations of §38 of Part I one can write ξ in the form

$$\xi = N^{-\frac{1}{2}} \sum_f \sum_{j=1}^3 e_{ff}(q_{ff}) e^{ifr + q_{ff}^*} e^{-ifr}. \quad (51.5)$$

$$g(\nu)d\nu = 4\pi V \left(\frac{1}{c_l^3} + \frac{2}{c_t^3} \right) \nu^2 d\nu. \quad (51.6)$$

Since we have compared each wave with a frequency ν_k to an oscillator oscillating with the same frequency, the quantity $g(\nu)d\nu$ which we have calculated represents the number of oscillators whose frequency lies between ν and $\nu + d\nu$. If the crystal were of infinite size and contained an infinitely large number of atoms, the number of possible frequencies or oscillators would also be infinite. In reality, however, it is equal to $3N$. Therefore we can write

$$3N = \sum g(\nu_k), \quad (51.7)$$

where the summation is carried out over all possible frequencies.

We have established the form of the function $g(\nu)$ in the range of long waves or small frequencies, in which it can be assumed to be a continuous function of the argument ν given by formula (51.6). However, in the range of high frequencies the form of the spectral function is unknown and depends on the concrete structure of a given crystal.

Debye proposed a method of calculating the thermodynamic functions of crystals which is, in essence, based on a certain interpolation.

Namely, the spectral function $g(\nu)$ is assumed to have the form (51.6) over the entire frequency range, and in the entire frequency range the summation is replaced by integration. However, the integration is carried out up to a certain limiting frequency ν_{\max} which is expressed in terms of the number of particles in the crystal by means of the condition (51.7). Thus, the spectral function $g(\nu)$ is assumed to have the form

$$g(\nu) = \begin{cases} 4\pi V \left(\frac{1}{c_l^3} + \frac{2}{c_t^3} \right) \nu^2, & \nu \leq \nu_{\max}, \\ 0, & \nu > \nu_{\max}. \end{cases} \quad (51.8)$$

This gives

$$3N = \int_0^{\nu_{\max}} 4\pi V \left(\frac{1}{c_l^3} + \frac{2}{c_t^3} \right) \nu^2 d\nu = 4\pi V \left(\frac{1}{c_l^3} + \frac{2}{c_t^3} \right) \frac{\nu_{\max}^3}{3}, \quad (51.9)$$

whence

$$\nu_{\max} = \left(\frac{9}{4\pi} \frac{N}{V} \frac{c_l^3 c_t^3}{2c_l^3 + c_t^3} \right)^{\frac{1}{3}}. \quad (51.10)$$

The largest, or limiting, frequency ν_{\max} turns out to depend only on quantities which can be measured experimentally — the velocities of sound c_l and c_t — and to be proportional to the density of the crystal $(N/V)^{\frac{1}{3}}$.

The introduction of such a “cut-off” spectral function (51.8) leads to expressions for thermodynamic functions which in the limiting cases of low and high temperatures go over into accurate expressions, and in the range of intermediate temperatures have the character of interpolation formulae.

By means of the expression for the limiting frequency ν_{\max} determined by formula (51.10) the spectral function $\nu(g)$ can be rewritten in the more compact form

$$g(\nu)d\nu = \frac{9N}{\nu_{\max}^3} \nu^2 d\nu. \quad (51.11)$$

§ 52. The partition function of a crystal

We have established in the preceding paragraphs that the thermal motion in a crystal containing N atoms is described by a set of $3N$ independent oscillators whose frequencies lie between zero and ν_{\max} . In order to find the partition function of the entire crystal it is necessary to find the partition function of a system consisting of $3N$ independent oscillators. Since they are independent, we can, obviously, write this function in the form of the product of the partition functions of all the oscillators, i.e.

$$Z = \prod_{k=1}^{3N} z_k, \quad (52.1)$$

where Z is the partition function of the crystal, and z_k is the partition function of the individual k th oscillator. It should be stressed that the oscillator is not an individual atom but characterizes a definite oscillation of the crystal as a whole. Hence in (52.1) one should not carry out the division by $(3N)!$, as should be done in the case of $3N$ identical independent particles. We have

calculated the partition function z_k of a quantum oscillator in §43. Taking the logarithm of (52.1) and substituting (43.2) into it, we find

$$\ln Z = \sum_{k=1}^{3N} \ln z_k = \sum_{k=1}^{3N} \ln \frac{\exp(-h\nu_k/2kT)}{[1 - \exp(-h\nu_k/kT)]}. \quad (52.2)$$

To calculate the sum (52.2) it is necessary to know all the possible frequencies ν_k of the crystal.

However, as we have already mentioned, this problem is still unsolved. Therefore we shall confine ourselves to the Debye approximation and shall replace the summation by the integration over "cut-off" spectrum (51.11). This gives

$$\begin{aligned} \ln Z &= \int_0^{\nu_{\max}} \ln \frac{\exp(-h\nu/2kT)}{[1 - \exp(-h\nu/kT)]} g(\nu) d\nu = \\ &= -\frac{9N}{\nu_{\max}^3} \int_0^{\nu_{\max}} \frac{h\nu^3}{2kT} d\nu - \frac{9N}{\nu_{\max}^3} \int_0^{\nu_{\max}} \ln(1 - e^{-h\nu/kT}) \nu^2 d\nu. \end{aligned} \quad (52.3)$$

To calculate the integrals in formula (52.3) we introduce a new variable

$$x = h\nu/kT, \quad (52.4)$$

and the characteristic temperature θ_c of the crystal:

$$\theta_c = h\nu_{\max}/k,$$

which is analogous to the characteristic temperature introduced in §43. We obtain

$$\ln Z = -\frac{9N\theta_c}{8T} - 9N \left(\frac{T}{\theta_c} \right)^3 \int_0^{\theta_c/T} x^2 \ln(1 - e^{-x}) dx. \quad (52.5)$$

The calculation of the above integral can be carried out only for low and high temperatures. We shall understand low temperatures to be temperatures which are considerably lower than the characteristic temperature θ_c of the crystal. For $T \ll \theta_c$ the limit of the integral can be replaced by infinity, since the integrand is very small for any large values of the argument x . This gives

$$\int_0^{\theta_c/T} x^2 \ln(1-e^{-x}) dx \approx \int_0^{\infty} x^2 \ln(1-e^{-x}) dx. \quad (52.6)$$

This integral (52.6) is calculated in Appendix IV. Substituting its value into (52.5), we have

$$\ln Z = -\frac{9N\theta_c}{8T} + \frac{\pi^4 N}{5} \left(\frac{T}{\theta_c}\right)^3. \quad (52.7)$$

The substitution of infinity for the limit of the integral (52.6) has an important physical meaning. It shows that at $T \ll \theta_c$ only vibrations with small frequencies ν are excited in the crystal (i.e. the small values of x are essential). For large frequencies (large x) the integrand reduces to zero, and the corresponding frequencies give no contribution to the value of Z . This justifies the approximation made in the preceding paragraph — the replacement of the discrete crystal by a continuous elastic medium in which only oscillations with small values of ν are excited.

For high temperatures $T \gg \theta_c$ the limit of the integral will be a small quantity. Hence x in the integrand is small, and the integrand can be expanded in a series in powers of x . In this case we have

$$\ln(1-e^{-x}) \approx \ln x,$$

so that

$$\int_0^{\theta_c/T} x^2 \ln(1-e^{-x}) dx \approx \int_0^{\theta_c/T} x^2 \ln x dx = \frac{1}{3} \left(\frac{\theta_c}{T}\right)^3 \ln \frac{\theta_c}{T} - \frac{1}{9} \left(\frac{\theta_c}{T}\right)^3. \quad (52.8)$$

Substituting formula (52.8) into (52.5), we find

$$\ln Z = -3N \ln \frac{\theta_c}{T} + N - \frac{9}{8} N \left(\frac{\theta_c}{T}\right). \quad (52.9)$$

By means of the expressions (52.7) and (52.9) one can find the thermodynamic functions of a crystal at high and low temperatures.

§ 53. The thermodynamic functions of a crystal

We shall first of all calculate the energy and heat capacity of a crystal at low temperatures. At low temperatures ($T \ll \theta_c$) the energy is equal to

$$E = kT^2 \frac{\partial \ln Z}{\partial T} = \frac{9}{8} Nk\theta_c + \frac{3\pi^4}{5} \frac{NkT^4}{\theta_c^3}. \quad (53.1)$$

The first term in formula (53.1) represents the energy of the crystal as $T \rightarrow 0$, i.e. the zero-point energy. The second term shows that the energy of the crystal increases rapidly (as T^4) with increasing temperature.

The heat capacity of the crystal at low temperatures is given by the formula

$$C_V = \left(\frac{\partial E}{\partial T} \right)_V = \frac{12\pi^4 Nk}{5} \left(\frac{T}{\theta_c} \right)^3. \quad (53.2)$$

It turns out to be proportional to the cube of the absolute temperature.

A characteristic feature of the expressions (53.1) and (53.2) is the fact that they involve a material constant of the crystal: its characteristic temperature θ_c . Hence at low temperatures different crystals possess different heat capacities (which are smaller the higher θ_c).

At high temperatures ($T \gg \theta_c$) the energy and heat capacity are equal respectively to

$$E = kT^2 \frac{\partial \ln Z}{\partial T} = 3NkT + \frac{9}{8} Nk\theta_c \approx 3NkT, \quad (53.3)$$

$$C_V = \left(\frac{\partial E}{\partial T} \right)_V = 3Nk. \quad (53.4)$$

As was to be expected, the values of E and C_V agree with those obtained from the law of equipartition of energy over degrees of freedom. They do not depend on the material constants of the crystal and are universal quantities. The independence of the energy and heat capacity on the material constants is due to the fact that at sufficiently high temperatures the energy of the crystal turns out to be independent of the vibrational frequencies of the crystal. This fact allows one to understand why formulae (53.3) and (53.4) turn out to be correct in spite of the fact that they are derived on the basis of an undoubtedly incorrect assumption. Indeed, in deriving them it was

assumed that the basic role is played by small frequencies (long waves), for which the discrete crystal can be considered as a continuous elastic medium. For $T \gg \theta_c$ in addition to low frequencies there must also be excited in the crystal high frequencies, which will give a considerable contribution to the partition function. Hence the approximate law of frequency distribution (51.8) will no longer be applicable. However, in the classical approximation, which is valid for sufficiently high temperatures, the value of Z and, consequently, also that of the energy of the crystal depend neither on the frequencies themselves nor on the character of their distribution.

In the intermediate range of temperatures $T \approx \theta_c$ the energy and heat capacity are expressed by more complex formulae, which are obtained by numerical integration of formula (52.5). Since the width of the transitional range is not large, they are of no special interest.

It should be noted that, although we have calculated the heat capacity at constant volume, the expression obtained agrees to a high degree of accuracy with the heat capacity at constant pressure, because in a solid body the two heat capacities are practically the same.

We now find the entropy S of the crystal. For low temperatures ($T \ll \theta_c$) from (53.1) and (52.7) we get

$$S = \frac{E}{T} + k \ln Z = \frac{4\pi^4}{5} Nk \left(\frac{T}{\theta_c} \right)^3. \quad (53.5)$$

For high temperatures ($T \gg \theta_c$) from (53.3) and (52.9) we obtain

$$S = \frac{E}{T} + k \ln Z = 3Nk \ln \frac{T}{\theta_c} + 4Nk. \quad (53.6)$$

Formula (53.6) agrees with the purely thermodynamic expression for the entropy and differs from the latter only in the fact that it does not contain an indefinite constant entropy. Formula (53.5) shows that as $T \rightarrow 0$ the entropy of an atomic crystal tends to zero as the cube of the temperature, which is in complete agreement with the requirements of the third law of thermodynamics, just as is the decrease of the heat capacity as $T \rightarrow 0$.

Finally, we find the free energy of the crystal.

From the conditions (52.7) and (52.9) we obtain

$$F = -kT \ln Z \approx -N \frac{\pi^4 kT}{5} \left(\frac{T}{\theta_c} \right)^3 + \frac{9Nk\theta_c}{8} \quad \text{for} \quad T \ll \theta_c, \quad (53.7)$$

$$F \approx -3NkT \ln \frac{T}{\theta_c} - NkT \quad \text{for} \quad T \gg \theta_c. \quad (53.8)$$

Proceeding from the free energy one can obtain the equation of state of the crystal, which has the following form for $T \gg \theta_c$:

$$p = - \left(\frac{\partial F}{\partial V} \right)_T = - \frac{3NkT}{\theta_c} \frac{\partial \theta_c}{\partial V}.$$

Since p turns out to be expressed in terms of the quantity $\partial \theta_c / \partial V$ and the latter cannot be calculated theoretically or found from sufficiently simple experiments, this equation of state is of no great practical importance.

It is interesting to find the law of distribution of energy levels in a solid body or, more precisely, the spacing between the energy levels. If $\Omega(\epsilon)$ is the number of levels per unit interval of energy, then the spacing between neighbouring energy levels is obviously equal to

$$D(\epsilon) = \Omega^{-1}(\epsilon).$$

By means of formulae (24.10) and (53.5) one can write

$$D(\epsilon) = e^{-\sigma} = e^{-S/k} = \exp \left[-\frac{4}{3} \pi^4 N (T/\theta_c)^3 \right].$$

The spacing between levels decreases with decreasing temperature as well as with decreasing number of particles. For temperatures which are very close to the absolute zero it turns out, in accordance with what was said in §35, to be equal to kT even for a macroscopic body.

§54. Comparison of theory with experiment

For the practical use of the expressions obtained and the comparison of calculated values with experimental data it is necessary to know the characteristic temperature θ_c of the crystal.

From the definition and formula (51.10) we find

$$\theta_c = \frac{h\nu_{\max}}{k} = \frac{h}{k} \left(\frac{9N}{4\pi V} \right)^{\frac{1}{3}} \left(\frac{c_1^3 c_t^3}{2c_1^3 + c_t^3} \right)^{\frac{1}{3}}. \quad (54.1)$$

Formula (54.1) contains in addition to numerical values and universal constants, two quantities which are determined by the properties of the crystal: the density N/V and the velocity of sound in the crystal. These quantities have been measured for many crystals. Since the velocity of sound, according to (50.14), is inversely proportional to the square root of the mass of the atoms, it is particularly large for very hard crystals made of light atoms. For such crystals the characteristic temperature is particularly high.

Table 8 gives the characteristic temperatures of certain crystal. It follows from this table that for crystals of the type lead and common salt room temperature (300 K) and higher temperatures (up to 1000 K) are relatively, though not very, high. Hence for such crystals the departures from classical laws and, in particular, from the classical value of the heat capacity are not very large in this region. Without much error, it can be assumed that their heat capacity is equal to 24 J/mol. However, at temperatures which are lower than 100 K the departure from this value becomes very appreciable for all these crystals.

Table 8

Crystal	θ_c (K)	Crystal	θ_c (K)
Pb	88	Cu	315
I	106	Be	1000

The situation is different for crystals with a high characteristic temperature, particularly in the case of diamond. For the latter room temperature appears to be low, and the applicability of classical laws is out of the question. The heat capacity of diamond already follows the T^3 law at room temperature.

Measurements of the variation of the heat capacity with temperature, which have been carried out for a very large number of crystals, show that the theory is in very good agreement with experiment. At temperatures $T \ll \theta_c$ the heat capacities indeed follow the T^3 law and tend to zero as $T \rightarrow 0$. At $T \approx \theta_c$ a gradual transition to the classical (constant) value of the heat capacity takes place. The complete form of the curve of the heat capacity of some crystals is shown in fig. III.34. The small circles on the curve show the measured values of the heat capacity of different crystals.

Fig. III.34

They are all presented on the universal scale T/θ_c . The agreement of theory with experiment proves to be very good.

It should, however, be kept in mind that the rough theory developed holds only for crystals made of particles whose internal structure can be disregarded. This means that one can disregard the effect of the temperature on the state of the particles. In most cases this condition is satisfied by crystals made of atoms. In atoms the spacing between the ground state and the first excited state is as a rule large in comparison with kT , and thermal motion cannot have an effect on the state of atoms. Hence their internal energy does not depend on the temperature and they give no contribution to the heat capacity. However, for certain atoms the lowest electronic levels lie very close to each other. Thus, for example, for the ions of gadolinium which enter into crystalline gadolinium sulphate the lowest energy level consists of eight sublevels which are spaced at distances corresponding in the temperature scale to the characteristic temperature 1.6 K. At very low temperatures, $T \approx 7$ K, in accordance with the results of §40, there appears an additional heat capacity superposed on the heat capacity of the crystal lattice. Since at such low temperatures the heat capacity of the crystal lattice is already very small, the increase of the heat capacity is very sharp. At $T = 1.6$ K the additional heat capacity exceeds that of the crystal lattice by a factor of almost 500. As the temperature decreases further the heat capacity of the system falls to zero.

In the case of crystals made of complex molecules the internal structure of the particles cannot, as a rule, be disregarded. In the first approximation one

can disregard the effect of the vibration of a molecule in the crystal lattice on its internal thermal motion. The molecule as a whole is vibrating in the crystal lattice, while vibrations of individual atomic groups take place inside it. In certain cases the internal motion of the molecule represents a free rotation. Thus, for example, H_2 molecules must be considered as rotating freely in the hydrogen crystal. The rotating H_2 molecules take part simultaneously in the thermal vibrations of the lattice. Disregarding the interaction of the internal motion in molecules with the motion of the molecule as a whole, the total energy E of the crystal can be written in the form

$$E = E_{\text{lat}} + E_{\text{intern}} ,$$

where E_{lat} is the mean energy of the vibrations of the crystal lattice, and E_{intern} is the mean internal energy of the molecule, which we have calculated in ch. 5. Correspondingly, the heat capacity of the crystal can be written in the form

$$C_V = C_{V_{\text{lat}}} + C_{V_{\text{intern}}} .$$

The contribution of the internal motion to the heat capacity can be very substantial in certain cases. Thus, for example, the heat capacity of intramolecular vibrations in benzene amounts to about 20% of the heat capacity of the lattice at $T \approx 150$ K and reaches about 80% of the latter at $T \approx 270$ K. Hence in calculating the heat capacity of complex crystals it is necessary to take into account the contribution of the internal motion, particularly at high temperatures. Good agreement of the theory with experiment justifies the simplifications made.

However, in a number of cases disagreement, though not considerable, is observed between theory and experiment. At high temperatures vibrational amplitudes become large, and it is no longer justified to disregard the squares of displacements in the expression for quasi-elastic forces *. The vibrational motion loses its simple harmonic character. The error which arises as a result of the assumption of the isotropy of the elastic medium is relatively negligible. The error arising because the discrete character of the crystal is disregarded turns out to be more considerable. The effect of the distribution of high frequencies, which we have disregarded in determining the number of the

* In this connection it should be noted that, as can be shown by calculation, a crystal for which the forces were exactly proportional to the displacements would have a coefficient of thermal expansion equal to zero.

normal vibrations of the crystal, shows up in the fact that for hard crystals the characteristic temperature θ_c turns out not to be a constant but a function of the temperature of the crystal. For example, in the case of lithium its value changes from 330 K at a temperature of the crystal equal to 20 K to 410 K at a temperature of 120 K. A similar phenomenon occurs in the case of diamond. All the errors mentioned are so negligible that they have only been noticed relatively recently because of the increased accuracy of measurements.

It should also be noted that the existence of anomalies at low temperatures, which are similar to those existing for gadolinium, can lead to seeming contradictions with the third law of thermodynamics. Usually the value of the heat capacity as $T \rightarrow 0$ is found by an extrapolation from values which are measured at higher temperatures. If this extrapolation is carried out from a certain temperature which is higher than that at which the increase of the heat capacity occurs, then a considerable error arises. The value of $\int_0^T T^{-1} C_V dT$ obtained from the extrapolation can differ appreciably from the experimental value of the entropy at a high temperature found from other data. Hence in order to find the true values of thermodynamic functions it is advisable to carry out the measurements of the heat capacity at temperatures as low as possible.

The Theory of Fluctuations

§55. Small fluctuations in macroscopic systems

In the preceding discussions we have more than once pointed to a difference between the statistical and purely thermodynamic ideas on the nature of thermal processes. From the laws of statistical physics the existence of fluctuations necessarily follows. A system undergoing a fluctuation can pass spontaneously over from a more probable state into one of the less probable states. In this case the trend of the process is the reverse of that for which an increase in entropy occurs.

The probability of fluctuations in a closed system can be calculated by means of the Boltzmann formula. Simple estimations carried out by means of this formula, as well as the general considerations discussed in §36, show that the probability of any appreciable fluctuations in a system which contains a large number of particles is extremely low. The phenomenon of fluctuations can in practice be observed in two cases: (1) when the dimensions of the system are sufficiently small; in this case fluctuations will occur often and their scale will be relatively large; (2) when the dimensions of the system are not small, but rather small fluctuations occur. Such small fluctuations may occur often, but the departure of the system from an equilibrium state will be relatively small. In this chapter we shall consider both of these cases of fluctuations.

In order to estimate correctly the role which the investigations of fluctuations played in the development of molecular-statistical concepts, it should be kept in mind that the existence of fluctuations was predicted theoretically at the time when the second law of thermodynamics seemed to many to be one of the dogmas of physics. The representatives of the so-called school of energeticians denied the existence of material atoms and molecules. Statistical physics, in which the laws of classical mechanics were unified with statistical laws, seemed to be internally inconsistent, and was accepted with distrust by many physicists. Hence the discovery of numerous examples of fluctuation processes was a brilliant confirmation of the laws of statistical physics and was one of the most important events in the final establishment of molecular theory. In the studies by Einstein and Smoluchowski it was shown that a number of physical processes, which had been known for a long time, are due to fluctuation phenomena, and a quantitative theory of these processes was developed which proved to be in excellent agreement with experimental facts. The significance of these discoveries can best be expressed in the words of Smoluchowski himself *:

“At present we do not regard the dogmas of physics with the same esteem as before. Great changes concerning the problem of the significance of kinetic atomistics and thermodynamics have taken place. They are associated with the fact that we have only recently managed to interpret, on the basis of kinetic theory, facts which were known a long time ago; for example, Brownian motion discovered as far back as 1827, the phenomenon of critical opalescence discovered more than 20 years ago, the well-known blue coloration of the sky, and so on. The new thing which we encounter in these interpretations, and which is in contradiction with every-day established notions, lies in the fact that they were the first to take seriously into account the Maxwell velocity distribution law. As a result they were the first to consider heat as a process of motion, whereas before this the concept of the nature of heat was usually considered as a kind of poetic simile.”

We shall begin the consideration of fluctuation processes with the second case, i.e. the case of systems whose dimensions are large.

We shall below expound the general theory of small fluctuations occurring in an arbitrary macroscopic system. We take a closed system which is in a state of statistical equilibrium having an entropy S_0 . We now assume that the state of the system changes in such a way that it passes over into a non-equilibrium state in which its entropy is equal to S . We assume that the change in the state of the system can be characterized by a change in a certain internal

* M.Smoluchowski, Phys. Z. 13 (1912) 1059.

parameter ξ whose value depends on the state of the entire system. In an equilibrium state the parameter ξ has a value $\xi = \xi_0$, whereas in a non-equilibrium state its value differs from ξ_0 .

As an example of the parameter ξ one can take the density ρ of a gas confined in a closed, thermally insulated container. In an equilibrium state the density is constant over the entire volume of the container, i.e. $\xi_0 = \rho_0 = \text{const}$. As a result of a fluctuation the system can spontaneously go over into a non-equilibrium state with a variable density $\xi = \rho(x)$. Other examples will be discussed later.

The entropy of the system will be a function of the parameter ξ , so that one can write that $S = S(\xi)$. In an equilibrium state $S_0 = S(\xi_0)$. The probability that the closed system considered will get into a state characterized by a value of the parameter ξ which lies in the interval between ξ and $\xi + d\xi$ can be found by means of the Boltzmann formula:

$$dw = \text{const} \cdot \exp\left(\frac{S(\xi) - S(\xi_0)}{k}\right) d\xi = \text{const} \cdot \exp\left(\frac{\Delta S}{k}\right) d\xi, \quad (55.1)$$

where the constant is determined by the normalization condition *. The value of the change in the entropy is obviously negative.

The applications of formula (55.1) to actual cases of fluctuations will be considered in the following section. Formula (55.1) is applicable to fluctuations in a system with a constant energy.

However, one very often has to consider fluctuations occurring not in a closed, but a quasi-closed system which constitutes a small part of a closed system. Such a quasi-closed system can be considered as a subsystem placed in a reservoir with a constant temperature T_0 . We shall assume that fluctuations occur only in the subsystem, while the reservoir is always in an equilibrium state. The state of the subsystem will be characterized by the value of a certain external parameter λ . In going over from an equilibrium state to a non-equilibrium state the parameter λ changes from λ_0 to λ . As λ changes, the values of the thermodynamic quantities characterizing the subsystem also change. We shall assume that the variations of the macroscopic parameter λ are sufficiently slow, so that at every instant an equilibrium statistical distribution exists in the subsystem. Then we can consider that the thermodynamic quantities in the subsystem are interrelated by the usual

* Strictly speaking, the constant in (55.1) also depends on the parameter ξ . It can, however, be shown that for a system containing a sufficiently large number of particles the dependence on ξ of the factor which stands in front of the exponential is insignificant in comparison with the dependence on the exponential.

equilibrium relations. The process of the transition from an equilibrium state into a non-equilibrium state in a subsystem placed in a reservoir can be considered as a transition performed under the action of a certain external source of work. As the parameter λ changes by an amount $\Delta\lambda = \lambda - \lambda_0$ the source does work $\Delta W(\lambda)$ on the subsystem.

We now write an expression for the probability that the subsystem will go over into a state with a value of λ between λ and $\lambda + \Delta\lambda$ while the reservoir remains in an equilibrium state. Since the reservoir and subsystem together constitute a closed system, formula (55.1) is applicable to them. However, in it the change in the entropy must be written in the form

$$\Delta S = \Delta S_0 + \Delta S',$$

where $\Delta S'$ is the change in the entropy of the subsystem. Then the probability that the subsystem will go over into a state with λ lying in the interval $\lambda, \lambda + d\lambda$ under the action of the external source of work is given by the formula

$$dw = \text{const} \cdot \exp\left(\frac{\Delta S_0 + \Delta S'}{k}\right) d\lambda. \quad (55.2)$$

But, by virtue of our assumption of the slowness of the variation of the macroscopic parameters, one can write for $\Delta S'$ the usual equilibrium expression:

$$\Delta S' = \frac{\Delta E' + p_0 \Delta V' - \Delta W}{T_0}, \quad (55.3)$$

where T_0 and p_0 are the equilibrium temperature and equilibrium pressure of the system (which are equal to the corresponding quantities of the reservoir), and E' and V' are the energy and volume of the subsystem. (In the last formula it is seen clearly that ΔW represents the work done by an external source and not by the reservoir. The work done by the reservoir is equal to $-p_0 \Delta V'$.) Further,

$$\Delta S_0 = \frac{\Delta E_0 + p_0 \Delta V_0}{T_0}.$$

But by virtue of the fact that the system is closed (reservoir+subsystem) the total volume of the system remains constant, so that

$$\Delta V_0 = -\Delta V'.$$

The energy conservation law gives

$$\Delta E' + \Delta E_0 = 0,$$

hence

$$\Delta S_0 = -\Delta S' - \frac{\Delta W(\lambda)}{T_0}. \quad (55.4)$$

Substituting (55.4) into (55.2), we find

$$dw = \text{const} \cdot \exp \left(-\frac{\Delta W(\lambda)}{kT_0} \right) d\lambda. \quad (55.5)$$

Thus, in the most general case, it can be said that the work which must be done on a macroscopic system in order to change the parameter λ , characterizing the state of the system, by an amount $\Delta\lambda$ is a measure of the probability of small fluctuations in the system. This does not mean, however, that a system can undergo a fluctuation only when real work from without is done on it. This is particularly clearly seen from the example of a closed system on which no work is done. The work ΔW is only a quantitative characteristic of a fluctuation. The work ΔW can be written as the change in the potential energy as the system is displaced in a certain imaginary (and sometimes also real) field of force. Denoting the potential of this field by $u(\lambda)$, we have

$$\Delta W = u(\lambda) - u(\lambda_0) = u(\lambda),$$

if $u(\lambda_0)$ is chosen as the zero-point potential energy. Then formula (55.5) can be written in the form

$$dw = \text{const} \cdot \exp \left(-\frac{u(\lambda)}{kT_0} \right) d\lambda = w(\lambda) d\lambda. \quad (55.6)$$

We arrive thus at a formula which is an analogue of the Boltzmann formula. In what follows we shall see that this analogy has a completely clear meaning.

To calculate the probability of a fluctuation according to formulae (55.5) or (55.6) it is necessary in each individual case to find the work done or the change in the potential energy which takes place in the fluctuation process.

By virtue of the smallness of the fluctuations the expression for $u(\lambda)$ can be expanded in a power series of the small parameter $\lambda - \lambda_0$, and one can confine oneself to the first terms of the expansion:

$$u(\lambda) = u'(\lambda_0)(\lambda - \lambda_0) + \frac{1}{2}u''(\lambda_0)(\lambda - \lambda_0)^2 + \dots,$$

where the primes denote the derivatives with respect to λ . In an equilibrium state the potential energy of the field must have a minimum, so that

$$u'(\lambda_0) = 0 \quad \text{and} \quad u''(\lambda_0) > 0.$$

Hence the probability distribution (55.6) can be written in the form

$$dw = \text{const} \cdot \exp\left(-\frac{u''(\lambda_0)(\lambda - \lambda_0)^2}{2kT_0}\right) d\lambda. \quad (55.7)$$

The probability distribution (55.7) is called the Gaussian distribution. The value of the constant $u''(\lambda_0)$ depends on the nature of that real or fictitious field of force in which the system is "displaced" from the position λ_0 to the position λ . By means of the probability distribution of small fluctuations (55.7) one can find the mean value of the fluctuation of the parameter λ :

$$\Delta^2 = \overline{(\lambda - \lambda_0)^2} = \text{const} \int (\lambda - \lambda_0)^2 \exp\left(-\frac{u''(\lambda_0)(\lambda - \lambda_0)^2}{2kT_0}\right) d\lambda.$$

The constant in (55.7) is determined by the normalization condition

$$\text{const} = \left[\int \exp\left(-\frac{u''(\lambda_0)(\lambda - \lambda_0)^2}{2kT_0}\right) d\lambda \right]^{-1}.$$

Thus,

$$\Delta^2 = \frac{\int (\lambda - \lambda_0)^2 \exp\left(-\frac{u''(\lambda_0)(\lambda - \lambda_0)^2}{2kT_0}\right) d\lambda}{\int \exp\left(-\frac{u''(\lambda_0)(\lambda - \lambda_0)^2}{2kT_0}\right) d\lambda}. \quad (55.8)$$

The fluctuations of the parameter λ occur in both directions from its value in an equilibrium state. Since the integrand in the integrals in the numerator and denominator of the expression (55.8) rapidly decreases with increasing

absolute value of the difference $\lambda - \lambda_0$, the integration can be carried out in the range from $-\infty$ to $+\infty$, as we have done in normalizing the Maxwell distribution. Thus, finally,

$$\Delta^2 = \frac{\int_{-\infty}^{\infty} (\lambda - \lambda_0)^2 \exp \left(-\frac{u''(\lambda_0)(\lambda - \lambda_0)^2}{2kT_0} \right) d\lambda}{\int_{-\infty}^{\infty} \exp \left(-\frac{u''(\lambda_0)(\lambda - \lambda_0)^2}{2kT_0} \right) d\lambda} = \frac{kT_0}{u''(\lambda_0)}. \quad (55.9)$$

By means of formula (55.9) the probability distribution (55.7) can be written in the form

$$dw = (2\pi\Delta^2)^{-\frac{1}{2}} \exp \left(-\frac{(\lambda - \lambda_0)^2}{2\Delta^2} \right) d\lambda.$$

The probability of a given fluctuation decreases sharply with its increasing value, as well as with decreasing Δ^2 . The latter quantity is proportional to the absolute temperature. Hence it can be stated that the intensity of fluctuations decreases with decreasing temperature *.

In the following sections the general relations obtained will be applied to concrete cases of small fluctuations in macroscopic systems.

§56. Brownian motion

As the first case where fluctuations turn out to be easily observable we shall consider the so-called Brownian motion. Brownian motion is the continuous chaotic motion of small particles suspended in a liquid or a gas which may be observed under a microscope.

A complete quantitative theory of Brownian motion, which not only explained its nature but also allowed one to predict a number of its characteristic features, was developed in the studies of Einstein and Smoluchowski (1905–1906). The investigations of Brownian motion played a major role in the triumph of the molecular-kinetic theory because Brownian motion was the first physical process in which the existence of molecules was detected in a direct and obvious way. The significance and importance of the theory of Brownian motion are not confined to the historical aspect. On the contrary, it

* For an exception to this rule see B.G. Levich, *Vvedenie v statisticheskuyu fiziku (Introduction to statistical physics)* (Gostekhizdat, Moscow, 1954) § 63.

is only relatively recently that a number of cases of Brownian motion have become of particular interest in association with the creation of new, very accurate measuring devices (see § 58).

Passing on to the analysis of the theory of Brownian motion, we shall consider a macroscopic particle suspended in a volume of liquid or gas, and shall seek the forces acting on it due to the molecules of the medium. The molecules of the medium are in continuous thermal motion. Hence the molecules of the liquid or gas in which the particle is suspended will continually collide with the particle and transfer momentum to it in each collision. In other words, the molecules of the medium will exert a pressure on the surface of the particle. The collisions of the molecules with the surface of the particle are completely random, from all directions. If the surface of the particle is sufficiently large, so that a large number of molecules impinge on it in a very short time interval, then it can be assumed that the momenta which are transferred to the particle from all directions are, on the average, balanced. The situation is different in the case of very small particles (with a size of the order of 10^{-4} cm). Such particles still contain an enormous number of molecules and are macroscopic bodies. Nevertheless, the surface of such particles is so small that in a short time a relatively small number of molecules impinge on it. The resultant of the forces exerted by the molecules of the medium on the surface of the particle turns out to be different from zero. As a result the particle will be given a random motion whose direction and velocity will vary at a very high frequency (of the order of 10^{12} times per second). The character of the displacements is shown in fig. III.35, in which the position

Fig. III.35

of the particle every 30 seconds is drawn. The side of each square corresponds to a distance of 3×10^{-4} cm.

The number of molecules striking the particle and the momentum which they transfer to the particle will undergo large fluctuations. Thus, the Brownian motion is due to the fluctuations of the pressure exerted by the molecules of the medium on the particle suspended in it. Although its motion is not directly a molecular motion, it serves as a kind of indicator of molecular motion. As we have more than once stressed, the phenomena of fluctuations contradict the propositions of pure thermodynamics. This can be illustrated particularly clearly by the example of Brownian motion.

The very fact of the persistence of Brownian motion and the impossibility of abolishing it points to the continuous violation of the requirements of the second law of thermodynamics. Indeed, if a particle suspended in a medium obtained a single momentum from any external source, then its motion would rapidly be slowed down as a result of the energy loss due to viscous friction. Hence the impossibility of abolishing Brownian motion is indicative of the existence of processes which are the reverse of the processes of viscous friction and which are accompanied by a decrease in the entropy. To maintain its motion the particle continuously draws energy from the medium surrounding it, which directly contradicts the second law of thermodynamics.

In order to construct a quantitative theory of Brownian motion we can make use of the general relations introduced in the preceding paragraph.

Let a very small but macroscopic particle with mass μ be suspended in a certain medium, a liquid or a gas. We assume that the position of this particle is characterized by a certain parameter (a generalized coordinate) λ . Such a parameter can be, for example, the distance of the particle from a certain plane of the container which is chosen as the origin (other examples will be given below). The particle will be acted upon on the part of the medium by a force which varies rapidly and randomly in time and is due to the fluctuations of the thermal motion of the molecules of the medium. Under the action of this fluctuation force, which we shall call for brevity Brownian force, the particle will undergo very small displacements, so that the value of its parameter λ will vary continually by very small amounts $\Delta\lambda$.

Instead of observing the motion of one particle in time one can, following Einstein, consider a great number of identical particles undergoing Brownian displacements, and find the number of particles passing through a certain imaginary surface in the medium.

We denote by $c(\lambda)$ the number of particles per unit volume which are at a distance between λ and $\lambda + d\lambda$ from the surface $\lambda = 0$.

Let $\Delta = [(\Delta\lambda)^2]^{1/2}$ denote the mean square displacement of particles in a

certain short time τ . Then on the average $[\frac{1}{2}c(\lambda - \frac{1}{2}\Delta)]\Delta$ particles moving from left to right will pass through 1 cm^2 of an imaginary surface in the solution during the time τ . Analogously, $[\frac{1}{2}c(\lambda + \frac{1}{2}\Delta)]\Delta$ particles moving in the opposite direction will pass through this surface in the same time. As a result the following number of particles will pass through 1 cm^2 of the imaginary surface:

$$N = j\tau = [\frac{1}{2}c(\lambda - \frac{1}{2}\Delta) - \frac{1}{2}c(\lambda + \frac{1}{2}\Delta)]\Delta, \quad (56.1)$$

where j is the particle flux.

Assuming Δ to be small and $c(\lambda)$ to be a slowly varying function of the coordinate λ , we can write

$$N \approx -\frac{\Delta^2}{2} \frac{\partial c}{\partial \lambda}$$

or

$$j = -\frac{\Delta^2}{2\tau} \frac{\partial c}{\partial \lambda}. \quad (56.2)$$

The flux of particles is proportional to the gradient of their concentration and is directed in the direction of the decrease of the concentration. The factor of proportionality $\Delta^2/2\tau$ is called the diffusion coefficient D :

$$D = \frac{\Delta^2}{2\tau}. \quad (56.3)$$

Thus, the mean square displacement of the particle is equal to

$$\Delta^2 = \overline{(\Delta\lambda)^2} = 2D\tau. \quad (56.4)$$

The mean part traversed by the particle turns out to be proportional to the square root of the observation time τ .

The diffusion coefficient D can be expressed in terms of the temperature and physicochemical constants of the medium. That is, we assume that the flux of particles is due not only to the gradient of concentration but also to an external force \mathbf{f} acting on every one of the particles.

Under the action of a force \mathbf{f} a small particle in a viscous medium moves with a velocity \mathbf{u} which for steady motion is equal to

$$\mathbf{u} = b\mathbf{f} = \frac{\mathbf{f}}{C\eta a}, \quad (56.5)$$

where $b = (C\eta a)^{-1}$ is a quantity called the mobility of the particle, a is its radius, η is the viscosity of the medium, and C is a numerical coefficient equal to 6π for spherical particles. Formula (56.5) is called the Stokes formula. A simple calculation shows that the time required to establish steady motion is very short for small particles.

The total flux of particles can be written in the form

$$j = -D \frac{\partial c}{\partial \lambda} + uc \quad (56.6)$$

or

$$j = -D \frac{\partial c}{\partial \lambda} + bfc = -D \frac{\partial c}{\partial \lambda} - bc \frac{\partial U}{\partial \lambda}, \quad (56.7)$$

where U is the potential energy corresponding to the force \mathbf{f} .

We now assume that the flux of particles caused by the external field has the same value as that produced by the gradient of concentration but the opposite direction. Then the total flux of particles j reduces to zero. In this case the particle concentration distribution is determined by the condition

$$-D \frac{\partial c}{\partial \lambda} - bc \frac{\partial U}{\partial \lambda} = 0$$

or

$$c = c_0 e^{-bU/D}. \quad (56.8)$$

On the other hand, we know that particles which do not interact with each other follow, in an external field, the Boltzmann distribution, and

$$c = c_0 e^{-U/kT}. \quad (56.9)$$

Comparing these last expressions, we find

$$D = bkT. \quad (56.10)$$

Thus, the diffusion coefficient of particles is connected with their mobility by the universal formula (56.10), which for spherical particles assumes the form

$$D = \frac{kT}{6\pi\eta a}. \quad (56.11)$$

Substituting the value of D from (56.11) into (56.4), we find

$$\Delta = [(\Delta\lambda)^2]^{1/2} = \left(\frac{kT}{3\pi\eta a}\right)^{1/2} \tau^{1/2}. \quad (56.12)$$

Thus, the mean path traversed by particles increases with the temperature of the medium.

All the quantities contained in formula (56.12) are known or can be measured. It should be noted that the value of the Boltzmann constant k was at one time determined from formula (56.12). The degree of agreement of these formulae with experiment can be estimated from the fact that in 1910–1915 the value of Avogadro's number $N = R/k$ found from measurements of Brownian motion ($N = 6.44 \times 10^{23}$) was considered to be one of the most accurate values of this quantity.

Experiments on Brownian motion demonstrated in a direct and obvious way one more important inference of statistical mechanics. That is, the statement on the reversibility of molecular processes. The experiments consisted of observing the number of Brownian particles in a sharply limited (for example, by the corresponding illumination) field of view under a microscope. Owing to the Brownian motion, particles enter and leave the field of observation from the non-illuminated part of the solution. Let us assume that at a certain instant of time the concentration of Brownian particles in the field of observation was higher than in the remaining solution. According to the second law of thermodynamics equalization of concentration must then take place by means of the diffusion of particles from the illuminated volume to the non-illuminated one. After the final equalization of concentrations in the system a total equilibrium must be established which should not subsequently be violated. From the point of view of statistical physics the phenomenon should proceed in a completely different way. The number of particles in a sufficiently small volume should increase and decrease equally frequently, so that the notions of diffusion and equalization of concentrations would lose any meaning. After the lapse of a recovery time τ^* the number of particles which was initially equal, say, to n , should come back

to the same value. The length of the recovery time was calculated by Smoluchowski. As we have mentioned already, it increases sharply with the size of the system, in the case given with the value of the number n . The results of the observations are given in tables 9 and 10.

Table 9
Observed frequency of variation of the number of particles $n \rightarrow m$ in the viewing field

n	$m=0$	$m=1$	$m=2$	$m=3$	$m=4$	$m=5$	$m=6$
0	210	126	35	7	0	1	—
1	134	281	117	29	1	1	—
2	27	138	108	63	16	3	—
3	10	20	76	38	24	6	0
4	2	2	14	22	13	11	3
5	—	0	2	10	10	1	3

Table 10
Mean recovery time

Observation time	$\tau^*(\text{obs.})$	$\tau^*(\text{cal.})$
0	6.1	5.5
1	3.1	3.2
2	4.1	4.0
3	7.8	8.1
4	18.6	20.9

In the first table the frequency of variation of the number of particles in the field of observation is given. The number of particles in this field in the first observation is denoted by n , while m denotes the number of particles in a subsequent observation. The frequency of a transition $n \rightarrow m$ means the number of cases in which n was replaced by m . For example, the number 27 in the third row of the second column of table 9 means that in 27 cases the number of particles which in the first observation was equal to two in the second observation reduced to zero. The mean number of particles which should have been found in the field of view amounted to $\bar{n} = 1.43$. The measurements were carried out in time intervals $\Delta t = 1.39$ sec.

An analysis of the numbers of table 9 indicates immediately the correct-

ness of the statistical point of view, and serves as a direct illustration of the reasoning of § 25. Indeed, according to the propositions of thermodynamics, we should expect a continuous decrease of the number of particles ($m < n$) in the case where the initial value $n > \bar{n}$, and an increase of the number of particles in the reverse case. Nothing of the sort is found in table 9. On the contrary, for $n > \bar{n}$, in subsequent observations an even larger number of particles is very often observed. Thus, for $n = 3$ a smaller number of particles ($m=0,1,2$) is observed in 106 cases in the second observation, and a larger or the same number of particles ($m=3,4,5$) is observed in 68 cases.

From table 9 it is seen that for a small number of particles the numbers which stand on the two sides of the major diagonal are practically equal to each other. For example, the frequency of the transition from $n = 3$ to $m = 0$ amounts to 10. The frequency of the transition from $n = 0$ to $m = 3$ is equal to 7. The frequency of the transition from $n = 2$ to $m = 4$ is equal to 16, while that from $n = 4$ to $m = 2$ is equal to 14, and so on. This means that the process of Brownian motion has a strictly reversible character. Fluctuations occur so frequently that no systematic trend of them with time is observed. If, however, the number of particles n is considerable, so that the scale of fluctuations is large, then in correspondence with the reasoning of § 25 a resolution of the fluctuations can be expected. In this case the most probable trend of the process is the same as that predicted by thermodynamics: particles will most often go out (diffuse) of the observation zone, and the number of particles in it should in most cases decrease.

From table 9 it is seen that for $n = 5$ (such an n already sufficiently substantially exceeds \bar{n}) the number of particles decreases in 22 cases and only in 4 cases does it increase or remain constant. If the number of particles n were very large and very much exceeded the mean number \bar{n} , then it would decrease in an overwhelming majority of cases, and the process would become irreversible.

The data of table 10 are no less convincing. This table gives the calculated and observed times of recovery of the number of particles in the observation field (in units of $\Delta t = 1.39$ sec) for a suspension with a mean number of particles $\bar{n} = 1.55$. From the table it is seen that after the lapse of time intervals τ^* , which are in good agreement with those calculated theoretically, the number of particles initially found in the field of view again recurs. The recovery time increases sharply with the value of the departure of n from \bar{n} , so that large fluctuations are very seldom repeated (see also table 9). All these facts are convincingly indicative of the validity of the molecular-statistical point of view.

§57. Fluctuations of thermodynamic quantities in a homogeneous system

We shall now consider the fluctuations of thermodynamic quantities with reference to a system in a reservoir.

A quantitative measure of the probability of a fluctuation is the work which must be done on the subsystem in order to bring it from the initial equilibrium state into the final fluctuation state.

Because of the smallness of the fluctuations the transitions can be assumed to be reversible.

The work done in a reversible transition for a system in a medium is expressed by the general thermodynamic formula (28.7):

$$\Delta W = \Delta E - T_0 \Delta S + p_0 \Delta V, \quad (57.1)$$

where ΔE , ΔS and ΔV are the changes in the corresponding quantities for the transition from the initial to the final state. A concrete expression for the work ΔW can be obtained for particular cases of the process.

We shall confine ourselves to the calculation of this work for fluctuations of the volume at a constant temperature and fluctuations of the temperature at a constant volume.

We shall first of all consider the fluctuations of the volume at a constant temperature ($T = T_0 = \text{const}$).

The work done in an isothermal change in the volume at a constant temperature is equal to

$$\Delta W = \Delta E - \Delta(TS) + p_0 \Delta V = \Delta F + p_0 \Delta V. \quad (57.2)$$

It should be stressed that formula (57.2) shows that the work ΔW represents the work done on the subsystem by an external source of work (but not by the medium).

For a small isothermal change in the volume ΔV the free energy in formula (57.2) can be expanded in a series in powers of ΔV , and rewritten in the form

$$\begin{aligned} \Delta W &= p_0 \Delta V + \left(\frac{\partial F}{\partial V} \right)_T \Delta V + \left(\frac{\partial^2 F}{\partial V^2} \right)_T \frac{(\Delta V)^2}{2} + \dots \approx \\ &\approx p_0 \Delta V - p \Delta V - \left(\frac{\partial p}{\partial V} \right)_T \frac{(\Delta V)^2}{2}. \end{aligned} \quad (57.3)$$

Since the process can be considered as quasi-static, in the process of fluctua-

tion the equilibrium pressure in the subsystem can be assumed to be equal to the pressure in the medium. Hence we find finally

$$\Delta W = - \left(\frac{\partial p}{\partial V} \right)_T \frac{(\Delta V)^2}{2}. \quad (57.4)$$

Substituting (57.4) into (55.5), we find the probability for the volume V to lie between V and $V + dV$:

$$dw = \text{const} \cdot \exp \left[\left(\frac{\partial p}{\partial V} \right)_T \frac{\Delta V^2}{2kT} \right] dV. \quad (57.5)$$

The constant is found from the normalization condition:

$$\text{const} \cdot \int_{-\infty}^{\infty} \exp \left[\left(\frac{\partial p}{\partial V} \right)_T \frac{(\Delta V)^2}{2kT} \right] dV = 1. \quad (57.6)$$

From formulae (57.5) and (57.6) it follows that the derivative $(\partial p / \partial V)_T$ must be negative. If this condition turned out to be unfulfilled, the probability of fluctuation would not decrease but increase with its magnitude. In such a substance there would occur volume fluctuations as a result of which the volume of the system would indefinitely increase or decrease down to zero. The substance would be in an unstable state. Thus, the condition of stability of the states of a homogeneous substance is given by the formula

$$\left(\frac{\partial p}{\partial V} \right)_T < 0. \quad (57.7)$$

If condition (57.7) is fulfilled, the integral (57.6) can easily be calculated. Then

$$\text{const} = \left(\frac{2\pi kT}{|(\partial p / \partial V)_T|} \right)^{-\frac{1}{2}}.$$

The normalized probability distribution of isothermal volume fluctuations has the form

$$dw = \left(\frac{|(\partial p / \partial V)_T|}{2\pi kT} \right)^{\frac{1}{2}} \exp \left[- \left| \left(\frac{\partial p}{\partial V} \right)_T \right| \frac{(V - V_0)^2}{2kT} \right] dV. \quad (57.8)$$

By means of the probability distribution (57.8) we find the mean square fluctuation of the volume $(\Delta V)^2 = \overline{(V - V_0)^2}$. Obviously, we have

$$\begin{aligned} \overline{(\Delta V)^2} &= \overline{(V - V_0)^2} = \\ &= \left(\frac{|\partial p / \partial V|_T}{2\pi kT} \right)^{\frac{1}{2}} \int_{-\infty}^{\infty} (V - V_0)^2 \exp \left(- \left| \left(\frac{\partial p}{\partial V} \right)_T \right| \frac{(V - V_0)^2}{2kT} \right) dV = \\ &= \frac{kT}{|\partial p / \partial V|_T}. \end{aligned} \quad (57.9)$$

Introducing the value of $\overline{(\Delta V)^2}$ into the distribution (57.8), one can rewrite it in a more compact form:

$$dw = [2\pi \overline{(\Delta V)^2}]^{-\frac{1}{2}} \exp \left[- \frac{(V - V_0)^2}{2 \overline{(\Delta V)^2}} \right] dV. \quad (57.10)$$

It follows from formulae (57.9) and (57.10) that the scale and probability of fluctuations increase with increasing temperature of the substance, as well as with increasing isothermal compressibility.

We apply formula (57.9) to the case of an ideal gas:

$$\overline{(\Delta V)^2} = \frac{kT}{|\partial p / \partial V|_T} = \frac{V^2 kT}{NkT} = \frac{V^2}{N}. \quad (57.11)$$

In what follows we shall be interested in the value of the mean square fluctuation of the density $\rho = v_0^{-1} = mV^{-1}$ (where m is the mass contained in the volume V in which the fluctuation takes place). We have

$$\overline{(\Delta \rho)^2} = m^2 \overline{\left(\Delta \frac{1}{V} \right)^2} = \frac{m^2}{V^4} \overline{(\Delta V)^2} = \frac{m^2}{V^2} \frac{kT}{V^2 |\partial p / \partial V|_T} = \frac{\rho^2}{V} kT \gamma_T,$$

where γ_T is the isothermal compressibility. The relative density fluctuation in the volume V is equal to

$$\overline{\left(\frac{\Delta \rho}{\rho} \right)^2} = \frac{kT \gamma_T}{V}. \quad (57.12)$$

We shall also find the fluctuation of the number of particles confined in a given volume. The quantity $(\Delta V)^2$ represents the mean square fluctuation of

the volume V of the system which contains N particles. The fluctuation of the volume per particle V/N is equal to

$$\overline{\left(\Delta \frac{V}{N}\right)^2} = \frac{kT}{N^2 |(\partial p / \partial V)_T|}.$$

Assuming the volume V to be fixed, we find the fluctuation of the number of particles in this volume:

$$\overline{(\Delta N)^2} = \frac{N^2 kT}{V^2 |(\partial p / \partial V)_T|}. \quad (57.13)$$

In particular, for an ideal gas

$$\overline{(\Delta N)^2} = N. \quad (57.14)$$

The independence of the fluctuation of the number of particles in a given volume on the temperature of the ideal gas is associated with the fact that in an ideal gas the motion of each particle is independent of the motion of other particles. With increasing temperature in an ideal gas only the mean square velocity increases, but the character of the motion does not change.

Formulae (57.8) and (57.9) lose their meaning in the case where the isothermal compressibility becomes infinite (and the derivative $(\partial p / \partial V)_T$ reduces to zero). A formal application of formula (57.9) leads to an absurd result: an infinitely large fluctuation of the volume. In reality, however, when the derivative $(\partial p / \partial V)_T$ reduces to zero the expression (57.4) for the work ΔW , on which the derivation of formula (57.9) is based, changes. The expansion of (57.3) must be continued, so that instead of (57.3) we must write

$$\begin{aligned} \Delta W &\approx p_0 \Delta V + \left(\frac{\partial F}{\partial V}\right)_T \Delta V + \left(\frac{\partial^2 F}{\partial V^2}\right)_T \frac{(\Delta V)^2}{2} + \left(\frac{\partial^3 F}{\partial V^3}\right)_T \frac{(\Delta V)^3}{6} + \dots \approx \\ &\approx p_0 \Delta V - p \Delta V - \left(\frac{\partial p}{\partial V}\right)_T \frac{(\Delta V)^2}{2} - \left(\frac{\partial^2 p}{\partial V^2}\right)_T \frac{(\Delta V)^3}{6}. \end{aligned} \quad (57.15)$$

We assume that the second derivative $(\partial^2 p / \partial V^2)_T$ is different from zero. Then, dropping infinitesimal quantities of higher order in (57.15), one can write

$$\Delta W = - \left(\frac{\partial^2 p}{\partial V^2}\right)_T \frac{(\Delta V)^3}{6}. \quad (57.16)$$

Substituting (57.16) into the normalization condition (57.6), we see that it cannot be satisfied for any value of the constant $(\partial^2 p / \partial V^2)_T$. This means that the assumption that the condition $(\partial^2 p / \partial V^2)_T \neq 0$ can be fulfilled for $(\partial p / \partial V)_T = 0$ leads to a contradiction.

Hence it is seen that if $(\partial p / \partial V)_T = 0$, then at the same time the condition

$$\left(\frac{\partial^2 p}{\partial V^2} \right)_T = 0. \quad (57.17)$$

must be fulfilled.

These two conditions determine the position of the critical point (see §64).

At the critical point the probability of a density fluctuation turns out to be considerably higher than in the ordinary state of substances, because here the work done in an isothermal change in the volume is very small.

It should, however, be stressed that for finding a quantitative expression for the probability distribution of fluctuations at the critical point the use of formula (55.5) with the substitution of the expansion (57.15) in it would be incorrect.

In the critical state of a substance its compressibility is so large that small forces have a great effect. Because of this, fluctuations here are not only large but, what is most important, lose their local character. This means that it is senseless to make a statement about the volume fluctuation at a given point of the substance*.

Now consider the fluctuations of the temperature of a subsystem at constant volume. The work which should be done on the subsystem in order to bring it from an equilibrium state with temperature T_0 into a non-equilibrium state with temperature T is equal to

$$\Delta W = \Delta E - T_0 \Delta S.$$

We expand the energy change ΔE in a series in powers of ΔS and confine ourselves to the first terms of the expansion. Since the energy is a potential with respect to the entropy and volume, we have

* The theory of fluctuations for a substance at the critical point cannot be expounded in this book. The reader is referred to the following book: L.D.Landau and E.M.Lifshitz, *Course of theoretical physics, Vol. 5: Statistical physics* (Pergamon Press, London, 1958).

$$\Delta E \approx \left(\frac{\partial E}{\partial S} \right)_V (\Delta S) + \left(\frac{\partial^2 E}{\partial S^2} \right)_V \frac{(\Delta S)^2}{2} = T_0 \Delta S + \left(\frac{\partial T}{\partial S} \right)_V \frac{(\Delta S)^2}{2}.$$

But

$$\Delta S = \left(\frac{\partial S}{\partial T} \right)_V \Delta T.$$

Hence, finally,

$$\begin{aligned} \Delta W &= T_0 \Delta S + \left(\frac{\partial T}{\partial S} \right)_V \frac{(\Delta S)^2}{2} - T_0 \Delta S = \\ &= \left(\frac{\partial T}{\partial S} \right)_V \left(\frac{\partial S}{\partial T} \right)_V \frac{(\Delta T)^2}{2} = \left(\frac{\partial S}{\partial T} \right)_V \frac{(\Delta T)^2}{2} = \frac{C_V}{2T_0} (\Delta T)^2. \end{aligned}$$

The probability that the temperature of the subsystem will undergo a fluctuation and that its temperature will lie between T and $T + dT$ is equal to

$$dw = \text{const} \cdot \exp \left(-\frac{C_V(T-T_0)^2}{2kT_0} \right) dT. \quad (57.18)$$

Normalizing the distribution (57.18), we find

$$dw = \left(\frac{C_V}{2\pi kT_0^2} \right)^{\frac{1}{2}} \exp \left(-\frac{C_V(T-T_0)^2}{2kT_0^2} \right) dT. \quad (57.19)$$

From the distribution (57.19) it follows that the heat capacity of a homogeneous substance at constant volume must be an essentially positive quantity. Otherwise the substance would be in an unstable state. Thus, in addition to (57.7) we obtain the second condition of stability of the states of a homogeneous substance:

$$C_V > 0. \quad (57.20)$$

If the heat capacity of the body were negative, then the body could be heated taking heat away from it. In other words, a perpetual motion machine of the second kind could be constructed.

It can be shown that the fluctuations of the volume and temperature are independent. Without dwelling on a strict proof of this statement, we note

only that it also follows from general physical reasoning. The state of a homogeneous body is completely determined by three thermodynamic parameters which are interconnected by one relation: the equation of state. Hence changes in two thermodynamic parameters in a homogeneous body can always take place independently of each other. In a homogeneous substance the conditions (57.7) and (57.20) are sufficient for the stability of the states of the system. It should be noted that the necessary conditions for stability are the constancy of the temperature and pressure in a homogeneous system.

In conclusion we note that the conditions of stability which we have obtained are not necessarily fulfilled in a non-homogeneous system, for example in a system placed in a field of force, or in a system consisting of several phases. In this case the state of the system depends, for example, on the strength of the external field as well as the parameters p , T , S and V , and other quantities. Hence the expressions for the work done in a fluctuation and the conditions of stability will be changed.

§58. Effect of fluctuations on the sensitivity of measuring devices

Fluctuations play an important role in the operation of modern sensitive instruments: balances, galvanometers, etc. The sensitivity of such devices is so high that they allow one to observe phenomena of the same scale as fluctuations caused by the thermal motion of molecules in the device itself. This leads to an important consequence: in a single direct measurement of a physical quantity whose value is smaller than the fluctuations of the device itself, the latter records its proper thermal motion (background) and not the quantity to be measured. In this sense it is said that the thermal motion imposes a limit of sensitivity upon a given form of the device (for a single measurement).

A further increase of the sensitivity and the measurements of quantities which lie below the thermal motion background are associated with carrying out repeated measurements (or with a change in the construction of the device).

Indeed, if a device records only its proper thermal motion, then its mean deflection will be equal to zero. But if an external action is superposed on the background, then the device will fluctuate about a new position, and its mean deflection will be different from zero. The larger the number of measurements carried out, i.e. the longer the observation time, the lower the values of a physical quantity (lying below the background) which can be measured.

We shall illustrate this by the analysis of several simple examples.

A suspended small mirror. One of the simplest and most sensitive devices is a light small mirror suspended on a fine filament, usually of quartz. The sensitivity of the device is determined by the possibility of recording very small angles of rotation of the mirror on the filament. The limit of sensitivity, i.e. the smallest angles of rotation which can be recorded in single measurements are determined by the fact that they must be larger than the oscillations of the mirror caused by the thermal motion of the molecules of the mirror and filament. This thermal motion leads to random rotations of the suspended mirror through angles whose order of magnitude is determined by the value of the mean square angle of rotation. We shall calculate this quantity.

In order that the mirror "randomly", i.e. under the action of the molecular thermal motion, be deflected from the equilibrium position $\varphi = 0$ through a certain angle φ , it is necessary that work be done against the elastic forces of the filament. This work is produced on account of the energy of the thermal motion. The angle φ plays the role of the parameter determining the deflection of the system from the equilibrium position. The probability of the deflection of the system from the equilibrium position $\varphi = 0$ through an angle φ is determined by formula (55.6) in which the potential energy of the torsion of the filament will stand for the potential energy. For small angles of rotation

$$u(\varphi) = \frac{1}{2}a\varphi^2,$$

where $a = \pi^2 r^2 G / 2l$ (here r is the radius of the filament, l is its length, and G is the shear modulus of the material of the filament).

Thus,

$$dw = \text{const} \cdot e^{-a\varphi^2/2kT} d\varphi = \frac{e^{-a\varphi^2/2kT} d\varphi}{\int_{-\infty}^{\infty} e^{-a\varphi^2/2kT} d\varphi}. \quad (58.1)$$

Here the constant is determined from the normalization condition.

The mean square angle of the deflection is equal to

$$\overline{\varphi^2} = \frac{\int_{-\infty}^{\infty} \varphi^2 e^{-a\varphi^2/2kT} d\varphi}{\int_{-\infty}^{\infty} e^{-a\varphi^2/2kT} d\varphi} = \frac{kT}{a}.$$

This result has a simple meaning: the mean potential energy of our system with one degree of freedom is equal to

$$\bar{u} = \overline{\frac{1}{2}a\varphi^2} = \frac{1}{2}kT \quad (58.2)$$

in accordance with the law of equipartition. For $T = 300$ K and $a = 10^{-6}$ erg (such a value of a is possessed by very fine quartz filaments) we have $(\varphi^2)^{\frac{1}{2}} = 2 \times 10^{-4}$. This quantity determines the angle through which the small mirror rotates, one the average, "by itself". If a quantity measured from a deflection of the mirror causes a rotation through a smaller angle, then in a single measurement it is the proper deflection due to thermal motion which is recorded.

It is clear, however, that in the absence of a systematic deflection force the mean deflection of the small mirror will be equal to zero, while in the presence of such a force the mirror will undergo oscillations about a displaced position of equilibrium. Carrying out repeated measurements of the oscillations of the small mirror one can find the mean position about which the oscillations take place. By this means one can determine a quantity whose values lie below the thermal background or sensitivity for a single measurement.

Spring-balance. Completely analogous results can be obtained for the spring-balance. The pressure fluctuations of the air surrounding it and the thermal motion of the mechanism of the balance will lead to random changes in the load of the balance. This change in the load will be compensated for by a quasi-elastic force $\kappa \Delta x$. The change in the potential energy of the system for a displacement by Δx is equal to

$$u = \frac{1}{2}\kappa(\Delta x)^2.$$

The mean potential energy, according to the law of equipartition, is equal to $\frac{1}{2}kT$. Hence the mean change in the length of the spring is equal to

$$[(\Delta x)^2]^{\frac{1}{2}} = (kT/\kappa)^{\frac{1}{2}}. \quad (58.3)$$

The measurement of a mass m by the balance is possible if the extension of the spring caused by it is larger than the length fluctuation $[(\Delta x)^2]^{\frac{1}{2}}$ of the spring. The extension of the spring by a load m is equal to $\Delta x = mg/\kappa$. Hence the limiting small mass which can be found in a single measurement is equal to

$$m \approx \kappa g^{-1} [(\Delta x)^2]^{\frac{1}{2}} = (kT\kappa)^{\frac{1}{2}} g^{-1}.$$

Gas thermometer. Suppose that we are measuring a temperature using a gas thermometer filled with an ideal gas. The temperature measured by the ther-

momenter will not remain constant but will continuously undergo fluctuations just as other thermodynamic quantities.

In an ideal gas the fluctuation of the temperature can easily be expressed in terms of the fluctuation of the volume. From the Clapeyron equation it follows that

$$\Delta T = \frac{p \Delta V}{Nk} = \frac{T}{V} \Delta V,$$

where ΔT and ΔV denote small changes in the temperature and volume. If small changes in the volume are understood to be changes due to fluctuations, then one can write

$$\Delta V = [\overline{(\Delta V)^2}]^{\frac{1}{2}} = \left(\frac{kT}{(-\partial p / \partial V)_T} \right)^{\frac{1}{2}} = \frac{V}{N^{\frac{1}{2}}},$$

so that

$$\Delta T = [\overline{(\Delta T)^2}]^{\frac{1}{2}} = TV^{-1} \Delta V = TN^{-\frac{1}{2}}.$$

Changes in the temperature which are smaller than ΔT cannot be measured by means of a gas thermometer. If the thermometer contains altogether 10^{-4} mole of a gas (i.e. if its volume is 0.02 litre), then $N = 6 \times 10^{23} \times 10^{-4} = 6 \times 10^{19}$, so that the minimal measurable change in the temperature is

$$\Delta T \approx 10^{-10} T.$$

This is so small that all really measurable changes in the temperature are extremely large in comparison with the limit of sensitivity.

Thus, the sensitivity of a gas thermometer is not in practice limited by fluctuations in the temperature. The examples given show that the effect of fluctuations on the sensitivity of devices varies widely depending on the character of the device.

Systems with a Variable Number of Particles

§59. The Gibbs grand canonical distribution

In considering in §13 the interaction of a subsystem with the bodies surrounding it (the reservoir) we have assumed that this interaction consists only of an energy exchange. In reality, however, the interaction of a subsystem with its surroundings amounts not only to an exchange of energy but very often also involves an exchange of particles. In the process of interaction the subsystem exchanges particles with the medium surrounding it. Particles which are going out and coming in carry energy with them, so that the energy exchange and particle exchange take place simultaneously. In this case not only the energy but also the number of particles in the system is variable. In order to characterize the state of such a system it is insufficient to indicate the total energy of the system; it is also necessary to indicate how many particles are contained in the system. Owing to the interaction with the surroundings, the subsystem singled out can be in different quantum states which differ by the number of particles contained in the system. Before passing over to the derivation of the statistical distribution for this case, we shall present certain examples of subsystems with a variable number of particles.

We assume that our subsystem represents a macroscopic drop or crystal

which is in equilibrium with the vapour or melt respectively. The latter play the role of the surroundings (the reservoir). Molecules from the surface of the liquid go to the vapour, while molecules from the vapour condense on the surface of the liquid. The same occurs with molecules on the surface of the crystal. If there is no systematic transfer of particles from the vapour to the liquid or vice versa, then in the system an equilibrium state will be established in which the number of particles going in the two directions is equal.

As another example of a system with a variable number of particles we consider one in which an equilibrium chemical reaction occurs. In the course of the chemical reaction the number of particles in the subsystem which has been selected changes (for example, the molecules of a compound AB): it decreases owing to the decomposition $AB \rightarrow A+B$ and increases owing to the synthesis $A+B \rightarrow AB$.

In an equilibrium state a continuous exchange of energy and particles takes place between the subsystem and the reservoir. Equilibrium conditions for the energy exchange were found to be the equality of the temperatures and pressures. An additional equilibrium condition for the exchange of particles will now be found.

We consider the derivation of the statistical distribution of a system with a variable number of particles, i.e. the distribution of the probabilities w_{in} that the subsystem will be found in the i th state and contain n particles. Finding the statistical distribution in this case differs from the case considered in § 16 only by the fact that the number of states of the subsystem with given energy $\Omega(\epsilon_i)$ must be replaced by the number of states with given energy and given number of particles $\Omega(\epsilon_i, n)$. Correspondingly, the number of states of the reservoir will be $\Omega_0(E_0, N_0)$. The sum of the number of particles in the subsystem and reservoir remains constant:

$$N = n + N_0 = \text{const.}$$

Then instead of formula (16.5) we obtain

$$w_{in} \approx \Omega_0(E - \epsilon_i, N - n) \Omega(\epsilon_i, n),$$

and, instead of (16.7),

$$\Omega_0(E - \epsilon_i, N - n) = \exp \{ \sigma(E - \epsilon_i, N - n) \}. \quad (59.1)$$

Since the dimensions of the subsystem are small, its energy and the number of particles contained in it are small in comparison with the energy and the

number of particles in the entire closed system: $\epsilon_i \ll E$ and $n \ll N$. Hence, as in §16, we can expand the function $\sigma(E - \epsilon_i, N - n)$ in a series in powers of ϵ_i and n and confine ourselves to the first terms of the expansion. This gives

$$w_{in} \approx \exp \left[\sigma(E, N) - \left(\frac{\partial \sigma}{\partial E_i} \right)_{\epsilon_i=0} \epsilon_i - \left(\frac{\partial \sigma}{\partial n} \right)_{n=0} n \right] \Omega(\epsilon_i, n), \quad (59.2)$$

or

$$w_{in} \approx \text{const} \cdot \exp \left[-\frac{\epsilon_i - \mu n}{\theta} \right] \Omega(\epsilon_i, n), \quad (59.3)$$

where the symbol "const" denotes the constant quantity $e^{\sigma(E, N)}$ which does not depend on ϵ_i and n ; θ denotes as before the statistical temperature $(\partial \epsilon_i / \partial \sigma)_{\epsilon_i=0}$, and

$$\frac{\mu}{\theta} = - \left(\frac{\partial \sigma}{\partial n} \right)_{n=0}. \quad (59.4)$$

The derivative in formula (59.4) is taken at a constant value of the energy and the external parameters. The molecular meaning of the quantity μ will be obtained in the next section.

It should be stressed that, in contrast to θ , μ can have any sign. Indeed, in formula (59.5) the summation is carried out over a finite number of particles, in contrast to the summation over an infinite number of levels in formula (16.12).

The value of the constant can be found from the normalization condition:

$$\sum_i \sum_n w_{in} = 1,$$

where the summation is carried out over all energy levels and all possible numbers of particles in the system. Obviously, we have

$$\text{const} \cdot \sum_i \sum_n \exp \left[\frac{\mu n - \epsilon_i}{\theta} \right] \Omega(\epsilon_i, n) = 1,$$

hence

$$\text{const} = \left[\sum_i \sum_n \exp \left(\frac{\mu n - \epsilon_i}{\theta} \right) \Omega(\epsilon_i, n) \right]^{-1}. \quad (59.5)$$

The probability distribution of the states of a system with a variable number of particles can finally be written in the form

$$w_{in} = \frac{\exp \left[\frac{\mu n - \epsilon_i}{\theta} \right] \Omega(\epsilon_i, n)}{\sum_i \sum_n \exp \left[\frac{\mu n - \epsilon_i}{\theta} \right] \Omega(\epsilon_i, n)}. \quad (59.6)$$

Formula (59.6) differs from formula (16.13) only by the fact that instead of one variable characterizing the state of the system, the energy, it contains two variables: the energy ϵ_i and the number of particles n in the system. We shall call the probability distribution (59.6) the grand canonical distribution.

We introduce the notation

$$\tilde{Z} = \exp \left[-\frac{\mu n}{\theta} \right] \sum_i \sum_n \exp \left[\frac{\mu n - \epsilon_i}{\theta} \right] \Omega(\epsilon_i, n).$$

For a constant number of particles in the system $n = \bar{n}$ the quantity \tilde{Z} is the same as the ordinary partition function.

The probability distribution (59.6) can be written by means of \tilde{Z} in the standard form:

$$w_{in} = \tilde{Z}^{-1} \exp [-\epsilon_i/\theta] \Omega(\epsilon_i, n).$$

The number of states of the system $\Omega(\epsilon_i, n)$ can (in the quasi-classical approximation) be expressed in terms of the volume $\Delta\Gamma$ of phase space according to formula (1.26):

$$\Omega(\epsilon_i, n) = \frac{\Delta\Gamma_n}{h^{3n}}, \quad (59.7)$$

where $\Delta\Gamma_n$ is the volume of the phase space of a system containing n particles. It is obvious that with a change in the number of particles the number of degrees of freedom $3n$ and the value of the phase volume also change:

$$\Delta\Gamma_n = \Delta q_1 \Delta q_2 \dots \Delta q_{3n} \Delta p_1 \Delta p_2 \dots \Delta p_{3n}. \quad (59.8)$$

Then for the probability that the system be in the energy state corresponding to the phase volume element $d\Gamma_n$ and contain n particles we obtain

$$dw_{in} = \frac{\exp[-\epsilon_i/\theta] d\Gamma_n}{\tilde{Z} h^{3n}}. \quad (59.9)$$

Knowing the probability distribution (59.6) or (59.9), one can find the mean values of all quantities characterizing a state of a system with a variable number of particles.

According to the general formula for obtaining mean values, we find the mean value of any quantity \bar{L} which depends on the state of the subsystem and on the number of particles:

$$\bar{L} = \frac{\sum_i \sum_n L \exp\left[\frac{\mu n - \epsilon_i}{\theta}\right] \Omega(\epsilon_i, n)}{\sum_i \sum_n \exp\left[\frac{\mu n - \epsilon_i}{\theta}\right] \Omega(\epsilon_i, n)}. \quad (59.10)$$

In particular, the mean value of the number of particles for an arbitrary value of the energy of the system is equal to

$$\bar{n} = \frac{\sum_i \sum_n n \exp\left[\frac{\mu n - \epsilon_i}{\theta}\right] \Omega(\epsilon_i, n)}{\sum_i \sum_n \exp\left[\frac{\mu n - \epsilon_i}{\theta}\right] \Omega(\epsilon_i, n)} = \theta \frac{\partial}{\partial \mu} \ln \sum_i \sum_n \exp\left[\frac{\mu n - \epsilon_i}{\theta}\right] \Omega(\epsilon_i, n). \quad (59.11)$$

For a system with a variable number of particles it is natural to call \tilde{Z} the grand partition function or the grand sum (or integral) over states.

It is convenient to introduce a quantity z which is called the activity and is by definition equal to $z = e^{\mu/\theta}$. By means of the activity, \tilde{Z} can be written in the form

$$\tilde{Z} = \sum_{n=1}^N z^n Z_n, \quad (59.12)$$

where Z_n is the statistical sum for n particles.

In the classical approximation we can write

$$\tilde{Z} = \sum e^{\mu n/\theta} Z_n \approx \sum e^{\mu n/\theta} e^{-F_n/\theta} \approx e^{(\mu \bar{n} - F)/\theta} \approx e^{(\mu N - F)/\theta}.$$

In the next paragraph it will be shown (see formula (60.4)) that $\mu N = \Phi$, where Φ is the Gibbs thermodynamic potential. Hence for \tilde{Z} we find

$$\tilde{Z} = e^{(\Phi - F)/\theta} = e^{pV/\theta}, \quad (59.13)$$

or

$$p = (\theta/V) \ln \tilde{Z}. \quad (59.14)$$

Analogously, (59.11) can be written in the form

$$\bar{n} = N = \theta \frac{\partial \ln \tilde{Z}}{\partial \mu} = \frac{\partial \ln \tilde{Z}}{\partial \ln z}. \quad (59.15)$$

We now have to consider the establishment of the physical meaning of the parameter μ .

In §17 the physical meaning of the quantity θ introduced formally has been elucidated, and it has been shown that it represents the statistical temperature. The condition of statistical equilibrium between quasi-independent subsystems which can interact weakly with each other and exchange energy was the equality of their temperatures. It is remarkable that the formally introduced quantity μ also turns out to have an important physical meaning which can be revealed by means of reasoning which is completely analogous to that of §17.

Consider a certain system which is in a state of statistical equilibrium. We single out from it two subsystems which are also in a state of statistical equilibrium and are weakly interacting with each other. This interaction consists of a mutual exchange of energies and particles between the two subsystems. For each of them one can write the probability distribution of states in the form

$$w_1 = A_1 \exp \left[\frac{\mu_1 n_1 - \epsilon_{i1}}{\theta} \right] \Omega_1 \quad \text{and} \quad w_2 = A_2 \exp \left[\frac{\mu_2 n_2 - \epsilon_{k2}}{\theta_2} \right] \Omega_2.$$

where the index 1 marks the quantities referring to the first subsystem, and the index 2 marks the quantities referring to the second subsystem.

Since the subsystems are quasi-independent, one can apply the theorem of multiplication of probabilities to them, and for the probability of finding simultaneously the first subsystem in the i th state and the second subsystem in the k th state one can write

$$w_{12} = w_1 w_2 = A_1 \exp \left[\frac{\mu_1 n_1 - \epsilon_{i1}}{\theta_1} \right] A_2 \exp \left[\frac{\mu_2 n_2 - \epsilon_{k2}}{\theta_2} \right] \Omega_1 \Omega_2. \quad (59.16)$$

On the other hand, the two subsystems together can be considered as one subsystem with an energy equal to the sum $\epsilon_{i1} + \epsilon_{k2}$ and with a number of particles equal to $n_1 + n_2$. Since this subsystem is an equilibrium in state, one can also write the grand statistical distribution for it in the form

$$w_{12} = A \exp \left[\frac{\mu(n_1 + n_2) - (\epsilon_{i1} + \epsilon_{k2})}{\theta} \right] \Omega. \quad (59.17)$$

If the subsystems are in equilibrium with each other, then their states should not change when an interaction is established between them. This means that the probability distribution of states in a system which is formed of two subsystems must remain unchanged. For this it is necessary that the expressions (59.16) and (59.17) should be identical. The latter condition requires, however, that the following equalities should be fulfilled:

$$\theta = \theta_1 = \theta_2, \quad (59.18)$$

$$\mu = \mu_1 = \mu_2. \quad (59.19)$$

The first of these is the well-known condition of equality of temperatures in all quasi-independent subsystems constituting an equilibrium system. This condition has been obtained in § 17 for subsystems whose interaction reduced to an energy exchange. The second equality is essentially new. It shows that the quantity μ which refers, as θ , to the reservoir (see § 17), in a state of statistical equilibrium must have the same value in all parts of the system.

In addition to the conditions of the constancy of the temperature and pressure, the constancy of μ is a necessary condition for statistical equilibrium in a system. The appearance of the additional condition of equilibrium is associated with the fact that we are now considering subsystems which can mutually exchange not only energy but also particles.

We shall call the quantity μ the chemical potential of the reservoir. In the case where the subsystem which we have singled out is itself a macroscopic system, the conditions of equilibrium allow one to refer μ to the system itself and not to the reservoir. Indeed, in an equilibrium state the chemical potentials of the reservoir and the macroscopic subsystem must be equal. However, it makes no sense to speak of the chemical potential of a microscopic subsystem, for example, a molecule. It should be noted that the same also holds for the statistical temperature θ . It also represents the temperature of the reservoir, but for a macroscopic subsystem it can be identified with the temperature of the latter. However, one cannot speak of the temperature of an individual molecule.

From the point of view of molecular concepts the condition (59.18) expresses the requirement that the amounts of energy which are given away and obtained by the subsystem should be equal to each other. The condition states that in the exchange of particles not only the numbers of particles coming in and going out of the subsystem must be equal to each other, but also the mean energies carried by the particles must be the same. If that were not so (for example, if only fast particles went out and only slow particles came in) then the equilibrium state would be violated.

§60. The basic thermodynamic equality and the calculation of chemical potentials

In order to elucidate the thermodynamic properties of a system with a variable number of particles it is first of all necessary to find the basic thermodynamic equality for such systems. The latter can be obtained most simply in the following way.

Since the quantities involved in the basic thermodynamic equality (24.5) — the energy, entropy and volume — possess additive properties, this equality can be written not only for the quantities E , σ and V but also for the specific values of these quantities related to unit mass or to one particle.

Let a system contain N particles. Then the energy, entropy and volume per particle can be written in the form E/N , σ/N and V/N . Writing the basic thermodynamic equality for the specific values related to one particle, we have

$$d\left(\frac{E}{N}\right) = \theta d\left(\frac{\sigma}{N}\right) - p d\left(\frac{V}{N}\right).$$

It is obvious that this equality will hold irrespective of the cause of the change in the specific value of the energy and the other quantities, i.e. irrespective of whether this change is due to a change in the quantities themselves or to a change in the number of particles in the system. Hence in the equality one can consider N to be a variable quantity and write

$$\frac{dE}{N} - \frac{E dN}{N^2} = \theta \frac{d\sigma}{N} - \theta \sigma \frac{dN}{N^2} + pV \frac{dN}{N^2} - \frac{p dV}{N},$$

hence

$$dE = \theta d\sigma - p dV + \left(\frac{E - \theta \sigma + pV}{N} \right) dN.$$

Setting

$$\mu = \frac{E - \theta \sigma + pV}{N}, \quad (60.1)$$

we obtain

$$dE = \theta d\sigma - p dV + \mu dN. \quad (60.2)$$

Whence it follows that the following equalities holds:

$$\mu = \left(\frac{\partial E}{\partial N} \right)_{\sigma, V}; \quad \frac{\mu}{\theta} = - \left(\frac{\partial \sigma}{\partial N} \right)_{E, V}. \quad (60.3)$$

The comparison of formulae (60.3) and (59.4) convinces us of the identity of the quantity μ determined by formula (60.1) and the chemical potential. The first of the equalities (60.1) shows that the chemical potential is equal to the derivative of the energy with respect to the number of particles. From the point of view of the practical calculation of chemical potentials the equality (60.1) is of special importance. It shows that the chemical potential μ represents the Gibbs thermodynamic potential related to one particle:

$$\mu = \frac{E - \theta \sigma + pV}{N} = \frac{\Phi(p, T)}{N}. \quad (60.4)$$

The latter justifies the term chemical potential. The chemical potential μ is

most conveniently expressed as a function of the pressure and temperature according to formula (60.4).

Formula (60.2) represents the basic thermodynamic equality written for a system with a variable number of particles.

We note in addition that, passing over in (60.2) from the energy to the free energy in the usual way, i.e. by subtracting the differential $d(TS)$ from both sides of (60.2), we can write

$$dF = -SdT - pdV + \mu dN, \quad (60.2')$$

whence

$$\mu = \left(\frac{\partial F}{\partial N} \right)_{T,V}. \quad (60.3')$$

The relations obtained can easily be generalized to the case of systems containing particles of different kinds. In what follows we shall consider the statistical properties of systems with a variable number of particles, and we shall need concrete expressions for chemical potentials. They can be obtained for gases and crystals.

By means of (37.11) we find for the chemical potential of an ideal monatomic gas

$$\mu = -\frac{5}{2}kT \ln kT + kT \ln p - kTj, \quad (60.5)$$

where the quantity j , which is often called the chemical constant, is equal to

$$j = \ln \left(\frac{2\pi m}{h^2} \right)^{\frac{3}{2}}.$$

For a diatomic gas one can analogously obtain

$$\mu = -\frac{7}{2}kT \ln kT + kT \ln p - kTj + kT \ln (1 - e^{-h\nu/kT}) + \epsilon_0, \quad (60.6)$$

where the chemical constant j and the zero point energy ϵ_0 are equal to

$$j = \ln \left[\left(\frac{2\pi m}{h^2} \right)^{\frac{3}{2}} \frac{8\pi^2 I}{h^2} \right]; \quad \epsilon_0 = \frac{1}{2}h\nu.$$

In the case of crystals, by the definition of the chemical potential we have

$$\mu = \frac{F + pV}{N} = \frac{F}{N} + pv,$$

where F is given by formulae (53.7) and (53.8), and v denotes the volume per particle in the crystal. At a low temperature $T \ll \theta_c$,

$$\mu = -\frac{\pi^4 kT}{5} \left(\frac{T}{\theta_c}\right)^3 + pv. \quad (60.7)$$

Analogously at a high temperature $T \gg \theta_c$,

$$\mu = -3kT \ln \frac{T}{\theta_c} - kT + pv. \quad (60.8)$$

The last formulae involve the product pv which is contained in the equation of state of the crystal expressed in terms of quantities which are difficult to measure. However, in view of the smallness of the volume v per particle, one can in most cases drop the small term pv .

In conclusion we shall make use of the value found for the chemical potential in order to write the Maxwell distribution in the form of the Gibbs distribution with a variable number of particles. For this we express μ not in terms of the pressure but in terms of the volume of the system. We obtain

$$\mu = kT \ln \left[\frac{N}{V} \left(\frac{h^2}{2\pi m} \right)^{\frac{3}{2}} \frac{1}{(kT)^{\frac{3}{2}}} \right], \quad (60.9)$$

whence

$$\frac{N}{V} \left(\frac{1}{2\pi m kT} \right)^{\frac{3}{2}} = \frac{1}{h^3} e^{\mu/kT}.$$

Substituting this into the Maxwell distribution (9.3), we obtain

$$dn = e^{(\mu - \epsilon)/kT} \frac{d\Gamma}{h^3}. \quad (60.10)$$

We note that the chemical potential of an ideal gas is a very large negative quantity.

§61. Conditions of phase equilibrium

One of the most important cases of statistical equilibrium in a system with a variable number of particles is that of phase equilibrium. Imagine a homogeneous quasi-closed macroscopic system, which is separated from other bodies by an interface and is in an equilibrium state. We shall call such a system a phase of the substance.

The concept of phase is a generalization and a more precise definition of the concept of state of aggregation. As an example of a phase one can point to a vapour which is in equilibrium with its condensate. In this case the exchange of energy and particles between the vapour and its surroundings, the reservoir, takes place through the interface vapour—liquid or vapour—solid. As other examples we mention: a crystal in equilibrium with its melt; a crystal modification in equilibrium with another; an electron gas in vacuum in equilibrium with an electron gas in a metal. In what follows we shall quote examples of other, more complex phase equilibria.

In all cases of phase equilibrium the existence of an interface between different phases is characteristic. In a state of statistical equilibrium the number of particles passing over from one phase into another, and the energy carried by them are exactly equal to the corresponding quantities in the reverse direction. If there were no interface sharply separating the phases, it would be senseless to speak of a particular quasi-closed subsystem as a phase. We shall illustrate this by an example. Imagine that two phases, representing uniform isotropic states of a substance, are in equilibrium, and are connected by a certain interface. Then we shall call the less dense phase the vapour or gas phase, and the more dense one the liquid phase. If however, we have a uniform system, then, as will be explained in detail in §64, the notion of liquid or gas is inapplicable to it: by changing the physical conditions of the system it can be transformed continuously from a state with a high density to one with a low density. The state with the high density cannot be called the liquid, and the state with the low density cannot be called the gas. They both represent cases of a uniform state of the substance. Thus, the presence of an interface between phases is the necessary condition for one to speak of the existence of phases and phase equilibria.

Let us write down the condition for statistical equilibrium between phases, confining ourselves in the beginning to two phases of a substance. Each of the phases can be considered as a quasi-closed subsystem, and the set can be considered as a closed system in a state of statistical equilibrium. Hence the conditions of equilibrium between two phases can be written in the form of (59.14) and (59.15):

$$T_1 = T_2, \quad (61.1)$$

$$\mu_1(p_1, T) = \mu_2(p_2, T). \quad (61.2)$$

In addition to these conditions it is necessary that the forces applied to the interface by the two equilibrium phases be equal to each other. Otherwise the interface between the phases would move and the equilibrium in the system would be violated.

It is convenient to relate the condition of chemical equilibrium to unit interface, replacing forces by pressures. Thus, in addition to the conditions of equality of temperatures and chemical potentials one has the condition of equal pressures in the two phases.

This simple reasoning can be strictly substantiated, by considering the condition for mechanical equilibrium, which is the requirement of minimum free energy of the closed system at $T = \text{const}$ and $\mu = \text{const}$. The condition of mechanical equilibrium in a system consisting of two phases at $T = \text{const}$ can be written in the form

$$dF = dF_1 + dF_2 = -p_1 dV_1 - p_2 dV_2 = 0.$$

Since the volume of the entire system remains unchanged,

$$dV_1 = -dV_2$$

and

$$p_1 = p_2. \quad (61.3)$$

Thus, the pressures in the two phases must be equal to each other. Taking into account the conditions (61.1) and (61.3), formula (61.2) can be written as

$$\mu_1(p, T) = \mu_2(p, T). \quad (61.4)$$

Since in a state of equilibrium T and p have equal values in the two phases, on the basis of eq. (61.4) one of these quantities can be expressed in terms of the other. As a result of this we obtain the equation

$$p = p(T) \quad (61.5)$$

for the dependence of the equilibrium pressure on the equilibrium temperature. Eq. (61.5) represents a certain curve in the (p, T) plane, called the phase equilibrium curve. All points of this curve correspond to the contact of equilibrium phases. At pressures which are larger and smaller than the equilibrium pressure at given temperature, one of the phases, the one which has a lower thermodynamical potential, is stable. If, for example, one of the phases is a liquid, and the second is its vapour, then the region in the (p, T) -plane which lies above the curve corresponds to the liquid phase, while the region lying below the curve corresponds to the gas phase. The equilibrium liquid-gas phase transition takes place along the curve.

Correspondingly, in the crystal-melt equilibrium the region above the phase equilibrium curve corresponds to the crystal phase, melting points lie on the curve, and the stable phase below the curve is liquid. In a phase transition the liberation or absorption of latent heat takes place. The latent heat for the transition of a molecule from one phase into the other is equal to (since the process is a reversible and equilibrium process)

$$l = \int T ds ,$$

where s is the entropy related to one molecule. Since in the phase transition the temperature is constant, it can be taken out of the integral sign and one can write

$$l = T\Delta s = T(s_2 - s_1) .$$

Thus, the latent heat of a phase transition is equal to the difference between the entropies multiplied by the temperature of the transformation. The latent heat is taken to be positive if heat is absorbed in the phase transition. Latent heat which is liberated is taken to be negative.

§62. The equation of the phase equilibrium curve. Equilibrium between the vapour and the condensed phase

The dependence of the chemical potential on the temperature and pressure is known for only a few simple systems. In most cases the concrete form of the function $\mu(p, T)$ is unknown. Hence the equation of the equilibrium curve (61.5) cannot be written in an explicit form. However, it turns out that the differential equation of the equilibrium curve has a simpler form and contains only quantities which can easily be measured.

To obtain the differential equation of the equilibrium curve we differentiate the condition (61.4). We have

$$d\mu_1 = d\mu_2 \quad (62.1)$$

or

$$\frac{\partial\mu_1}{\partial p} dp + \frac{\partial\mu_1}{\partial T} dT = \frac{\partial\mu_2}{\partial p} dp + \frac{\partial\mu_2}{\partial T} dT. \quad (62.2)$$

From formula (62.2) we find the slope of the equilibrium curve

$$\frac{dp}{dT} = \frac{\partial\mu_2/\partial T - \partial\mu_1/\partial T}{\partial\mu_1/\partial p - \partial\mu_2/\partial p}. \quad (62.3)$$

Eq. (62.3) is just the differential equation of the equilibrium curve sought. In order to bring it into final form it is necessary to express the quantities appearing in it in terms of those measured directly. According to (29.10) and (29.11) we have

$$S = -\frac{\partial G}{\partial T}, \quad V = \frac{\partial G}{\partial p}.$$

Hence

$$\frac{\partial\mu}{\partial T} = -\frac{S}{N} = -s, \quad \frac{\partial\mu}{\partial p} = \frac{V}{N}, \quad (62.4)$$

where N is the number of particles. Substituting this into (62.3), we find

$$\frac{dp}{dT} = \frac{S_1 - S_2}{V_1 - V_2}. \quad (62.5)$$

Replacing the difference between the entropies by the heat of transformation l , we obtain

$$\frac{dp}{dT} = \frac{lN}{(V_2 - V_1)T}. \quad (62.6)$$

Formula (62.6) is usually referred to one mole of the gas phase.

Denoting the latent heat of the phase transition of one mole of a substance lN by L , and the change in the molar volume by ΔV , we find finally

$$\frac{dp}{dT} = \frac{L}{T\Delta V}. \quad (62.7)$$

Formula (62.6) is called the Clapeyron–Clausius equation. The Clapeyron–Clausius formula relates the change in the equilibrium pressure p for an infinitesimal change in the equilibrium temperature T to directly measured quantities. We shall discuss it for concrete cases of phase equilibria in following sections.

It is easily seen that if a phase transition takes place as the temperature increases, then the latent heat is always absorbed, i.e. $L > 0$. Indeed,

$$L = T(S_2 - S_1) = NT \left(\frac{\partial \mu_1}{\partial T} - \frac{\partial \mu_2}{\partial T} \right). \quad (62.8)$$

The character of the temperature variation of chemical potentials in a phase transition taking place with an increase in the temperature is shown in fig. III.36. Up to point 1 the stable phase is the first one, whose chemical potential μ_1 is smaller than that of the second phase μ_2 . After point 1 the situation is reversed. At point 1 phase equilibrium occurs. At it the chemical potentials of the two phases are equal to each other. Its ordinate represents the temperature of the phase transition (at a given pressure). From fig. III.36 it is seen that at point 1 the slope of curve μ_1 must be larger than that of curve μ_2 . Otherwise above this point μ_1 will not become larger than μ_2 .

Fig. III.36

Hence at point 1 we have

$$\frac{\partial \mu_1}{\partial T} > \frac{\partial \mu_2}{\partial T}.$$

Then it follows from formula (62.8) that if the phase transition takes place with an increase in temperature its latent heat is always positive. The numerical value of the latter cannot be found theoretically, since it is expressed in terms of the entropies of the phases, and the explicit form of these functions is unknown in most cases.

The theorem proved above allows one to establish the sign of the temperature coefficient of the equilibrium pressure dp/dT for different phase transitions. If a phase transition takes place with an increase in the temperature (melting, boiling, sublimation), so that L is positive, then, according to the Clapeyron–Clausius formula, the sign of dp/dT is determined by the sign of the quantity ΔV , the change in volume in the phase transition. In evaporation and sublimation the volume of the phase increases sharply, so that $\Delta V > 0$ always. Hence for these phase transitions dp/dT is also positive, i.e. the equilibrium pressure increases with increasing temperature or, conversely, the equilibrium temperature increases with increasing pressure. As the pressure is lowered the temperatures of the boiling point and of the sublimation point decrease. Such a relation between the equilibrium pressure and the equilibrium temperature is in agreement with well-known experimental facts (increase in the boiling point in high-pressure boilers, decrease in the boiling point with the height, and so on).

In melting two cases are encountered: when ΔV is positive, so that the density of the liquid phase is smaller than that of the solid phase, and when ΔV is negative, so that the liquid phase is more dense. For bodies of the first type $dp/dT > 0$, so that the melting point increases with increasing pressure.

The number of bodies which are more dense in the liquid phase is relatively small. Examples of such bodies are water, cast iron, bismuth, and a number of alloys. For these $dp/dT < 0$, i.e. the melting point decreases with increasing pressure. This feature of the melting of ice and other substance is well known.

It is interesting to note that in the vicinity of absolute zero the temperature coefficient dp/dT tends to zero, so that the equilibrium pressure at the melting point ceases to depend on temperature. Indeed, from the third law of thermodynamics it follows that in melting the change in the entropy $\Delta S \rightarrow 0$ as $T \rightarrow 0$. Consequently, the latent heat of melting reduces to zero, and with it, by virtue of (62.6), also dp/dT . Such behaviour of the dependence of

Fig. III.37

dp/dT on temperature does indeed take place for liquid helium II, which is a stable phase as $T \rightarrow 0$ at pressures below 30 atm. At pressures above ≈ 30 atm the stable phase is solid helium. The phase equilibrium curve (solid helium \rightleftharpoons liquid helium II) is almost horizontal. Its slope $dp/dT \rightarrow 0$ as $T \rightarrow 0$ (fig. III.37).

As we have already pointed out, the explicit form of the equilibrium curve cannot in general be found. If the dependence of the latent heat of transformation and of the change in the molar volume on temperature and pressure is known, then the Clapeyron–Clausius equation can be integrated. Then the dependence of the equilibrium pressure of the phase transition on temperature, i.e. the form of the equilibrium curve, can be found. The dependence of the quantities mentioned on temperature and pressure is usually complex, and the integration is carried out numerically. The situation is essentially simplified if one of the equilibrium phases is vapour, i.e. in the case of boiling or sublimation.

In the case of equilibrium between a condensed phase and vapour it can be assumed that the molar volume of the vapour is considerably larger than the molar volume of the condensed phase — a liquid or a crystal. Hence the change in the volume in the phase transition can be equated with the volume of the gas phase (related to the corresponding number of particles):

$$\Delta V = V_{\text{vap}} - V_{\text{cond.phase}} \approx V_{\text{vap}}.$$

In this case the Clapeyron–Clausius equation assumes the form

$$\frac{dp}{dT} = \frac{L}{TV_{\text{vap}}}. \quad (62.9)$$

If the vapour which is in equilibrium with the condensed phase is sufficiently rarefied, so that it can be considered as an ideal gas, then

$$V_{\text{vap}} = NkT/p. \quad (62.10)$$

It should be noted that this proposition is only fulfilled with sufficient accuracy at relatively low pressures. Substituting (62.10) into (62.9), we have

$$\frac{dp}{p} = \frac{L}{NkT^2} dT. \quad (62.11)$$

The dependence of L on the temperature can be found by means of a method which is completely analogous to that applied in deriving the Clapeyron–Clausius equation.

Differentiating L with respect to T , we have

$$\frac{dL}{dT} = T \left(\frac{\partial \Delta S}{\partial T} \right)_p + T \left(\frac{\partial \Delta S}{\partial p} \right)_T \frac{dp}{dT} + \Delta S$$

or

$$\frac{dL}{dT} = \Delta C_p - T \frac{\partial(\Delta V)}{\partial T} \frac{dp}{dT} + \Delta S,$$

or, taking into account (62.9) and (62.10),

$$\frac{dL}{dT} = \Delta C_p - \frac{T\Delta S}{V_{\text{vap}}} \frac{\partial V_{\text{vap}}}{\partial T} + \Delta S = \Delta C_p.$$

Thus, the latent heat of transformation at a temperature T is equal to

$$L = L_0 + \int_0^T (\Delta C_p) dT, \quad (62.12)$$

where L_0 is the latent heat at $T = 0$. This quantity represents the work which must be done at absolute zero in order to break the bonds existing between the molecules in the condensed phase and to transform them into non-interacting molecules. The latent heat of transformation from the condensed phase into the gas assumes a particularly clear meaning: it is equal to the

work done in order to overcome the bonds plus the energy which must be transferred to the system in order to compensate for the difference between the energies of thermal motion in the condensed phase and the gas.

Substituting formula (62.12) into (62.11), we have

$$\frac{dp}{p} = \frac{L_0 dT}{NkT^2} + \frac{dT}{NkT^2} \int_0^T (\Delta C_p) dT. \quad (62.13)$$

Integrating (62.13), we obtain

$$\ln p = -\frac{L_0}{NkT} + \int_0^T \frac{dT'}{NkT'^2} \int_0^{T'} (\Delta C_p) dT'' + i$$

or

$$p = \exp \left[-\frac{L_0}{NkT} + \int_0^T \frac{dT'}{NkT'^2} \int_0^{T'} (\Delta C_p) dT'' + i \right], \quad (62.14)$$

where i is a constant which is usually called the vapour pressure constant.

Formula (62.14) shows that the pressure of a saturated equilibrium vapour decreases rapidly with decreasing temperature.

In the case of evaporation the basic part of the latent heat of transformation usually corresponds to the first term of (62.12). Hence formula (62.14) is often approximately written in the form

$$p \sim \exp \left[-\frac{L_0}{NkT} + i \right]. \quad (62.15)$$

Formula (62.14) involves the unknown vapour pressure constant i , the latent heat of transformation at absolute zero, L_0 , and the difference between the heat capacities of the two equilibrium phases.

By means of statistical methods the value of all these quantities, except L_0 , can be obtained mathematically, provided the condensed phase is a crystal. The smallness of the pressure of the saturated vapour allows one to consider the vapour as an ideal gas and to make use of the chemical potential determined by formula (60.5).

Equating the chemical potential of the gas (for simplicity of the formulae a monatomic gas) and the crystal we obtain the equation of the sublimation curve. In this case we choose the zero energy in such a way that the energy of a motionless molecule of the gas is equal to zero. The energy of a crystal

molecule, measured from this level, is negative (since the molecule is bound in the crystal lattice) and will be denoted by $\epsilon_0 = -L/N$.

It is obvious that ϵ_0 is equal to the work which must be done at absolute zero to tear a molecule away from its neighbours in the crystal lattice and to bring it into the gas phase in a state in which it will also be at rest. Thus, $-\epsilon_0$ represents the heat of sublimation at absolute zero referred to one molecule and taken with the opposite sign. Equating μ_{gas} and μ_{cryst} , we find the conditions of equilibrium in a system (crystal \rightleftharpoons gas) at low temperature:

$$\ln p = \frac{5}{2} \ln kT + j - \frac{\epsilon_0}{kT} - \frac{\pi^4}{5} \left(\frac{T}{\theta_c} \right)^3,$$

or

$$p = (kT)^{\frac{5}{2}} \exp \left[-\frac{L_0}{NkT} - \frac{\pi^4}{5} \left(\frac{T}{\theta_c} \right)^3 \right] \exp j. \quad (62.16)$$

The basic term in (62.16) is the one which contains the latent heat of transformation at absolute zero.

Let us compare formula (62.16) with the general formula (62.14). For this we have to calculate the double integral in (62.14). Using for $C_{p \text{ cryst}}$ its value from formula (53.2), we have

$$\Delta C_p = -C_{p \text{ cryst}} + C_{p \text{ gas}} = \frac{5}{2} Nk - \frac{12\pi^4 Nk}{5} \left(\frac{T}{\theta_c} \right)^3$$

and

$$\begin{aligned} \int_0^T \frac{dT'}{NkT'^2} \int_0^{T'} \Delta C_p dT'' &= \\ &= \int_0^T \frac{dT'}{NkT'^2} \int_0^{T'} \left[\frac{5}{2} Nk - \frac{12\pi^4}{5} Nk \left(\frac{T''}{\theta_c} \right)^3 \right] dT'' = \\ &= \int_0^T \frac{dT}{T'^2} \left(\frac{5}{2} T' - \frac{3\pi^4 T'^4}{5\theta_c^3} \right) = \frac{5}{2} \ln T - \frac{\pi^4}{5} \left(\frac{T}{\theta_c} \right)^3. \end{aligned} \quad (62.17)$$

Substituting (62.17) into the general expression for the pressure (62.14), we obtain an expression which is the same as (62.16) provided the constant i

contained in (62.14) is assumed to be equal to the chemical constant j . Thus, the constant of the pressure of a saturated vapour can be calculated by means of statistical considerations.

Formula (62.16) is in good quantitative agreement with experiment.

The equilibrium curve at high temperatures can be obtained in exactly the same way.

Equating the chemical potentials (60.5) and (60.8), we find

$$\ln p = \frac{5}{2} \ln kT + j + \frac{\epsilon_0}{kT} - 3kT \ln \frac{T}{\theta_c} - 1. \quad (62.18)$$

The same result can also be obtained from the general formula (62.14).

It should be noted that, as is seen from (62.16), the pressure of a saturated vapour increases very rapidly with increasing temperature. If the characteristic temperature θ_c of the crystal is relatively large, so that the condition $T \gg \theta_c$ is fulfilled at high temperatures, then the corresponding density of the saturated vapour will be too large for the vapour to be considered as an ideal gas.

In this case it is necessary in formula (62.16) to make use of the chemical potential for a van der Waals gas. In practice empirical formulae for the vapour pressure curve are more often used.

It is useful to compare, for the example given, the practical potentialities of the thermodynamic and statistical methods.

We have obtained formula (62.14) which is of very general character and which establishes the equilibrium pressure of the vapour above any condensed phase by the thermodynamic method. However, this general formula involves quantities whose numerical value can be determined only from experimental data.

The expression for the vapour pressure has been obtained by statistical methods in the presence of strong restricting assumptions, but within this framework the quantitative values of all the quantities have been obtained and their molecular meaning has been elucidated.

§63. Theory of phase transitions

Up to now we have confined ourselves to thermodynamic reasoning, assuming as an experimental fact the existence of phases and the possibility of phase transitions.

We now have to discuss the phenomena of phase transitions from the

statistical point of view. A phase transition is always associated with the rupture of the continuity of certain thermodynamic quantities. In the example of a phase transition considered above, which is called a phase transition of the first kind, thermodynamic potentials remain continuous, whereas their entropy $S' = (\partial F / \partial T)_p$ and specific volume $v = V/N^{-1} = -N^{-1}(\partial F / \partial p)_T$ undergo a finite jump.

In addition to phase transitions of the first kind there are also the so-called phase transitions of the second kind, in which the second derivatives of the thermodynamic potentials — the heat capacity $C_p = T(\partial S / \partial T)_p$ and the coefficient of thermal expansion $\alpha = -V^{-1}(\partial V / \partial T)_p$ — undergo a break, changing discontinuously by amounts ΔC_p and $\Delta \alpha$.

We shall in what follows encounter numerous examples of phase transitions of the second kind (see Part IV §20 and §21). It should be stressed that the very existence of phase transitions appears to be rather unexpected from the point of view of statistical physics. One would think that the statistical sum (or integral) determines thermodynamic potentials as continuous functions of the parameters which characterize the state of the systems, for example, the temperature and volume.

Indeed, we can write the equation of state of a phase of a system with a given number of particles N occupying a volume V . It follows that from (59.14) that

$$p = \frac{kT}{V} \ln \tilde{Z} = \frac{kT}{V} \ln \sum z^n Z_n(V, T, n), \quad (63.1)$$

$$\frac{1}{v} = \frac{N}{V} = \frac{kT}{V} \frac{\partial \ln \tilde{Z}}{\partial \mu} = \frac{1}{V} \frac{\partial \ln \left[\sum z^n Z_n(V, T, n) \right]}{\partial \ln z} = \frac{\partial p}{\partial \ln z}. \quad (63.2)$$

Eliminating z from (63.1) and (63.2), one can find the function $f(p, V/N, T)$, i.e. the equation of state. If the law of interaction between molecules is taken in the form (46.2) and if the phase volume is assumed to have a finite fixed value V , then in Z_n one can carry out the integration over the momenta and write (in the classical approximation)

$$Z_n = \left(\frac{2\pi m kT}{h^2} \right)^{\frac{3}{2}} \frac{1}{n!} \int \exp \left[- \frac{\sum u(r_{ij})}{kT} \right] dV_1 \dots dV_n. \quad (63.3)$$

* In this section we follow the book by K. Huang, *Statistical mechanics* (John Wiley, New York, 1963). For the details of the theory we refer the reader to this book and to original studies by Yang and Lee, *Phys. Rev.* 87 (1952) 410.

It is obvious that all statistical integrals Z_n are essentially positive quantities which depend on the volume V and temperature T as parameters. We write the expression for \tilde{Z} in more detail:

$$\tilde{Z} = \sum_{n=1}^N Z_n z^n = Z_1 z + Z_2 z^2 + \dots + Z_N z^N. \quad (63.4)$$

The grand partition function \tilde{Z} is a polynomial of the n th power with respect to z with essentially positive coefficients. Hence \tilde{Z} is a monotonically increasing function of the activity z . By virtue of the continuity of functions, $Z_n(V, T, n)$ is also a continuous function of the temperature and volume (or the density $\rho = N/V$).

From the form of the function \tilde{Z} and formula (63.1) it is seen that $p(z)$ is a monotonically increasing function of the activity z , as is shown in fig. III.38a. The inverse specific volume $1/v$ is also, by virtue of (63.2), a monotonically increasing function of z (fig. III.38b). According to formula (57.7), the necessary condition for a stable existence of any phase is the requirement $(\partial p / \partial v)_T < 0$, i.e. the requirement of a monotonic decrease of the pressure with increasing volume per particle. Therefore the curve $p(v)$ has the form shown in fig. III.38c.

We see that at given temperature the pressure is a monotonic function of the volume and that there is no tendency for the appearance of discontinuities on the curve which expresses the equation of state of an arbitrary phase.

If, however, the function \tilde{Z} reduces to zero, then according to (63.1) and (63.2) the pressure p and the volume v will become indefinite, and our reasoning will lose its validity. Therefore it is necessary to discuss in more detail the behaviour of \tilde{Z} as a function of the activity z and the volume v .

Fig. III.38

The very existence of phase transitions (discontinuities in thermodynamic quantities) is associated with the behaviour of the system as $\tilde{Z} \rightarrow 0$, where the functions p and v have singularities.

In order to find the values of z for which the grand partition function \tilde{Z} reduces to zero, it is necessary to know its explicit expression as a function of z and V . Finding the grand partition function for real systems appears, for the present, to be an impracticable problem.

It turns out, however, that in the limiting case where the number of particles N in the system and its volume V increase indefinitely ($N \rightarrow \infty$, $V \rightarrow \infty$) but in such a way that the specific volume v remains limited to $v \leq v_0$, it is possible to investigate the behaviour of $\tilde{Z}(z, v)$ without determining its explicit form. In this case it can be shown that from the behaviour of $\tilde{Z}(z)$ there follows the possibility of the existence of phase transitions.

We write the expression (63.4) in the form

$$\tilde{Z}(z, V, T) = \prod_{i=1}^N (z - z_i), \quad (63.5)$$

where z_i are the roots of the polynomial (63.4). Since all coefficients of the polynomial (63.4) are positive, the roots z_i cannot be positive. They are either negative, complex-conjugate quantities in pairs, or equal to zero.

Although only the positive and, in the last resort, zero values of z have a real meaning, from the mathematical point of view it is convenient to introduce into the treatment the complex values of z , and to consider the function of a complex variable $\tilde{Z}(z)$. Then we pass over to the limit in formulae (63.1), (63.2) and (63.5), writing

$$p = kT \lim_{V \rightarrow \infty} \left[\frac{1}{V} \ln \tilde{Z}(z, V, T) \right], \quad (63.6)$$

$$\frac{1}{v} = kT \lim_{V \rightarrow \infty} \left[\frac{1}{V} \frac{\partial \ln [\tilde{Z}(z, V, T)]}{\partial \ln z} \right], \quad (63.7)$$

$$\tilde{Z}(z, V, T) = \lim_{N \rightarrow \infty} \prod_{i=1}^N (z - z_i). \quad (63.8)$$

The number of roots z_i increases indefinitely, and they are distributed in a complex plane. A mathematical study carried out by Yang and Lee showed

that there are limits in formulae (63.6) and (63.7) and that for $V \rightarrow \infty$ the function $V^{-1} \ln \tilde{Z}(z)$ is an analytic function of z in certain regions R of the complex plane, including the real axis, which does not contain zero z_i .

This means that in a system with $V \rightarrow \infty$ for all values of z in these regions the pressure has no singularities (i.e. there are no phase transitions). In fig. III.39 these regions are denoted by R_1 and R_2 . Zero z_i are denoted by solid dots.

However, in contrast to a system with a finite value of N (a finite number of zeros), in a system with $N \rightarrow \infty$ and $V \rightarrow \infty$ the number of zero z_i is indefinitely large. Therefore, filling the plane of the complex variable, they can at certain points approach arbitrarily close to the real axis. Let z_0 be such a point on the real axis (fig. III.39). The zero of the function \tilde{Z} is located in an arbitrarily small region about the point z_0 . Since the pressure p is an analytic function at the point $z = z_0$, it must remain continuous (fig. III.40a). However, the inverse specific volume $1/v$ which, according to (63.2), is the derivative of the pressure can have a discontinuity at the point z_0 :

$$\Delta \left(\frac{1}{v} \right) = \Delta \frac{\partial \ln \tilde{Z}}{\partial \ln z}.$$

Fig. III.39

Fig. III.40

Fig. III.41

If such a discontinuity takes place as is shown in fig. III.40b, then the equation of state [the function $p(v)$] assumes the form shown in fig. III.40c. This is a typical curve of a phase transition of the first kind. When the specific volume changes from v_b to v_a , the pressure remains unchanged.

According to the above, a discontinuity in the derivative is possible but not obligatory. If, however, the pressure and its first derivative are continuous for $z = z_0$, then the second derivative of the pressure $\partial^2 p / \partial z^2$ can have a discontinuity. In this case a break arises on the curve $1/v(z)$, as is shown in fig. III.41b. Correspondingly, the equation of state will have the form shown in fig. III.41c. Such a curve is characteristic of phase transitions of the second kind.

It should be stressed that the theory which is discussed points to the possibility of phase transitions, but allows one to establish neither the position of the points of a phase transition nor the character of the transition itself. Also, the existence of isolated points z_0 is not proved. It is important therefore, that it has been possible to calculate the partition function in an explicit form for the simplest two-dimensional lattice consisting of particles which can be in two states (i.e. the Ising model). This calculation is cumbersome and cannot be presented here *. It turns out that in such a lattice one observes a phase transition of just the same type (with an isolated point z_0) as assumed above.

§64. Phase equilibrium curves

The phase equilibrium curve, i.e. the curve of the dependence of the equilibrium pressure p on the equilibrium temperature T in the (p, T) -plane,

* See L.D.Landau and E.M.Lifshitz, *Course of theoretical physics*, Vol. 5: *Statistical physics* (Pergamon Press, London, 1958).

has a different form for different phase equilibria. As we have already pointed out, the general form of the curve cannot be determined theoretically. One can only make some general observations apropos of this curve.

In considering the problem of the interrelation between a liquid and a gas (§48) we have already pointed out the absence of a fundamental difference between these states of matter. The existing qualitative differences between a liquid and a gas are associated with different roles of the interaction between atoms. As the temperature of a gas decreases or the density increases the mean distance between the atoms decreases. This corresponds to a decrease in the mean free path and to a relative increase in the mean energy of interaction (in comparison with kT). Under certain conditions the thermodynamic potential of a system of widely spaced freely moving particles (a gas) turns out to be higher than that of a system in which the distances between the molecules are small (a liquid). At this moment a phase transition (condensation) takes place. The chaotic free motion of molecules, which is characteristic of a gas, becomes a disorderly motion of individual molecules in a "cage" formed by their closest neighbours. Although the motion of atoms in a gas differs considerably from that in a liquid, this difference is of rather a quantitative character and, in any case, the nature of the motion does not differ: in both cases the motion has a completely random character. From this it follows that under certain conditions the transition from a random motion at small densities to a random motion at large densities can occur gradually, without a jump at the condensation point. In other words, by changing the parameters p , V and T in a certain way one can get a continuous transition from the liquid state to the gaseous state and vice versa, without a discontinuous phase transition associated with the absorption or release of latent heat.

The possibility of a continuous transition between the liquid state and the gaseous state imposes an essential restriction upon the character of the liquid–gas phase equilibrium curve. Namely, a continuous transition between a liquid phase and a gaseous phase is possible only if the phase equilibrium curve $p(T)$ ends at a certain point C (fig. III.42), which is called the critical point (according to Mendeleyev – the point of absolute boiling).

Let p_c and T_c be the pressure and temperature at the critical point, called the critical pressure and critical temperature respectively. For all values of p and T lying below p_c and T_c the transition from the liquid into the gas and vice versa occurs with an intersection of the phase equilibrium curve. On the curve itself the two phases are in equilibrium with each other and are separated by a certain interface. Above the point C there is a uniform state of the substance in which there are no interfaces. This state is often called the

Fig. III.42

transcritical state. The uniform state of a substance can have a large or a small density, depending on the temperature and pressure. However, it makes no sense to call a substance above the critical point a liquid or a gas.

The transition from point 1 (liquid) to point 2 (gas) can be performed in the way shown by the solid line as well as in the way shown by the dotted line in fig. III.42. In the first way the phase equilibrium curve is intersected, so that the transition is accompanied by the release or absorption of latent heat. In the second way the transition takes place via the transcritical state and proceeds continuously, without the jump-like change in the character of the motion and without the release or absorption of latent heat. The possibility of a continuous transition from the liquid state into the gaseous state emphasizes the relative character of the terms "liquid" and "gas".

Strictly speaking, use can be made of the terms "liquid" and "gas" only when they exist simultaneously and are separated by an interface, i.e. when they are phases.

We shall find the conditions which determine the position of the critical point in the (p, T) -plane. Since it lies on the phase equilibrium curve, equilibrium conditions are fulfilled at it, in particular the conditions

$$\Delta p = 0, \quad \Delta T = 0,$$

where Δp and ΔT are the differences between the pressures and temperatures in the phases.

Near the critical point the difference between the two phases becomes small, and at the critical point itself it completely vanishes. In particular, the change in the density in the phase transition is very small and the densities

of the two phases are close to each other, in contrast to points lying large distances from the critical point.

If the difference between the densities of the phases is denoted by $\Delta\rho$, then one can always write the formal expansion

$$\Delta p = \left(\frac{\partial p}{\partial \rho}\right)_T \Delta\rho + \frac{1}{2} \left(\frac{\partial^2 p}{\partial \rho^2}\right)_T (\Delta\rho)^2 + \frac{1}{6} \left(\frac{\partial^3 p}{\partial \rho^3}\right)_T (\Delta\rho)^3 + \dots \quad (64.1)$$

Because of the phase equilibrium the sum of this series is equal to zero. Near the critical point the expansion is simplified. Sufficiently near the critical point $\Delta\rho$ can be assumed to be infinitesimal and in the expansion (64.1) one can drop higher terms of the expansion and write

$$\Delta p = \left(\frac{\partial p}{\partial \rho}\right)_T \Delta\rho = 0. \quad (64.2)$$

Since $\Delta\rho$ is an arbitrary infinitesimal quantity, it follows from (64.2) that

$$\left(\frac{\partial p}{\partial \rho}\right)_T = 0. \quad (64.3)$$

The derivative in (64.3) is taken at the critical point. Thus, at the critical point

$$\left(\frac{\partial p}{\partial \rho}\right)_T \sim \left(\frac{\partial p}{\partial V}\right)_T = 0. \quad (64.4)$$

If the quantity $(\partial p/\partial V)_T$ reduces to zero, then it is necessary for the stability of the substance that the following condition should simultaneously be fulfilled:

$$\left(\frac{\partial^2 p}{\partial V^2}\right)_T = 0. \quad (64.5)$$

Otherwise the fluctuations of the volume, as we have explained in § 57, would be infinitely large. The conditions (64.3) and (64.4) determine the position of the critical point. They are the same as the well-known conditions for the inflection point on the van der Waals curve.

Near the critical point the substance possesses a number of remarkable properties. The differences between the properties of the liquid and gaseous

phases progressively decrease and vanish at the critical point. It can be shown * that near the critical point the densities of the two phases depend on the temperature according to the law

$$\rho = \rho_c \pm [\text{const} \cdot (T - T_c)]^{\frac{1}{2}},$$

where the plus sign refers to the liquid and the minus sign to the gas. At the critical point the latent heat of transition reduces to zero, while the heat capacity C_p becomes infinite. The surface tension in the liquid-gas interface also reduces to zero at the critical point. The fact that the compressibility becomes infinite at the critical point leads to an essential decrease in the work of compression or expansion of a volume element in the system near the critical point.

Transitions from the crystalline state into an isotropic state have a different character. We understand an isotropic state to be the amorphous, liquid, or gaseous state. In this case a transition from a state of ordered motion into a state of chaotic motion takes place. To an ordered motion of atoms (or ions) in a crystal there corresponds the location of the atoms near the points of the crystal lattice and associated with this ordered distribution a definite crystal symmetry. As the temperature increases an increase occurs in the vibrational amplitudes of the atoms at the crystal lattice points and the number of violations of the regularity of the lattice increases, but the general ordered character of the motion and the symmetry of the lattice are preserved up to the melting point (or the sublimation point). A catastrophic disruption of the lattice occurs at the melting point, the symmetry vanishes, and the ordered motion is replaced by a chaotic motion.

In contrast to transitions between different isotropic phases, a continuous transition between a crystal and one of the isotropic phases is impossible. This impossibility is associated with a fundamental difference in the character of motion in these phases. This is also seen from symmetry considerations. It is impossible to transform, in a continuous way, an infinitely symmetric (isotropic) body into one with a definite finite symmetry. The same holds for phase transitions between different crystal modifications. Each modification possesses a definite ordered motion of atoms and a symmetry corresponding to this motion. In a phase transition the changes in the character of the motion and symmetry of the crystal occur discontinuously without fail. Owing to this a crystal \rightleftharpoons isotropic-phase equilibrium curve or a crystal \rightleftharpoons

* L.D. Landau and E.M. Lifshitz, *Course of theoretical physics*, Vol. 5: *Statistical physics* (Pergamon Press, London, 1958).

crystal equilibrium curve cannot have an end point and must go off to infinity. The transition from one phase into another is always associated with an intersection of the equilibrium curve and has the character of a jump*.

§65. Surface tension and surface pressure

Up to now we have considered the equilibrium of phases in contact, without taking into account the particular properties of the interface and their effect on the equilibrium. If, however, the phases which are in equilibrium possess a developed surface, a complete disregard of surface effects can introduce a fundamental error into calculations which are carried out. In this section we shall take into account the effect of the surface on the phase equilibrium.

Molecules which are distributed in a thin layer directly adjacent to the interface are in conditions which differ from those of molecules inside the main volume. They interact not only with molecules of their own phase but also with the contiguous layer of molecules of the other phase. Owing to this the structure and physical properties of the thin layer of substance, whose thickness is of the order of magnitude of the radius of the molecular interaction, turn out to be different from those of the main volume.

A detailed treatment of the properties of the surface layer would require a knowledge of the mechanism of the molecular interaction. Such a theory would be very complex. Therefore we have to simplify the problem, replacing the surface layer of finite thickness by an idealized infinitely thin interface which separates the two phases. Such an idealized infinitely thin surface layer we shall, for brevity, call the surface. The area of the surface is a new parameter characterizing the state of the system. For a given volume the system can have different values of the surface area Σ , a definite state of the system corresponding to each value of Σ .

A change in the surface of a system is accompanied by a gain or expenditure of energy. In order to form a new surface a particle from the volume must be brought to the surface, which requires that work be done. We denote by γ the generalized force corresponding to the parameter Σ .

If a change in the surface takes place at constant temperature, then the

* For more details about phase transitions see B.G. Levich, *Vvedenie v statisticheskuyu fiziku (Introduction to statistical physics)*, (Gostekhizdat, Moscow, 1954) §76, and for a particularly full exposition, L.D. Landau and E.M. Lifshitz, *Course of theoretical physics*, Vol. 5: *Statistical physics* (Pergamon Press, London, 1958).

work done in changing the surface ($dW = -\gamma d\Sigma$) is equal to the decrease in the free energy ($-dF_{\text{surf}}$), so that

$$dF_{\text{surf}} = \gamma d\Sigma . \quad (65.1)$$

The quantity γ , which represents the free energy per unit surface, is called the surface tension. The surface tension γ depends on the nature of the surface (in other words, on the nature of the phases forming it), as well as on the temperature. The value of γ does not depend, however, on the area of the surface. Hence one can write that

$$F_{\text{surf}} = \gamma \Sigma . \quad (65.2)$$

At constant temperature and volume there corresponds to an equilibrium state of an unclosed system the minimum value of the free energy. The phase contact area represents an example of such a system. Hence the phase contact area in an equilibrium state has the minimum possible value of the free energy. For a simultaneous change in the value of the surface and temperature in the system the change in the free energy of the surface has the form

$$dF_{\text{surf}} = -S_{\text{surf}} dT + \gamma d\Sigma . \quad (65.3)$$

From formula (65.3) it follows that the entropy of the surface is defined by the relation

$$S_{\text{surf}} = - \left(\frac{\partial F}{\partial T} \right)_{\Sigma} = \Sigma \frac{d\gamma}{dT} , \quad (65.4)$$

which allows one to express S_{surf} in terms of the surface tension.

In addition to the free energy of the surface one can write the expression for the energy of the surface E_{surf} :

$$E_{\text{surf}} = F_{\text{surf}} + TS_{\text{surf}} = \gamma \Sigma - T \frac{d\gamma}{dT} \Sigma = \left(\gamma - T \frac{d\gamma}{dT} \right) \Sigma . \quad (65.5)$$

This formula shows that it would be erroneous to define the surface tension as the energy per unit surface.

For the differential of the surface energy we can write

$$dE_{\text{surf}} = T dS_{\text{surf}} + \gamma d\Sigma . \quad (65.6)$$

From the above equality the relation

$$\left(\frac{\partial S_{\text{surf}}}{\partial \Sigma}\right)_{\Sigma_{\text{surf}}} = -\frac{\gamma}{T} \quad (65.7)$$

follows.

It should be noted that (65.4) cannot directly be substituted into (65.7). This would lead to the incorrect formula $d\gamma/dT = -\gamma/T$. The derivative in (65.7) is taken for a constant surface energy, but from (65.5) it follows that

$$\frac{d\gamma}{dT} \Sigma = \frac{\gamma \Sigma - E_{\text{surf}}}{T},$$

while from (65.4) it follows that

$$S_{\text{surf}} = -\frac{\gamma \Sigma - E_{\text{surf}}}{T}.$$

Differentiating the last expression for $E_{\text{surf}} = \text{const}$, we arrive again at formula (65.7).

The change in the surface energy can be resolved into the work done and the amount of heat absorbed:

$$dE_{\text{surf}} = TdS_{\text{surf}} + \gamma d\Sigma = dQ + dW.$$

Taking into account (65.4), it follows from this that the amount of heat which is absorbed as the area of the surface is reversibly increased by 1 cm^2 is equal to

$$Q = (T\Delta S)_{\Delta\Sigma=1} = -T \frac{d\gamma}{dT}. \quad (65.8)$$

The heat capacity of unit surface (for the constant value of the surface area $\Sigma = 1$) can be defined as

$$c_{\Sigma} = \left(\frac{\partial E}{\partial T}\right)_{\Sigma=1} = -T \frac{d^2\gamma}{dT^2}. \quad (65.9)$$

All quantities characterizing the thermodynamic properties of the surface are determined in terms of the surface tension and its derivatives with respect to the temperature.

The temperature dependence of the surface tension can at present be established theoretically only for quantum liquids (liquid helium II). It is impossible to separate the motion of the molecules of the surface layer from the motion of particles inside the liquid at high temperatures. Hence available attempts to calculate the surface tension without taking into account this connection are beneath criticism.

The surface tension changes the phase equilibrium condition. The condition of equilibrium in a system consisting of two phases and an interface for

$$dF = dF_1 + dF_2 + dF_{\text{surf}} = -p_1 dV_1 - p_2 dV_2 + \gamma d\Sigma = 0.$$

Since the volume of the entire system remains constant, $dV_2 = -dV_1$, so that

$$-(p_1 - p_2)dV_1 + \gamma d\Sigma = 0$$

or

$$p_1 = p_2 + \gamma \frac{d\Sigma}{dV_1}. \quad (65.10)$$

The quantity $d\Sigma/dV_1$ represents the curvature of the interface

$$\frac{d\Sigma}{dV_1} = \frac{1}{r_1} + \frac{1}{r_2},$$

where r_1 and r_2 are the major radii of curvature. In the case of a spherical surface

$$\frac{d\Sigma}{dV_1} = \frac{d(4\pi r^2)}{d(\frac{4}{3}\pi r^3)} = \frac{2}{r}.$$

In this case the radius vector is assumed to be positive if it is directed towards the first phase. Thus, we have finally

$$p_1 = p_2 + \gamma \left(\frac{1}{r_1} + \frac{1}{r_2} \right). \quad (65.11)$$

The quantity $\gamma(r_1^{-1} + r_2^{-1})$ is called the Laplace pressure, and formula (65.11) is called the Laplace formula. The Laplace formula shows that the pressure

in the first phase is balanced by the sum of the pressure in the second phase and the Laplace pressure. In the particular case of a plane interface the Laplace pressure reduces to zero, since for a plane surface $r_1 \rightarrow \infty$, $r_2 \rightarrow \infty$.

The presence of surface tension changes not only the condition of mechanical equilibrium but also the phase equilibrium condition for particle exchange.

That is, although particles cannot be detained in the interface in the case of phase equilibrium and can go from one phase into the other without hindrance, condition (61.4) will now be fulfilled for a somewhat changed value of the pressure (in comparison with the pressure at the point of phase transition at the same temperature for a plane interface).

Let us consider the case of phase equilibrium between the drops of a liquid and its vapour. We shall assume the drops to be spheres of radius r .

The equilibrium condition for the particle exchange will have the form

$$\mu_1(p'', T) = \mu_2(p', T), \quad (65.12)$$

where p'' is the pressure of the saturated vapour, p' is the corresponding pressure in the liquid drop, and T is the transformation temperature. We assume the latter to be equal to the transformation temperature in the case of a plane surface. The same condition at a plane surface has the form

$$\mu_1(p, T) = \mu_2(p, T). \quad (65.13)$$

Subtracting (65.13) from (65.12), we find

$$\mu_1(p'', T) - \mu_1(p, T) = \mu_2(p', T) - \mu_2(p, T). \quad (65.14)$$

Since the compressibility of the liquid is very small, the difference between the pressures p' and p is also small. In view of this one can write that

$$\begin{aligned} \mu_2(p', T) - \mu_2(p, T) &= \mu_2(p + \Delta p, T) - \mu_2(p, T) = \\ &= \frac{\partial \mu_2}{\partial p} \Delta p = v_2 \Delta p, \end{aligned} \quad (65.15)$$

where v_2 is the volume per particle in the liquid phase, and Δp is the difference between the pressures in the liquid for a spherical surface and plane surface. This difference is obviously equal to

$$\Delta p = \frac{2\gamma}{r}.$$

The change in the pressure of the saturated vapour above a spherical drop in comparison with a plane surface is in general not small, and the left-hand side of (65.14) cannot be expanded in a series. We shall rewrite it, making use of the general formula for the chemical potential (60.5) of an ideal gas. Assuming the vapour to be an ideal gas, we find

$$kT \ln \frac{p''}{p} = v_2 \frac{2\gamma}{r}. \quad (65.16)$$

Formula (65.16) relates the pressure of the saturated vapour above the drop to its radius. Writing it in the form

$$p'' = p \exp \left[\frac{2v_2\gamma}{rkT} \right], \quad (65.17)$$

we see that p'' rapidly increases with decreasing radius of the drop, and that for small drops it can become considerable.

For example, for water drops with $\gamma \approx 80 \text{ erg/cm}^2$, $r = 10^{-6} \text{ cm}$ and $T \approx 300 \text{ K}$ the pressure $p'' \approx 1.1p$, i.e. the pressure of the vapour above the drop exceeds that above a plane surface by 10%.

Formula (65.17) shows that a system consisting of a set of drops of different size is in a state of unstable equilibrium. Small drops possessing an excess energy which is associated with the surface tension will evaporate, while the vapour will condense on big drops. This process, which is called the distillation of drops, will go on until the entire liquid transforms into drops of the largest size.

Another important phenomenon, which is associated with the change in the pressure of the vapour above a curved surface, is observed in capillary tubes wetted by a liquid. In such capillary tubes the surface of the meniscus will be concave, so that one has to write a minus sign in formula (65.17). The pressure of the saturated vapour above a concave surface turns out to be smaller than that above a plane surface. Owing to this, condensation of the vapour takes place in fine capillary tubes before it does above a plane surface at the same temperature. This phenomenon is called capillary condensation.

Formula (65.17), which has been derived for equilibrium in a liquid-vapour system, is qualitatively valid also in other cases of phase equilibrium, for example, a crystal-vapour system.

§66. Gas adsorption

One of the most important effects associated with the particular properties of the phase contact area is adsorption. By adsorption is meant the accumulation of a substance on the surface of a solid or liquid phase. As a rule the adsorbed substance is distributed over the phase contact area and does not penetrate at all into the condensed phase. The phenomenon of adsorption is observed for many different combinations of phases. In practice one most often has to deal with the adsorption of gases on the surface of a solid body. In this section we shall confine ourselves to the treatment of this case of adsorption.

For the present, the nature of the forces which bind molecules adsorbed on a surface with the molecules of the solid or liquid backing (called the adsorbent) cannot be considered as well established. In a number of cases they have the character of van der Waals forces, in other cases a stronger bond is established between the adsorbed molecules and the molecules of the adsorbent, corresponding to the formation of a particular chemical combination. Intermediate cases are also possible. As a rule, adsorbed molecules are distributed on the surface of the adsorbent in the form of a monomolecular layer. Adsorbed molecules most often possess no mobility, and in the process of adsorption they are fixed to quite definite points on the surface of the crystal. We shall call such points on the surface of a crystal at which the adsorption of molecules takes place sites. The sites can be the edges of the faces of a crystal or any other outstanding points on the surface.

We denote the number of sites per cm^2 of the surface of the crystal by N_L . We assume that all sites on the surface are equivalent, so that the adsorbed molecule is bound to the surface at each of them to the same degree.

We write the partition function for a system of adsorbed particles, assuming that their density N_A (the number of particles per cm^2 of the surface) is small and that the interaction between adsorbed molecules can be disregarded. Every one of the adsorbed particles possesses a potential energy $(-u)$ which is a measure of the work done in removing the particle from the surface.

If it is assumed that the adsorbed molecules are oscillating about an equilibrium position with a frequency ν , then the partition function for each molecule can be written in the form

$$z_A = e^{u/kT} z_{\text{oscil}},$$

where z_{oscil} is the partition function of the oscillator.

The partition function for the entire set of adsorbed particles can be written in the form

$$Z_A = \frac{N_L!}{N_A!(N_L - N_A)!} (z_A)^{N_A}, \quad (66.1)$$

where the factor $\frac{N_L!}{N_A!(N_L - N_A)!}$ represents the statistical weight of the state.

Indeed, to a given energy of the system there correspond a number of states which differ in the distribution of the particles over sites. The number of ways in which N_A particles can be distributed over N_L sites is equal to $N_L!/[N_A!(N_L - N_A)!]$. It is this number which gives the statistical weight of a state of a given energy of the system of particles.

By means of (66.1) one can find the free energy and the chemical potential of the system. We have for the free energy

$$\begin{aligned} F_A &= -kT \ln Z_A = -kT \ln \left\{ \frac{N_L!}{N_A!(N_L - N_A)!} (z_A)^{N_A} \right\} \approx \\ &\approx -N_L kT \ln \frac{N_L}{e} + kT N_A \ln \frac{N_A}{e} + \\ &+ (N_L - N_A) kT \ln \frac{N_L - N_A}{e} - N_A kT \ln z_A. \end{aligned} \quad (66.2)$$

Correspondingly, the chemical potential of adsorbed particles is equal to [see (60.3')]

$$\begin{aligned} \mu_A &= \frac{\partial F_A}{\partial N_A} = kT \ln \frac{N_A}{e} - kT \ln \frac{N_L - N_A}{e} - kT \ln z_A = \\ &= kT \ln \frac{N_A}{N_L - N_A} - kT \ln z_A. \end{aligned} \quad (66.3)$$

By means of formula (66.3) one can consider the equilibrium between an adsorbed substance and the gas. Equating μ_A and the chemical potential of the gas given by formula (60.5), we obtain

$$kT \ln \frac{N_A}{N_L - N_A} + f(T) = kT \ln p + \varphi(T),$$

whence we find

$$\frac{N_A}{N_L - N_A} = \frac{p}{p_0(T)}, \quad (66.4)$$

where p_0 depends only on the temperature. Solving (66.4) for N_A , we obtain

$$N_A = N_L \frac{p}{p + p_0(T)}. \quad (66.5)$$

Formula (66.5) represents the adsorption isotherm: it determines the number of adsorbed molecules as a function of the pressure of the gas above the surface of a solid body at a given temperature. It is obvious that at low pressure, when $p \ll p_0$, this number is proportional to the pressure of the gas and to the number of sites:

$$N_A \approx N_L \frac{p}{p_0(T)}.$$

In this case the degree of occupation of the sites is small. At a large pressure $p \gg p_0$ the phenomenon of saturation occurs, the number of adsorbed molecules ceases to depend on the pressure and becomes a constant equal to the number of sites:

$$N_A \approx N_L.$$

The adsorption isotherms of formula (66.5) are shown in fig. 111.43.

At high temperatures a mobility of the adsorbed molecules across the surface arises. In the limit the adsorbed molecules can move across the surface of a solid body like the molecules of a "two-dimensional" gas. Then the form of the partition function z_A of the adsorbed molecule changes, but the form of the adsorption isotherm remains as before.

It should be noted that the simplest mechanism of adsorption considered here, for which all sites on the surface are characterized by one and the same binding energy ($-u$) and which leads to the isotherm (66.5), is seldom encountered. Usually there are different sites on the surface of a solid body with different values of the binding energy, i.e. the surface of the adsorbent is non-uniform. Moreover, when sites are densely occupied the interaction between molecules in the adsorbed layer becomes important and affects the shape of the isotherm. As a result of the superposition of these factors the

Fig. III.43

form of the isotherm can change and be very different from that shown in fig. III.43. By determining the form of the isotherm from experimental data and considering it as a result of the superposition of the isotherms (66.5) with different $p_0(T)$, one can obtain information about the non-uniformity of the surface.

As to gas adsorption on the surface of a liquid, the mechanism of adsorption here does not differ from that on the surface of a solid body at high temperatures; all points on the surface of a liquid are equivalent and the adsorbed particles are mobile on the surface for a relatively sparse population. The adsorption isotherm has the form (66.5). When the surface is very densely populated the interaction between the adsorbed molecules, which distorts the form of the isotherms, begins to play an important role.

§67. Chemical equilibrium in the gas phase

As the second example of a system with a variable number of particles we shall consider equilibrium in a system in which a chemical reaction occurs.

We assume for concreteness that in the course of the chemical reaction atoms A and B combine to form a molecule AB. The molecule AB in its turn dissociates into individual atoms A and B. Both processes, that of the combination and that of the dissociation, have a certain rate, by which is meant the number of events occurring per unit time. The rate of the direct process

$A+B \rightarrow AB$ is in general not equal to that of the reverse process $AB \rightarrow A+B$. Hence the chemical reaction proceeds mainly in one direction. However, after the lapse of a certain time, when reagents arising in the course of the more rapid reaction have accumulated while the amount of reagents vanishing in the course of the reaction have decreased the rate of the rapid reaction will decrease whereas that of the slow reaction will increase. As a result an equilibrium state will be established in the system. The number of molecules AB produced and disintegrated will be the same. In this case one speaks of the equilibrium reaction $A+B \rightleftharpoons AB$. It is more convenient to write the reaction in the form of an equality. If the reaction takes place between several substances, then each chemical reaction can be written in the form

$$\nu_i g_i = 0, \quad (67.1)$$

where the g_i are the chemical symbols of the reacting substances, and the ν_i are the number of reacting moles of the corresponding substances. We choose to write reactions in such a way that the coefficients ν_i for substances which are used up in the course of the reaction have a negative sign, while those for substances produced have a positive sign. For example, the reaction of the formation of water vapour from the mixture

must from this point of view be written in the form

$$2H_2O - 2H_2 - O_2 = 0,$$

so that

$$\nu_{H_2O} = 2, \quad \nu_{H_2} = -2, \quad \text{and} \quad \nu_{O_2} = -1.$$

Let us write the conditions of chemical equilibrium in an arbitrary system consisting of initial substances and reaction products. The set of molecules of the initial substance and the set of molecules of the reaction products can be considered as certain quasi-closed systems which are in a reservoir and are weakly interacting with each other. The latter condition is fulfilled if the number of atoms reacting per unit time is small in comparison with the total number of molecules in the system, which is always the case in a macroscopic system of substances for an equilibrium reaction.

One usually investigates the equilibrium states of a reacting system at a given temperature and pressure. The equilibrium condition is the requirement

$$G(p, T, N_i) \rightarrow \min ,$$

where N_i is the number of particles of a given kind. For constant given values of the temperature and pressure in the entire system the condition of the minimum can be rewritten in the form

$$dG = \left(\frac{\partial G}{\partial N_1} \right)_{p,T} dN_1 + \left(\frac{\partial G}{\partial N_2} \right)_{p,T} dN_2 + \dots = \sum \mu_i dN_i = 0$$

and, noting that the change in the number of particles of a given kind can be written in the form

$$dN_i = \nu_i dN ,$$

we obtain the equilibrium condition in a system in the presence of chemical reactions:

$$\sum \nu_i \mu_i = 0 . \quad (67.2)$$

When one molecule of the first subsystem transforms into one molecule of the second subsystem (the case which we have considered before) the coefficients ν_i are obviously equal to $\nu_1 = 1$, $\nu_2 = -1$. In this case formula (67.2) turns out to be identical with (61.4).

We see that chemical equilibrium is determined by the equality of the chemical potentials.

§68. The law of mass action

In order to apply the conditions (67.2) to definite cases of chemical equilibrium it is necessary to know the explicit form of the chemical potentials. The latter are known mainly for gases. Therefore the theory which follows will refer to chemical equilibrium in a mixture of gases. We have, in §60, calculated the chemical potential of a gas. In a mixture of ideal gases each of the gases behaves as though it alone occupied the entire volume of the container and has a chemical potential $\mu_i = N_i p_i / N$, where N_i is the number of particles of the i th gas and N is the total number of atoms of all kinds in the container. We write μ_i in the general form:

$$\mu_i = kT \ln p_i + \chi_i(T), \quad (68.1)$$

where

$$\begin{aligned} \chi(T) &= -\frac{5}{2}kT \ln kT - kTj_1, \\ j_1 &= \ln \left[\left(\frac{2\pi m}{h^2} \right)^{\frac{3}{2}} \right] \end{aligned} \quad (68.2)$$

for a monatomic gas,

$$\chi(T) = -\frac{7}{2}kT \ln kT - kTj_2 + kT \ln (1 - e^{-h\nu/kT}) + \epsilon_0, \quad (68.3)$$

$$j_2 = \ln \left[\left(\frac{2\pi m}{h^2} \right)^{\frac{3}{2}} \frac{8\pi^2 I}{\gamma h^2} \right]$$

for a diatomic gas at very high temperatures when vibrations are excited, and

$$\chi(T) = -\frac{7}{2}kT \ln kT - kTj_2 + \epsilon_0$$

for a diatomic gas at not very high temperatures, when vibrations are not excited.

Let us consider a reaction of the type

$$\nu_1 g_1 + \nu_2 g_2 - \nu_3 g_3 = 0.$$

The chemical equilibrium condition reads

$$\nu_1 \mu_1 + \nu_2 \mu_2 - \nu_3 \mu_3 = 0 \quad (68.4)$$

or

$$\nu_1 kT \ln p_1 + \nu_2 kT \ln p_2 - \nu_3 kT \ln p_3 = \nu_3 \chi_3 - \nu_1 \chi_1 - \nu_2 \chi_2. \quad (68.5)$$

Thus,

$$\frac{p_1^{\nu_1} p_2^{\nu_2}}{p_3^{\nu_3}} = K(T), \quad (68.6)$$

where

$$\ln K(T) = \frac{\nu_3 X_3 - \nu_1 X_1 - \nu_2 X_2}{kT} . \quad (68.7)$$

The quantity $K(T)$ depends only on the temperature and nature of the reacting molecules but not on the initial pressures or the amount of the reacting gases.

Formula (68.6) is called the law of mass action. The law of mass action shows that, irrespective of the initial composition of the reacting gas mixture, in the course of time there is established in it an equilibrium state for which the partial pressures have quite definite values which are related by formula (68.6). They do not depend on any parameters except the temperature, the difference between the zero point energies, and the chemical constants of the reacting gases. In the case where the reaction involves not three but a larger number of gases the mass action law must be written in the form

$$\prod \frac{(p_{i'})^{\nu_i'}}{(p_i)^{\nu_i}} = K(T) , \quad (68.8)$$

where the product is taken over all the gases taking part in the reaction, and the primes refer to reaction products.

The law of mass action was first discovered experimentally by N.N.Beketov, and it was introduced theoretically, on the basis of statistical considerations, by Guldberg and Waage.

The expression (68.8) has a clear statistical meaning: in order that the initial substances may react it is necessary that their molecules should simultaneously be in a very small volume v , whose size is of the order of magnitude of the diameter of the molecules. Since the gases are assumed to be ideal and the motion of the molecules is independent of one another, the probability that the molecules of the initial substances will simultaneously be found in a given volume is proportional to the numbers of these molecules in the gas. These numbers are in their turn proportional to the corresponding partial pressures. Thus, the probability of the direct reaction w_1 is proportional to $p_1^{\nu_1} p_2^{\nu_2} \dots$

$$w_1 = ap_1^{\nu_1} p_2^{\nu_2} \dots .$$

The same reasoning can also be applied to the reverse reaction. The probability of the reverse reaction w_2 is equal to

$$w_2 = b(p_1')^{\nu_1'} (p_2')^{\nu_2'}.$$

In an equilibrium state the rate of the direct reaction is equal to that of the reverse reaction. For this the probability of the direct process must be equal to that of the reverse process. Equating w_1 and w_2 and denoting by K the ratio of the factors of proportionality a/b , we arrive at formula (68.8).

The mass action law represents the basic law of chemical equilibrium. It can be derived in a purely thermodynamic way, but then the value of the constant $K(T)$ remains indefinite and must be found experimentally. By means of the statistical expressions for the μ_i which have been presented above, the constant K can be calculated theoretically. We shall give an example of such a calculation somewhat later.

The law of mass action is most often expressed not in terms of partial pressures but in terms of the so-called molar fractions:

$$c_i = p_i/p.$$

Substituting c_i into (68.6), we obtain

$$\frac{c_1^{\nu_1} c_2^{\nu_2}}{c_3^{\nu_3}} = p^{-\sum \nu_i} K(T). \quad (68.9)$$

From formula (68.9) it follows that, if the reaction proceeds without a change in the number of moles, so that $\nu_3 = \nu_1 + \nu_2$, the equilibrium does not depend on the total pressure p in the system. As an example of such a reaction we point to the reaction of the dissociation of hydrogen iodide

for which $\nu_1 = 1$, $\nu_2 = 1$, $\nu_3 = -2$.

If the reaction proceeds with a change in the number of moles, so that $\nu_3 \neq \nu_1 + \nu_2$, then the change in the total pressure shifts the equilibrium. This means that the ratio between the molar fractions of the initial substance and the reaction product changes as the total pressure changes. Let, for example, the dissociation of the N_2O_4 molecule into two NO_2 molecules takes place. We write the reaction in the form

The coefficients of the reaction are $\nu_{\text{NO}_2} = 2$, $\nu_{\text{N}_2\text{O}_4} = -1$, so that the reac-

tion proceeds with an increase in the number of moles. The law of mass action reads:

$$\frac{c_{\text{NO}_2}^2}{c_{\text{N}_2\text{O}_4}} = p^{-1} K(T) .$$

As the total pressure decreases the number of NO_2 molecules increases, i.e. the percentage of dissociated N_2O_4 molecules in the equilibrium mixture decreases. Thus, if the reaction proceeds with an increase in the number of moles, $|\nu_3| > \nu_1 + \nu_2$, then a decrease in the total pressure favours the reaction, whereas an increase in the pressure hampers it. In the case of reactions proceeding with a decrease in the number of moles, $|\nu_3| < \nu_1 + \nu_2$, the change in the total pressure acts in the reverse direction.

§69. Thermal dissociation of atoms

We have mentioned earlier the thermal dissociation of atoms which occurs at very high temperatures. When the temperature reaches such high values that the thermal energy kT becomes comparable with the energy required to tear an electron away from an atom (the ionization energy), then thermal ionization of atoms takes place. Atoms dissociate into positively charged ions and electrons which form the corresponding ideal gases. In addition to the process of ionization the reverse process also takes place: recombination, in the course of which an ion and an electron combine to form a neutral atom. Thus, at very high temperatures two reactions take place in the substance:

where A denotes the atom and I^+ denotes the ion (for simplicity we confine ourselves to the case of single ionization). If constant conditions of temperature and pressure are maintained in the system, then an equilibrium state will be established in which the number of dissociations is equal to the number of recombinations. A system in which an equilibrium reaction

takes place in principle does not differ at all from a system in which an equilibrium chemical reaction takes place. For such a system the law of mass action can be written in the form

$$\frac{c_{I^+} c_e}{c_A} = p^{(\nu_A - \nu_{I^+} - \nu_e)} K(T) = \frac{K(T)}{p}, \quad (69.1)$$

where c_e , c_{I^+} , c_A are the molar fractions of the electron gas, ion gas and atomic gas respectively. The constant $K(T)$ is given by

$$\ln K(T) = \frac{5}{2} \ln kT + j_e - \frac{\Delta\epsilon_0}{kT}. \quad (69.2)$$

In formula (69.2) all quantities referring to the ion and the atom have been cancelled, since the difference between the mass of the ion and the mass of the atom can be neglected. The chemical constant of the electron gas is equal to

$$j_e = \ln \left[\left(\frac{2\pi m_e}{h^2} \right)^{\frac{3}{2}} \right].$$

The quantity $\Delta\epsilon_0$ represents the ionization energy of the atom. Thus,

$$\frac{c_{I^+} c_e}{c_A} = \frac{1}{p} \exp \left(\frac{5}{2} \ln kT + j_e - \frac{\Delta\epsilon_0}{kT} \right) = \frac{K(T)}{p}. \quad (69.3)$$

Instead of molar fractions it is more convenient to introduce another, more obvious quantity, which is called the degree of dissociation. Let an α th part of atoms undergo dissociation, so that $N(1+\alpha)$ particles arise out of N atoms. The quantity α characterizing the fraction of ionized atoms is called the degree of dissociation. Obviously, we have

$$c_{I^+} = \frac{\alpha}{1+\alpha}, \quad c_e = \frac{\alpha}{1+\alpha}, \quad c_A = \frac{1-\alpha}{1+\alpha}.$$

Substituting molar fractions expressed in terms of the degree of dissociation into (69.3), we find

$$\frac{\alpha^2}{1-\alpha^2} = \frac{K}{p},$$

whence

$$\alpha = \left[1 + \frac{p}{K} \right]^{-\frac{1}{2}} = \left[1 + \frac{p}{(kT)^{\frac{5}{2}}} \left(\frac{h^2}{2\pi m} \right)^{\frac{3}{2}} \exp \frac{\Delta \epsilon_0}{kT} \right]^{-\frac{1}{2}}. \quad (69.4)$$

From this formula it is seen that the degree of dissociation increases rapidly with temperature. Estimates of the numerical values of the quantities contained in the coefficient of the exponential factor in the denominator show that this factor is very small.

Hence, provided $\Delta \epsilon_0/kT$ is not very large, the entire expression under the square root, and also α , is of the order of unity. This means that for values of kT which are comparable with the ionization energy the gas turns out to be practically completely ionized:

$$\alpha \approx 1; \quad c_{I^+} \approx \frac{1}{2}; \quad c_e \approx \frac{1}{2}; \quad c_A \approx 0.$$

The degree of ionization also increases with decreasing total pressure. This is in complete agreement with what was said at the end of §68 for reactions proceeding with an increase in the number of moles.

A well-known application of formula (69.4) is in the elucidation of a peculiar feature of the spectrum of the solar atmosphere which at first sight seems to be very strange. A method of investigating spectra which originate from different layers of the solar atmosphere (chromosphere) has been developed in astrophysics. Investigations have shown that in the deeper layers of the atmosphere, where the temperature is higher, the degree of dissociation of the vapour of calcium is lower than that in outer, cooler layers. In the case of calcium the ionization potential amounts to 6 eV. The degree of ionization α at 6000 K and a pressure $p = 1$ atm amounts to only 8%, whereas at the same temperature and a pressure of 10^{-2} atm it reaches 65%. The explanation lies in the fact that, owing to the effect of the coefficient of the exponential term containing p in formula (69.4), the increase in the degree of dissociation with decreasing pressure is more rapid than its decrease with decreasing temperature in going from the deeper to the outer layers of the solar atmosphere.

Statistical Distributions in Quantum Statistics and Some of Their Applications

§70. The identity of elementary particles and the calculation of the partition function

We have already pointed out more than once that classical concepts turn out to be inadequate for the study of the motion of atomic systems and that they must be replaced by the concepts of quantum theory. In ch. I we presented the minimum amount of information from quantum theory which was necessary for the subsequent exposition. However, for a more profound analysis of those changes which are introduced into statistical physics by quantum theory it is necessary to dwell on certain important results of quantum theory.

As we have already stressed, the following two propositions of quantum mechanics are of basic importance for statistical physics:

- (1) the existence of the discrete states of a system,
- (2) the principle of identity of elementary particles.

We have from the very beginning taken into account the discreteness of quantum states. We have established when it is necessary to take into account the discrete character of energy levels, and when they can be considered approximately as distributed continuously. Also, we have shown the effect of the discreteness of the energy spectrum on the behaviour of statistical

systems. However, up to now we have not taken the identity of particles into account in a systematic way. True, we have considered as one state those states differing from each other only by a permutation of the particles. For this we have divided the phase space by the number of possible permutations of the particles. This division represented the simplest attempt of taking into account the identity of particles. As a matter of fact, the division by $N!$ was carried out even before the appearance of quantum theory. Otherwise, as we have already pointed out in §37, incorrect expressions for thermodynamic functions were obtained from statistics. Considerations based on the principle of identity of elementary particles justified to a certain degree the division of the partition function by $N!$. However, the inconsistency of this operation is obvious. Indeed, we have assumed in the beginning that all particles are different from each other, so that one can in principle number them, ascribing a definite number or label to each particle. Proceeding from this point of view, we have calculated the possible states of a system consisting of N independent particles, integrating with respect to the coordinates and momenta of the first, second and so on particles. Thereupon, in contradiction with the initial assumption of the possibility of numbering the particles, we have proclaimed that the part of the states differing from each other only by a permutation of the particles to be completely identical and have required that all of them should be taken into account as one.

Experiment and theory show, however, that the identity of atomic particles has a much more profound character. The complete identity of atomic particles leads to the fact that the first of the operations which we have carried out — the numbering of particles — loses any physical meaning. It makes no sense to call one of the particles the first, another the second and so on and to integrate them over states, since there are no physical differences between the first, second and so on particles. If one calls the particle which is at the initial instant in a definite state the first particle, then at a subsequent instant it would already be impossible to assert that it is just the first particle which is in this state, because it would be impossible to distinguish the first particle from a "not first" particle. Hence it is necessary from the very beginning to renounce any attempt to distinguish between individual atomic particles, i.e. to renounce the property of a system of atomic particles which we have adopted *.

We shall now see what changes in the statistical distribution result from taking account of the complete identity of atomic particles. All further discussion will refer only to a monatomic ideal gas.

* Exceptions are the so-called systems of localized particles which are separated from each other by impenetrable barriers. We shall not consider such systems.

§ 71. A second method of deriving the statistical distribution

In order to derive the statistical distribution in a gas, taking into account the principle of the identity of elementary particles, we shall have recourse to a special method which is characteristic of the versatility of statistical methods. To make the difference between the classical and quantum considerations particularly striking, we shall first introduce the classical distribution (the Maxwell distribution) by means of this method.

Assume that the molecules in a gas can be in individual quantum states with energies of translational motion $\epsilon_1, \epsilon_2, \epsilon_3, \dots$ (for the convenience of the treatment we shall for the present assume that the energy levels are discrete). In the gas there is a certain distribution of particles over states, such that in the first state there are n_1 particles, in the second state there are n_2 particles, and so on. From the classical point of view we have to describe the states of the gas in the following way:

particles No. 1, 2, 3, ..., n_1 are in the state with energy ϵ_1 ,

particles No. $n_1 + 1, \dots, n_1 + n_2$ are in the state with energy ϵ_2 ,

particles No. $n_1 + n_2 + 1, \dots, n_1 + n_2 + n_3$ are in the state with energy ϵ_3 and so on.

Further, we choose as a quasi-closed subsystem all particles which are in a certain arbitrarily chosen quantum state with energy ϵ_k . All the remaining gas particles, which are in other energy states, then form a reservoir.

The choice of a group of particles which are in a given state as a subsystem is in complete agreement with those requirements which must be satisfied by a quasi-closed subsystem (§ 13). Indeed, as a result of collisions the particles possessing the energy ϵ_k go over into other states. Conversely, owing to the same mechanism other molecules, which earlier had an energy differing from ϵ_k and which, consequently, belonged to the reservoir, can go into the state with energy ϵ_k . If the number of molecules which are coming in or going out of the subsystem per unit time is small in comparison with the number of particles in it, then it can be assumed that the interaction between the subsystem and the reservoir is weak. This condition will be fulfilled if the collisions between the particles which cause the corresponding transitions occur sufficiently seldom, i.e. when the gas is rarefied. Since the interaction of the subsystem with the reservoir consists in the passage of particles from the subsystem to the reservoir and vice versa, the subsystem which we have chosen represents an example of a subsystem with a variable number of particles. It differs from the general case of a subsystem with a variable number of particles and a variable energy by the fact that the energy of each particle in the subsystem is fixed. However, the energy of the subsystem,

which is made up of the energies of all the particles contained in it, of course, also changes as the number of particles in it changes.

In order to avoid misunderstanding we stress that we are now speaking not of the states of an actually existing system but of the states of a conditionally introduced subsystem. Our subsystem is not a single system but a set of particles with a definite energy which are at different loci of the gas and are not bound to each other.

In the process of variation of a state of a real system the number of particles getting into the state with the given energy ϵ_k changes. In this sense the state of our subsystem varies. The energy of the subsystem is equal to

$$\epsilon = \epsilon_k n_k, \quad (71.1)$$

where n_k is the number of particles in the subsystem. The quantity ϵ varies together with n_k .

In order to characterize completely the state of the subsystem we have chosen, it is necessary to know the mean number of particles in it, i.e. the mean number of particles which are at the energy level we have chosen. For this calculation use can be made of the general formula (59.11) which gives the mean number of particles in a subsystem with a variable number of particles. In our special case this formula can be essentially simplified. We do not have to introduce the double summation over the possible values of the energy and the number of particles, because in our system the value of the energy is unambiguously determined by the number of particles contained in it according to formula (71.1). In summing over the possible values of the number of particles in the subsystem we automatically carry out the summation over the possible values of its energy. As a matter of fact, it is with this simplification that our choice of the subsystem has been associated. Thus, the mean number of particles \bar{n}_k in the subsystem is expressed by the formula

$$\bar{n}_k = kT \frac{\partial}{\partial \mu} \ln \sum_{n_k} \left(\exp \frac{\mu - \epsilon_k}{kT} \right)^{n_k} \Omega(n_k), \quad (71.2)$$

where instead of ϵ we have substituted its expression according to formula (71.1).

The summation in (71.2) is carried out over all possible values of the number of particles n_k in the subsystem. In order to actually perform the summation in formula (71.2) it is necessary to know the explicit expression for the statistical weight (the number of states) $\Omega(n_k)$ of the state of the system when it contains n_k particles. In quasi-classical statistics, where all

particles can be numbered, the states of our system will always be degenerate, provided the system contains more than one particle of a given kind. Indeed, if the system contains N identical particles, then it can be in states which differ from each other by a permutation of the particles. For example, let there be in our gas two molecules, No. 1 and No. 2, with energy ϵ_k . In the first state molecule No. 1 is at point 1 while molecule No. 2 is at point 2. In the second state the positions of the molecules are exchanged. The energy of the subsystem in the two states is the same and equal to $2\epsilon_k$. Thus, there are two states of the system with an energy $2\epsilon_k$ or, in other words, the states of the system are two-fold degenerate. In the general case the states of a system containing n_k particles are $n_k!$ -fold degenerate.

If we do not wish to consider states differing only by a permutation of the particles as different states (which would undoubtedly lead us to incorrect expressions for the thermodynamic functions), then for Ω use should be made of the general formula (1.26) and the total volume of the phase space must be divided by the number of possible permutations of molecules $n_k!$ and the size h^3 of a cell.

The volume of phase space corresponding to one quantum state with an energy ϵ_k is obviously equal to h^3 . Hence for $\Omega(n_k)$ we finally obtain

$$\Omega(n_k) = \frac{1}{n_k!}. \quad (71.3)$$

Substituting the expression (71.3) into formula (71.2), we find

$$\bar{n}_k = kT \frac{\partial}{\partial \mu} \ln \sum_{n_k=0}^N \frac{1}{n_k!} \left(\exp \frac{\mu - \epsilon_k}{\theta} \right)^{n_k}. \quad (71.4)$$

The number of particles n_k contained in the subsystem can vary from zero to the total number of particles in the gas N . However, the probability that all particles of the gas be found simultaneously in one energy state is extremely low. Hence for n_k which are close to N the terms of the sum (71.4) are so small that the sum rapidly converges. Therefore we shall not commit an error if we replace the upper limit N in the sum by infinity. This corresponds to the addition of infinitesimal terms to the sum. For such a substitution the sum (71.4) goes over into a simple series:

$$\sum_{n_k=0}^{\infty} \frac{1}{n_k!} \left(\exp \frac{\mu - \epsilon_k}{\theta} \right)^{n_k} = \sum_{n=0}^{\infty} \frac{x^n}{n!} = e^x, \quad (71.5)$$

where we have provisionally denoted $\exp(\mu - \epsilon_k)/\theta$ by x . Thus,

$$\bar{n}_k = kT \frac{\partial}{\partial \mu} \ln e^x = kT \frac{\partial}{\partial \mu} \exp \frac{\mu - \epsilon_k}{kT} = \exp \frac{\mu - \epsilon_k}{kT}. \quad (71.6)$$

In particular, if the states of the molecule and its energy vary continuously, which is always valid in classical statistics, then instead of a given energy level ϵ_k one has to consider states with an energy lying between ϵ and $\epsilon + \delta\epsilon$. Then instead of the number of particles n_k in a given quantum state one needs an expression for the mean number of particles with an energy between ϵ and $\epsilon + \delta\epsilon$, which we shall denote by dn . Obviously,

$$dn = \bar{n} \frac{d\gamma}{h^3} = \left(\exp \frac{\mu - \epsilon}{kT} \right) \frac{d\gamma}{h^3}, \quad (71.7)$$

where $d\gamma$ is the volume of phase space corresponding to an energy between ϵ and $\epsilon + \delta\epsilon$, and $d\gamma/h^3$ is the number of states with this energy. Formula (71.7) is the same as the Maxwell distribution in the form it had in formula (60.10).

In later sections we shall make use of the statistical distribution (71.2) to obtain the quantum laws of the distribution of molecules in an ideal gas.

In conclusion we note that the method of deriving the Maxwell-Boltzmann distribution described here is often called the method of cells in phase space.

§ 72. Quantum distributions for an ideal gas

As we have just stressed, it follows from the principle of identity of particles that one cannot distinguish between individual microscopic particles; electrons, photons, protons and other elementary particles or atoms or molecules*.

* In the latter case it is actually the same atoms or molecules, which behave identically in all possible fields of force, that are identical with one another. Atoms or molecules differing in any way, for example, containing nuclei of different isotopes or being in different rotational states, must be considered as particles of quite different kinds.

Applying the point of view of the identity of particles in a consequential way, one has to renounce the numbering of particles. One can then no longer speak of "two states differing by the exchange of two particles" or of " $n!$ identical states differing by a permutation of n particles". We have to speak of "a state with an energy ϵ_k in which there are respectively two particles or n_k particles".

Instead of indicating the state of the entire gas by listing the particles in different energy states, one has to indicate the number of particles in each of these states, i.e. to indicate that there are

n_1 particles in the state with energy ϵ_1 ,

n_2 particles in the state with energy ϵ_2 .

Thus, the description of the state of a gas turns out to be less detailed than in classical statistics.

Since one cannot speak of a permutation of particles in a given state, the division by $n!$ makes no sense. Each state, irrespective of the number of particles which are in it, has the same statistical weight, namely the weight equal to unity.

The change in the method of calculating states leads to a basic change in the form of the statistical distribution. To obtain the latter we shall make use of the method of the preceding section. The mean number of particles in a state with an energy ϵ_k is given by the formula

$$\bar{n}_k = kT \frac{\partial}{\partial \mu} \ln \sum_{n_k} \left(\exp \frac{\mu - \epsilon_k}{kT} \right)^{n_k} \Omega(n_k). \quad (72.1)$$

Now, however, another value of $\Omega(n_k)$ must be substituted into (72.1). Since the state of a system containing an arbitrary number of particles $0 \leq n_k \leq \infty$ is non-degenerate, and the necessity of dividing by $n_k!$ disappears, for the number of states of a system containing n_k particles we have, instead of (71.3),

$$\Omega(n_k) = 1. \quad (72.2)$$

We have again assumed $\Delta\gamma = h^3$. Substituting this value of $\Omega(n_k)$ into (72.1), we find

$$\bar{n}_k = kT \frac{\partial}{\partial \mu} \ln \sum_{n_k} \left(\exp \frac{\mu - \epsilon_k}{kT} \right)^{n_k}. \quad (72.3)$$

The summation is carried out over the number of particles in the state with energy ϵ_k . In performing the summation it is necessary to distinguish between two kinds of particles, about which we have spoken in §1; particles which do not obey the exclusion principle, and those which do.

In the first case no restriction is imposed upon the number of particles which are in a given state. Their number can take on all integer values between zero and the total number of particles in the system. Thus,

$$\bar{n}_k = kT \frac{\partial}{\partial \mu} \ln \sum_{n_k=0}^N \left(\exp \frac{\mu - \epsilon_k}{kT} \right)^{n_k}. \quad (72.4)$$

Replacing the upper limit of the sum by infinity, we obtain

$$\bar{n}_k = kT \frac{\partial}{\partial \mu} \ln \sum_{n_k=0}^{\infty} \left(\exp \frac{\mu - \epsilon_k}{kT} \right)^{n_k}. \quad (72.5)$$

If the following inequality holds

$$\exp \frac{\mu - \epsilon_k}{kT} < 1, \quad (72.6)$$

then the sum in (72.5) represents an infinitely decreasing geometric progression and can easily be calculated. Namely,

$$\sum_{n_k=0}^{\infty} \left(\exp \frac{\mu - \epsilon_k}{kT} \right)^{n_k} = \left(1 - \exp \frac{\mu - \epsilon_k}{kT} \right)^{-1}$$

whence

$$\bar{n}_k = kT \frac{\partial}{\partial \mu} \ln \left(1 - \exp \frac{\mu - \epsilon_k}{kT} \right)^{-1} = \left(\exp \frac{\epsilon_k - \mu}{kT} - 1 \right)^{-1}. \quad (72.7)$$

Formula (72.7) gives the mean number of particles in the ideal gas which are in a state with energy ϵ_k , if the particles do not obey the exclusion principle. To this class of particles there belong atoms having zero spin, the molecules of saturated compounds also with zero spin and, in addition, as will be shown below, light quanta. The distribution (72.7) is called the Bose-Einstein distribution.

It should be noted that, since the sum (72.5) must always converge for any value of the energy, in particular for $\epsilon_k = 0$, in addition to the inequality (72.6)

$$e^{\mu/kT} < 1 \quad (72.8)$$

must also hold. The inequality (72.8) shows that the chemical potential for particles obeying the Bose–Einstein distribution must be an essentially negative quantity:

$$\mu < 0. \quad (72.9)$$

It should be recalled that in the Boltzmann distribution μ is also an essentially negative quantity, but is always very large in absolute value (see §60).

In the case of particles obeying the exclusion principle the number of particles n_k which can simultaneously be in an individual quantum state cannot exceed unity. Consequently, the possible values of n_k are restricted to two: $n_k = 0$ and $n_k = 1$. Substituting unity for the upper limit of the summation in formula (72.1), we have

$$\begin{aligned} \bar{n}_k &= kT \frac{\partial}{\partial \mu} \ln \sum_{n_k=0}^1 \left(\exp \frac{\mu - \epsilon_k}{kT} \right)^{n_k} = \\ &= kT \frac{\partial}{\partial \mu} \ln \left(1 + \exp \frac{\mu - \epsilon_k}{kT} \right) = \left(\exp \frac{\epsilon_k - \mu}{kT} + 1 \right)^{-1}. \end{aligned} \quad (72.10)$$

The distribution (72.10) represents the distribution of the particles of an ideal gas over states in the case where the particles obey the exclusion principle. The distribution (72.10) is called the Fermi–Dirac distribution.

In all cases encountered in practice the spacing between the energy levels of the translational motion is so small in comparison with the thermal energy kT that the energy spectrum can be assumed to be continuous. Then instead of the mean number of particles at the k th energy level it is necessary to introduce the mean number dn of particles with an energy lying between ϵ and $\epsilon + \delta\epsilon$. It is obvious that $dn = \bar{n} h^{-3} d\gamma$ where $h^{-3} d\gamma$ is the number of states corresponding to an energy in the interval $\epsilon, \epsilon + \delta\epsilon$. Substituting the mean value of the number of particles which are in one state from (72.7) into (72.10), we find

$$dn = \left(\exp \frac{\epsilon - \mu}{kT} \pm 1 \right)^{-1} \frac{d\gamma}{h^3}, \quad (72.11)$$

where the plus sign refers to the Fermi distribution, while the minus sign refers to the Bose distribution. The chemical potentials figuring in the Bose and Fermi distributions are determined from the normalization condition

$$\int dn = N, \quad (72.12)$$

which expresses the constancy of the number of particles in a given volume.

Comparing the derivation of the Bose distribution and the Fermi distribution with that of the Maxwell-Boltzmann distribution, we see first of all that the two distributions represent a realization of the Gibbs distribution for the case of an ideal gas whose particles obey the laws of quantum mechanics. There is a profound difference between the statistical distribution laws for particles obeying the laws of classical mechanics and for particles obeying the laws of quantum mechanics. This difference is not associated with any change in the statistical laws and not even with taking account of the discrete character of the energy spectrum, but with a radical change in the method of calculating the statistical weight of states. The difference between the methods for the calculation of statistical weights in classical statistics and the two quantum statistics is associated with the principle of identity of particles and is due to a profound difference between the behaviour of classical mechanical systems and the behaviour of atomic particles.

The difference between statistical weights in the Bose statistics and Fermi statistics is due solely to the difference between the laws of quantum mechanics obeyed by particles with an integer spin and those obeyed by particles with a half-integer spin. In this sense the often applied terminology "the Maxwell-Boltzmann classical statistics" or "the Fermi-Dirac quantum statistics and the Bose-Einstein quantum statistics" should be recognized as most inadequate. In reality the different forms of statistics are not in question but the different laws of quantum mechanics obeyed by the corresponding particles, i.e. the two forms of quantum mechanics: that for particles with an integer spin and that for particles with a half-integer spin. Statistical laws in all cases remain completely invariable. If the particles obey the laws of quantum mechanics for particles with an integer spin, the application of the laws of statistics leads to the Bose-Einstein distribution for the particles of an ideal gas. But if the particles obey the laws of quantum mechanics for particles with a half-integer spin, then the same statistics leads to the Fermi-Dirac distribution. Finally, if the particles obey the laws of classical mechanics, one obtains the Maxwell-Boltzmann distribution for a system of these particles.

The following question naturally arises. Experiment shows that the motion of atomic particles is described by the laws of quantum mechanics. Hence the behaviour of any ideal gas consisting of atomic particles must be described by one of the quantum distributions (72.7) or (72.10). Hence, is the Maxwell-Boltzmann distribution simply incorrect and not valid for real gases? A negative answer can be given to this question even without analysing the distributions (72.7) and (72.10), on the basis of general considerations. The laws of quantum mechanics are the laws of motion of particles including the laws of classical mechanics as a first approximation. Under certain conditions the laws of classical mechanics are a sufficiently good approximation; within the limits of this approximation it can be assumed that the motion of particles obeys the laws of classical mechanics. Consequently, there must exist also such conditions where the Maxwell-Boltzmann distribution reflects with a sufficient degree of accuracy the actual behaviour of ideal gases. We shall call gases obeying classical statistics non-degenerate gases. Conversely, ideal gases whose behaviour is governed by quantum laws are unified under the general name degenerate gases.

Our first problem is the discussion of the question of under which conditions a gas is degenerate and under which conditions it is non-degenerate or, in other words, when classical statistics can be considered to be applicable and when the laws of quantum statistics must be taken into account. In solving this problem we shall proceed from the fact that the Bose-Einstein distribution and the Fermi-Dirac distribution are more accurate laws. Hence use can be made of the Maxwell-Boltzmann law only when the difference between it and the quantum distributions (72.7) and (72.10) becomes sufficiently small.

Comparing the distributions (72.7), (72.10) and (71.6) we see that they have, in the general case, an essentially different character (fig. III.44). However, this difference vanishes if the following inequality is satisfied:

$$\exp \frac{\epsilon - \mu}{kT} \gg 1. \quad (72.13)$$

All three distributions have the same functional form when the inequality (72.13) is fulfilled. The lack of coincidence of the curves in fig. III.44 for large ϵ is associated with the fact that to these curves there correspond different μ . In this case the one in the denominator in (72.7) and (72.10) can be neglected, and the Bose and Fermi distributions automatically go over into the Maxwell-Boltzmann distribution. Thus, the inequality (72.13) is the condition of applicability of classical statistics.

For the fulfillment of the inequality (72.13) at energies $\epsilon \approx kT$ (for

Fig. III.44

$\epsilon > kT$ the exponential rapidly increases) it is necessary that $e^{-\mu/kT} \gg 1$. Assume that this inequality is satisfied, so that for all energies

$$\left(\exp \frac{\epsilon - \mu}{kT} \pm 1 \right)^{-1} \approx \exp \frac{\mu - \epsilon}{kT}.$$

Then from the normalization condition (72.12) we find

$$\begin{aligned} N &= \int \exp \frac{\mu - \epsilon}{kT} \frac{dp_x dp_y dp_z dV}{h^3} = \\ &= \frac{2\pi(2m)^{3/2}}{h^3} V e^{\mu/kT} \int_0^\infty e^{-\epsilon/kT} \epsilon^{1/2} d\epsilon = \\ &= V \left(\frac{2\pi mkT}{h^2} \right)^{3/2} e^{\mu/kT}, \end{aligned}$$

whence

$$e^{-\mu/kT} = \frac{V}{N} \left(\frac{2\pi mkT}{h^2} \right)^{3/2}. \quad (72.14)$$

Thus, the criterion of the validity of the application of classical statistics is

$$e^{-\mu/kT} = \frac{V}{N} \left(\frac{2\pi mkT}{h^2} \right)^{3/2} \gg 1. \quad (72.15)$$

If the reverse inequality is fulfilled, then degeneracy arises and one cannot use the Maxwell—Boltzmann distribution.

We see that the criterion (72.15) contains several parameters. First of all, it contains the mass m of the particles; the larger the mass, the larger the left-hand side of the inequality. Further, (72.15) contains the density of the gas and its temperature T . As was to be expected, the inequality (72.15) is satisfied for high temperatures and is violated for low temperatures, so that at low temperatures quantum effects must appear. The fulfillment of the inequality (72.15) is also favoured by a small gas density.

In the inverse limiting case, when

$$\frac{V}{N} \left(\frac{2\pi mkT}{h^2} \right)^{\frac{3}{2}} \ll 1, \quad (72.16)$$

degeneracy of the gas arises. Thus, the degeneracy can be due to the following causes: (1) a small particle mass, (2) a large gas density, (3) a low temperature.

In order to estimate the order of magnitude of the quantities, we shall consider two numerical examples.

Suppose we have an electron gas. The mass of the electron is $m = 9.1 \times 10^{-28}$ g. We assume that the density of the electron gas is such that 1 cm^3 contains 6×10^{22} particles. Then it turns out that the condition of degeneracy is fulfilled up to temperatures of the order of 2000–3000 K.

In the case of atomic hydrogen, which is the lightest gas, degeneracy can arise only at very low temperatures and high densities, because the mass of a molecule of hydrogen is larger by a factor of 3700 than that of the electron. These temperatures and densities are considerably lower than those for which the interaction between atoms leading to condensation of the gas becomes important.

Thus, only in the case of an electron gas of high density can degeneracy occur at relatively high temperatures.

Another case of the quantum (degenerate) gas is the photon gas whose properties will be discussed in §76.

We shall not dwell in more detail here on the properties of the Bose and Fermi distributions, since it is more advisable to discuss them for real physical systems (the electron gas and the photon gas).

For all ordinary gases the difference between quantum statistics and classical statistics for not particularly large values of the temperature and density turns out to be negligibly small. The two quantum distributions, the Bose and Fermi distributions, can, with a high degree of accuracy, be re-

placed by the Maxwell distribution. The absence of any difference between Bose statistics and Fermi statistics can be understood if it is taken into account that the order of magnitude of the mean number \bar{n}_k of particles in an individual quantum state can be estimated by the following relations:

$$\bar{n}_k \approx e^{(\mu - \epsilon_k)/kT} \approx e^{\mu/kT} \ll 1.$$

In a non-degenerate gas for a high temperature and a small density of the gas the density of occupation of states is very small. In each state there is on the average much less than one particle, hence it is of no importance whether or not two or more particles can get into one state; even a pair will practically never in any event get into it.

In spite of the fact that classical statistics can always be applied to atomic gases (or, more precisely, quasi-classical statistics, since it is inevitable that we take into account discrete energy levels and introduce the factor $1/N!$), only the creation of quantum statistics made it possible to solve a number of the most important physical problems. Some of these will be discussed in following sections.

§73. Black-body radiation

The statistical theory of radiation played a very important role in the discovery of quantum theory. The classical electromagnetic theory of light, which explained a wide range of phenomena associated with the propagation of light and which was generally recognized by the end of the 19th century, encountered in the beginning of the 20th century insuperable difficulties in connection with the problem of the emission of light, in particular, with the problem of thermal radiation. We understand thermal radiation to be the whole of the radiation emitted by a heated body.

As is well known, the character of the light emitted, in particular its intensity as well as the dependence of the intensity on the frequency (the spectral composition of the radiation), is determined by the temperature and nature of the emitting body.

There are, however, cases where the spectral composition of the radiation does not depend on the nature of the emitter and is determined solely by its temperature. This is for so-called equilibrium radiation. Imagine a closed cavity with walls which do not conduct heat and which are maintained at a definite temperature T . The walls of the cavity will emit and absorb electromagnetic waves. Since all of the electromagnetic radiation is confined within

the closed cavity, a state of statistical equilibrium will be established in the system after a certain time. The walls of the cavity will emit as much electromagnetic energy per unit time as they absorb. A system of standing electromagnetic waves, stationary in time, will exist in the cavity.

The energy density of the corresponding electromagnetic field inside the cavity will be given by formula (12.6) of Part I:

$$\rho = \frac{E^2 + H^2}{8\pi}.$$

The thermal radiation will contain different frequencies. The energy density $\rho(\nu)$ in a given frequency interval $d\nu$ will, obviously, be different for different frequencies. The energy density of the radiation will also depend on the temperature T of the emitting walls. Thus,

$$\rho = \rho(\nu, T).$$

A simple thermodynamic consideration shows, however, that $\rho(\nu, T)$ does not depend on the nature of the emitter, in particular, on the nature of the walls (their absorption and emission properties, the state of the surface and so on).

Consider two cavities whose walls are heated to the same temperature but are made of different materials. We assume that the spectral energy density of the radiation depends on the nature of the emitter and is different in the two cavities. Then, by connecting the two cavities, one can disturb the state of equilibrium. Radiation will pass over to that cavity in which the density of radiation is smaller. As a result, the density will increase in this cavity, the walls of the cavity will absorb more radiation, and their temperature will increase. A difference between the temperatures of the walls of the two cavities will arise, which can be used for obtaining useful work.

The assumption which we have made leads to the conclusion of the possibility of spontaneous violation of the equilibrium state in a closed system and the possibility of constructing a perpetual motion machine of the second kind, which is, as is well known, impossible. Thus, it is proved that the spectral distribution of the energy density $\rho(\nu, T)$ of the equilibrium radiation is a universal function of the frequency ν and the temperature T .

A study of the absorption and emission properties of material bodies led Kirchhoff to the establishment of a very important theorem known as the Kirchhoff theorem.

The quantity $E(\nu)$, the energy emitted per cm^2 of the surface of a body

per second with a frequency between ν and $\nu + d\nu$ per unit frequency interval, will be called by us the radiative capacity of an arbitrary body.

Further, the part of the entire radiation energy with a frequency between ν and $\nu + d\nu$ incident on 1 cm^2 of the surface of a body which is absorbed inside the body * per unit frequency interval will be called by us the absorptive capacity of the body.

The Kirchhoff theorem reads that the ratio of the radiative capacity to the absorptive capacity $E(\nu)/A(\nu)$ is a universal function of the frequency and the temperature of the body but depends neither on the nature and properties of the body nor on its geometrical dimensions, i.e.

$$\frac{E(\nu)}{A(\nu)} = f(\nu, T). \quad (73.1)$$

It turns out that the universal function $f(\nu, T)$ is connected by a simple relation with the energy density of the equilibrium radiation $\rho(\nu, T)$ (T is the temperature of the body):

$$f(\nu, T) = \frac{c}{4\pi} \rho(\nu, T),$$

where c is the velocity of light. Thus, the Kirchhoff theorem can be written in the form

$$\frac{E(\nu)}{A(\nu)} = \frac{c}{4\pi} \rho(\nu, T).$$

The proof of the Kirchhoff theorem, which is of a very general character, can be found in any course on radiation theory **.

Since the absorptive capacity of a body can be found without any special difficulty from a measurement of the absorption coefficients and from geometrical considerations, finding the form of the function $\rho(\nu, T)$ appeared to be of great interest. From the Kirchhoff formula (73.1) it follows that a body with an absorptive capacity $A(\nu)$ equal to unity is of special importance.

* Not to be confused with the absorption coefficient, which characterizes the absorption of light per unit path in matter. The value of the absorptive capacity characterizes the absorption in the entire volume of the body.

** See, for example, M. Planck, *Vorlesungen über die Theorie der Wärmestrahlung* (Theory of thermal radiation) (Barth, Leipzig, 1913).

Such a body absorbs the entire electromagnetic energy incident on it for all frequencies. It is called an absolute black body.

For an absolute black body we have

$$E(\nu) = \frac{c}{4\pi} \rho(\nu, T). \quad (73.2)$$

Formula (73.2) shows that the absolute black body has a higher radiative capacity than all other bodies. Its radiative capacity is a universal function of the frequency ν and the temperature T .

By measuring the radiative capacity of an absolute black body, one can determine experimentally the form of the function $\rho(\nu, T)$.

Of course, not all bodies encountered in nature are absolute black ones. No matter what the nature of the surface of the body may be, a certain part of the radiative energy incident on it is reflected. However, the closed cavity filled with radiation which we have considered above is an absolute black body. Indeed, the entire radiation emitted by the walls of the cavity is also absorbed by them. If a small opening is made in the cavity, then by studying the spectral distribution of the radiation energy coming from this opening, one can find the function $\rho(\nu, T)$ experimentally. The size of the opening must be sufficiently small that radiation leakage through the opening does not lead to a fundamental departure from the equilibrium state. By means of such a model of an absolute black body the spectral energy distribution at different temperatures was investigated experimentally.

Fig. III.45 (see § 75) shows typical curves of this kind. The wavelength of the radiation is plotted on the horizontal axis, while the energy density of the radiation $\rho(\lambda, T)$ corresponding to a wavelength λ is plotted on the vertical axis. The energy density of radiation at a given wavelength is connected with $\rho(\nu, T)$ by the following relation:

$$\rho(\nu, T) d\nu = \rho(\lambda, T) d\lambda.$$

Taking into account that

$$d\nu = c \left| \frac{d\lambda}{\lambda^2} \right|,$$

we have

$$\rho(\lambda, T) = \frac{c}{\lambda^2} \rho(\nu, T).$$

Different curves in fig. III.45 refer to different temperatures. All the curves have a characteristic form. For long wavelengths the density of the radiation decreases with increasing λ . At a certain wavelength λ_{\max} it has a maximum, and then it again tends to zero in the direction of short wavelengths. The position of the maximum shifts in the direction of short wavelengths as the temperature increases.

§74. The classical theory of black-body radiation

We now pass on to the calculation of the spectral distribution function $\rho(\nu, T)$.

The electromagnetic radiation in a closed cavity forms a system of standing waves. We have considered such an electromagnetic field in §38 of Part I, where it has been shown that it can be replaced by a set of equivalent field oscillators. The energy of the field turned out to be equal to the sum of the energies of the oscillators. In the case of radiation in the cavity one has, corresponding to what has been said above, to ascribe to it a temperature which is equal to the temperature T of the radiating walls. We can therefore say that to each standing wave in the cavity there corresponds an oscillator with a frequency ν and an energy $\epsilon(\nu, T)$ which depends on the frequency as well as on the temperature T .

Every one of the oscillators which replace a system of standing waves can be in different states and can have a different energy $\epsilon(\nu, T)$. We shall, however, be interested not in the instantaneous but in the mean energy $\overline{\epsilon(\nu, T)}$ of the oscillators. Here the averaging is carried out over all possible states of the oscillator. The energy of the standing waves in unit volume of the cavity, whose frequencies lie between ν and $\nu + d\nu$, is numerically equal to the mean energy of all the oscillators which replace the normal oscillations and have frequencies in the same interval. If $g(\nu)d\nu$ is the number of oscillators, then the aforesaid can be written in the form

$$\rho(\nu, T)d\nu = \overline{\epsilon(\nu, T)} g(\nu)d\nu. \quad (74.1)$$

We have found the number of natural oscillations in §38 of Part I. In the case of electromagnetic waves it is necessary only to take into account that they are polarized and can have two directions of polarization. Formula (38.22) of Part I gives the number of oscillations with a frequency between ν and $\nu + d\nu$ for each direction of the polarization. For both directions of the polarization the number of oscillations must be doubled:

$$\rho(\nu, T) d\nu = \frac{8\pi\bar{\epsilon}}{c^3} \nu^2 d\nu. \quad (74.2)$$

The derivation of formula (74.2) did not involve any concepts of the quantum theory; it was obtained before the creation of the quantum theory. For the mean energy of the oscillator $\bar{\epsilon}$ its classical value

$$\bar{\epsilon} = kT$$

was taken, and the density of the equilibrium radiation at a temperature T was written in the form (the Rayleigh—Jeans law)

$$\rho(\nu, T) d\nu = \frac{8\pi kT}{c^3} \nu^2 d\nu. \quad (74.3)$$

The senselessness of formula (74.3) is obvious. It shows that the energy density of the electromagnetic field in a closed cavity increases monotonically with increasing frequency. Since oscillations of all frequencies, in particular $\nu \rightarrow \infty$, can arise in the cavity, formula (74.3) leads to an infinitely large energy density as $\nu \rightarrow \infty$:

$$E = \int_0^{\infty} \rho(\nu, T) d\nu \rightarrow \infty.$$

This result means that radiation sources confined in the cavity would have to emit radiation until the entire thermal energy contained in them went over into the radiation of the field and their temperature fell to absolute zero. Thus, for example, if a burning hot solid body placed in the cavity were the emitter, then from the result obtained it follows that equilibrium in the emitter—electromagnetic-field system would only be established after the hot body had cooled to absolute zero.

This conclusion has a simple meaning. According to the law of equipartition of energy, all degrees of freedom are equivalent and in an equilibrium state the same energy corresponds to each of them. The thermal energy contained in a crystal consisting of N atoms can be assumed to be distributed between $3N$ oscillators. The electromagnetic field in the cavity can also be considered as a set of oscillators. However, the number of these is immeasurably larger than $3N$. The wave numbers of possible standing waves in a closed cavity which has the form of a cube must satisfy the conditions

$$f_1 = \frac{\pi k_1}{L}, \quad f_2 = \frac{\pi k_2}{L}, \quad f_3 = \frac{\pi k_3}{L},$$

where L is the size of a face of the cube, and k_1, k_2, k_3 are numbers running over a series of integer values from zero to infinity. These conditions are equivalent to the conditions (38.11) for the crystal, but in the latter case the values of k_1, k_2 and k_3 are restricted by the number of particles N . Thus, the number of standing electromagnetic waves in the cavity and the corresponding number of electromagnetic field oscillators is infinitely larger than the number of oscillators needed for the description of thermal motion in a crystal. In an equilibrium state the entire energy must be contained in the field, since the same energy must correspond to each oscillator.

This result is in complete contradiction with experimental data. Experiment shows that the density of the thermal energy contained in the crystal is immeasurably larger than the density of the energy of the electromagnetic field. For example, at $T = 300$ K the density of thermal energy in a solid body turns out to be a factor of 10^{14} larger than the measured energy density inside a cavity with radiation. As to the spectral energy density distribution, expressed by formula (74.3), it turns out to be in agreement with the measured energy distribution in the black-body spectrum for small frequencies which satisfy the condition $h\nu \ll kT$. On the contrary, for large frequencies, when $h\nu \gg kT$, $\rho(\nu, T)$ increases with the frequency ν much more slowly than according to the law ν^2 .

Thus, the law of equipartition of energy leads to a complete disagreement of theory with experiment when applied to the problem of black-body radiation in the range of large frequencies. Historically, this was the first well investigated case of the inadequacy of classical concepts. The glaring contradiction with experiment to which classical statistics led, incited contemporary physicists to call the situation "the ultraviolet catastrophe". A way out of the contradiction was found by introducing the quantum theory.

§75. The Planck formula

The simplest, although not the most obvious method (from the physical standpoint) of finding the spectral distribution function $\rho(\nu, T)$ taking into account quantization consists of the following.

We substitute into formula (74.2) the value of the mean energy of a field oscillator calculated according to the theory of the quantum oscillator. We drop the zero energy of the oscillator $\frac{1}{2}h\nu$, choosing it to be the origin of energy. Then

$$\epsilon = nh\nu \quad (75.1)$$

and

$$\bar{\epsilon} = \frac{h\nu \sum_n n e^{-h\nu n/kT}}{\sum_n e^{-h\nu n/kT}} = \frac{h\nu}{e^{h\nu/kT} - 1}. \quad (75.2)$$

Substituting (75.2) into formula (74.2), we find the following expression for the mean energy of the vacuum electromagnetic field per unit volume for a frequency lying between ν and $\nu + d\nu$:

$$\rho(\nu, T)d\nu = \frac{8\pi h\nu^3 d\nu}{c^3(e^{h\nu/kT} - 1)}. \quad (75.3)$$

Formula (75.3) is called the Planck formula. This formula was first derived semi-empirically, since formula (75.2) for the energy of an oscillator was unknown. Formula (75.3) and the Planck constant h contained in it were found from experiment.

In the two limiting cases, $h\nu/kT \ll 1$ and $h\nu/kT \gg 1$, the Planck formula is simplified. In the first case

$$e^{h\nu/kT} \approx 1 + \frac{h\nu}{kT}$$

and formula (75.3) reduces to the form

$$\rho(\nu, T)d\nu \approx \frac{8\pi kT}{c^3} \nu^2 d\nu, \quad (75.4)$$

i.e. goes over into the classical formula (74.3) for the mean energy density of black-body radiation.

For $h\nu/kT \gg 1$

$$(e^{h\nu/kT} - 1)^{-1} \approx e^{-h\nu/kT},$$

so that

$$\rho(\nu, T)d\nu \approx \frac{8h\nu^3}{c^3} e^{-h\nu/kT} d\nu. \quad (75.5)$$

This last formula is called Wien's law.

Going from $\rho(\nu, T)$ to the spectral distribution of the radiation density with respect to wavelength, $\rho(\lambda, T)$, we can write formulae (75.3), (75.4) and (75.5) in the following forms:

$$\rho(\lambda, T) = \frac{8\pi hc}{\lambda^5} (e^{hc/kT\lambda} - 1)^{-1}, \quad (75.6)$$

$$\rho(\lambda, T) = \frac{8\pi kT}{\lambda^4} \left(\frac{hc}{kT\lambda} \ll 1 \right), \quad (75.7)$$

$$\rho(\lambda, T) \approx \frac{8\pi hc}{\lambda^5} e^{-hc/kT\lambda} \left(\frac{hc}{kT\lambda} \gg 1 \right). \quad (75.8)$$

The curves corresponding to formula (75.6) are shown in fig. III.45. For large wavelengths $\rho(\lambda, T)$ decreases with increasing wavelengths as λ^{-4} , while for small wavelengths $\rho(\lambda, T)$ tends to zero as $\lambda^{-5} e^{-hc/kT\lambda}$. The function $\rho(\lambda, T)$ has a maximum at a wavelength λ_{\max} which can be found from the condition

Fig. III.45

$$\frac{\partial \rho(\lambda, T)}{\partial \lambda} = 0$$

or

$$-\frac{5}{\lambda^6} \frac{1}{e^{hc/kT\lambda} - 1} + \frac{hc}{\lambda^7 kT} \frac{e^{hc/kT\lambda}}{(e^{hc/kT\lambda} - 1)^2} = 0.$$

Denoting the quantity $hc/kT\lambda_{\max}$ by x , we can write the last equation in the form

$$\frac{x e^x}{e^x - 1} = 5.$$

The solution of this transcendental equation gives

$$x = 4.96, \quad \lambda T \approx 2 \times 10^{-3} hc/k. \quad (75.9)$$

Formula (75.9) shows that the position of the maximum of the energy density of black-body radiation shifts in the direction of small wavelengths with increasing temperature. This is the so-called displacement law.

The value of the quantum constant h can be determined from the displacement law. After the proper choice of this value the Planck formula turns out to be in excellent agreement with experimental data.

§ 76. The statistics of the photon gas

As we have already pointed out in the introductory chapter, contemporary quantum theory, in accord with experimental data, states that radiation possesses corpuscular as well as wave properties. Although from the point of view of ordinary ideas it is impossible to combine the properties of a wave and a particle in one object, one sometimes has to make use of the wave aspect and sometimes the corpuscular aspect in order to explain different optical phenomena. Thus, for example, in the phenomena of interference or diffraction the wave nature of radiation is manifested, whereas in the photoelectric effect or the scattering of hard X-rays the corpuscular nature of radiation is revealed. From the corpuscular point of view, radiation can be considered as a flux of light quanta, or photons, moving in space with the velocity of light c . Photons arise and vanish when light is emitted and

absorbed by atoms respectively. Their energy is equal to $\epsilon = \Delta E$, where ΔE is the difference between the energy levels of the emitting system.

All photons move in vacuum with the same velocity, but different photons can have different energy and different momentum. The energy and momentum of photons are related by the expression

$$\epsilon = pc, \quad (76.1)$$

which is a general formula relating these quantities for any object moving with the velocity of light. The energy and momentum of a photon depend on the frequency according to the formulae

$$\epsilon = h\nu = \hbar\omega, \quad (76.2)$$

$$p = h\nu/c = \hbar\omega/c. \quad (76.3)$$

Like other material particles, photons also possess angular momentum (see § 1, as well as Part V).

It turns out that as an emitting system (an atom or a molecule) emits radiation its angular momentum must decrease by an amount which is a multiple of \hbar . The corresponding angular momentum is carried away by the outgoing photon. Thus, the angular momentum expressed in units of \hbar is an integer. Like all other particles with an integer angular momentum, photons obey Bose-Einstein statistics.

From the corpuscular point of view equilibrium radiation filling a closed cavity must be considered as a photon gas filling the volume V of the container. The particles of the photon gas are moving randomly in all directions in the container, and their directions of flight change in collisions with the walls of the container. There is no interaction between the photons. Hence the photon gas must in its properties be similar to an ordinary molecular ideal gas filling a closed container.

However, in addition to the similarity between the photon gas and the molecular gas there is also a very profound difference between them. The most fundamental difference between the photon gas and the molecular gas is the fact that for the photon gas one cannot speak of a fixed number of particles. In contrast to ordinary particles (electrons, protons or atoms), photons can arise or vanish at the moment of emission or absorption of light by atoms. Hence the number of photons in the cavity cannot be considered as fixed.

Another difference between photons and gas molecules is the fact that the

former all move with the same speed. In fact, however, this property of the photon gas is not associated with the specific nature of photons. For very large values of the kinetic energy of all particles their velocities approach the velocity of light and the differences between the velocities of individual particles are progressively smoothed over. Hence this difference between the photon gas and a molecular gas is not essential. Of importance only is the fact that in the photon gas, as well as in a molecular gas, there is a certain distribution of particles over momenta and energies.

Finally, there is one more difference between the photon gas and a gas of ordinary particles, a difference of principle rather than of a practical character. As has been shown in §6 and §16, the establishment of the velocity distribution (or the momentum distribution) of molecules is closely associated with the interaction occurring between them in molecular collisions. But photons do not collide with each other at all. An equilibrium distribution of photons can be established only in the case where there is a body in the cavity which can absorb and emit photons. In the process of absorption and subsequent emission photons of one frequency transform into photons of other frequencies. In this case the number of photons does not remain constant, although their total energy must be conserved. In particular, the walls of a cavity containing a "photon gas" can act as such a body.

We shall now show that, proceeding from the concept of a photon gas, one can arrive at the Planck formula with the same success as using the wave concept.

From the corpuscular point of view the function $\rho(\omega, T)$ can be interpreted in the following way. In the frequency interval $\omega, \omega + d\omega$, or in the corresponding energy interval of the photons $\epsilon, \epsilon + d\epsilon$, let there be $d\Omega$ quantum states of photons per unit volume. Further, let the mean number of photons in each state be equal to $\bar{n}(\epsilon)$. Then the mean number of photons with an energy between ϵ and $\epsilon + d\epsilon$ is equal to

$$d\bar{n} = \bar{n}(\epsilon)d\Omega. \quad (76.4)$$

Their mean energy is equal to $\epsilon\bar{n}(\epsilon)d\Omega$. But this energy represents none other than the energy density of radiation with a frequency between ω and $\omega + d\omega$. Thus,

$$\rho(\epsilon, T)d\omega = \epsilon\bar{n}(\epsilon)d\Omega. \quad (76.5)$$

Our problem is to find $\bar{n}(\epsilon)$, i.e. the mean number of particles in a gas of a variable number of particles. Taking into account the fact that photons are

particles with spin equal to unity, then for $\bar{n}(\epsilon)$ one can write the Bose-Einstein distribution.

It is necessary, however, to take into account the peculiar feature of the photon gas which is associated with the possibility of absorption and emission of photons by the walls of the container or by material bodies placed inside the cavity.

The number of particles in a photon gas is variable and depends on the state of the gas. Hence, in contrast to an ordinary molecular gas, the free energy of a photon gas depends not only on the variables V and T but also on the number of particles N in the gas. For a given value of V and T the number of photons in an equilibrium state will have a value N_0 such that the free energy $F(V, T, N_0)$ has its minimum value. Thus, it can be said that an equilibrium state of a photon gas occurs when the following equality is fulfilled:

$$\frac{\partial F(V, T, N)}{\partial N} = \mu(V, T) = 0. \quad (76.6)$$

Here we have made use of formula (60.3').

Eq. (76.6) shows that the chemical potential of an equilibrium photon gas is zero.

Thus, the mean number of particles of a photon gas per unit volume which have an energy ϵ , must, by virtue of (72.7) and (76.6), be written in the form

$$\bar{n}(\epsilon) = \frac{1}{e^{\epsilon/kT} - 1}. \quad (76.7)$$

The number of photons with an energy between ϵ and $\epsilon + d\epsilon$ is equal to

$$d\bar{n}(\epsilon) = \frac{2}{e^{\epsilon/kT} - 1} \frac{4\pi p^2 dp}{h^3} = \frac{8\pi}{h^3 c^3} \frac{\epsilon^2 d\epsilon}{e^{\epsilon/kT} - 1}. \quad (76.8)$$

The factor 2 is introduced to take into account the two-fold degeneracy of the states of photons with a given momentum p . For a given value of p there are two states corresponding to the two possible independent directions of polarization of light.

The total number of photons in the equilibrium radiation can be found by integrating (76.8) over all values of ϵ .

Making use of formula (76.2), ϵ can be expressed in terms of the frequency ω . Performing this substitution and passing over from the number of photons to their energy, we find

$$\begin{aligned}\rho(\omega, T)d\omega &= \epsilon \bar{n}(\epsilon)d\Omega = \\ &= \frac{8\pi}{h^3 c^3} \frac{\epsilon^3 d\epsilon}{e^{\epsilon/kT} - 1} = \frac{\hbar \omega^3 d\omega}{\pi^2 c^3 (e^{\hbar \omega/kT} - 1)},\end{aligned}\quad (76.9)$$

i.e. the Planck formula.

It should be stressed that if the Boltzmann distribution and not the Bose–Einstein distribution were applied to photons, then instead of the Planck formula one would obtain formula (75.5) which is valid only when $\hbar\omega/kT \gg 1$. Indeed, substituting the expression $\bar{n} = e^{-\epsilon/kT} = e^{-\hbar\omega/kT}$ for $\bar{n}(\epsilon)$ from (76.7), we obtain Wien's law (75.5) instead of the Planck formula (76.9).

Thus, classical statistics cannot be applied to photons. The region of applicability of classical statistics to the photon gas is restricted by the condition $\hbar\omega/kT \gg 1$. This condition is the reverse of that for classical statistics to be applicable to electromagnetic field oscillators. Thus, for high frequencies (or low temperatures) it is the corpuscular properties of radiation that are predominant, whereas for low frequencies (or high temperatures) it is the wave properties of radiation that are predominant.

The energy of electromagnetic radiation or the energy per unit volume of a photon gas is obtained from (76.9) by integrating over all frequencies:

$$u = \int_0^\infty \rho(\omega, T)d\omega = \frac{\hbar}{\pi^2 c^3} \int_0^\infty \frac{\omega^3 d\omega}{e^{\hbar\omega/kT} - 1}.$$

To calculate the integral we introduce a new variable, $x = \hbar\omega/kT$. Then

$$u = \frac{\hbar}{\pi^2 c^3} \left(\frac{kT}{\hbar}\right)^4 \int_0^\infty \frac{x^3 dx}{e^x - 1}.$$

The value of this integral is obtained in Appendix IV:

$$\int_0^\infty \frac{x^3 dx}{e^x - 1} = \frac{\pi^4}{15}.$$

Hence finally we have

$$u = \frac{\pi^3 k^4 T^4}{15(hc)^3} = \alpha T^4. \quad (76.10)$$

The energy density of black-body radiation turns out to be proportional to the fourth power of the absolute temperature (the Stefan—Boltzmann law).

The constant α figuring in (76.10) contains only the universal constants h , c and k . The Stefan—Boltzmann law is widely applied in heat engineering for the calculation of the radiative capacity of heated surfaces. Although radiators encountered in practice are not black bodies, the application of the Stefan—Boltzmann law leads to good results for all solid radiators except metals. For the latter the emitted energy increases as a higher power of the temperature.

The total energy of radiation in a volume V is equal to

$$E = \alpha VT^4. \quad (76.11)$$

Further, we find the free energy of black-body radiation. According to formula (30.12), we have

$$F = -T \int \frac{E dT}{T^2} = -\frac{1}{3} \alpha VT^4. \quad (76.12)$$

The entropy of radiation is

$$S = -\partial F / \partial T = \frac{4}{3} \alpha VT^3. \quad (76.13)$$

And the radiation pressure p is equal to

$$p = -\partial F / \partial V = \frac{1}{3} \alpha T^4 = \frac{1}{3} E / V. \quad (76.14)$$

Radiation pressure was first discovered by P.N. Lebedev. This discovery was of fundamental importance. It allowed proof of the impossibility of constructing a perpetual motion machine of the second kind in which radiation could be used as the working medium.

Radiation pressure, which is very small in terrestrial conditions, assumes an extremely great importance in astrophysics. As is shown by formula (76.14), the radiation pressure increases very rapidly with increasing temperature. At very high temperatures, such as occur in astrophysical conditions, the radiation pressure turns out to be larger than the gas pressure, and plays a basic role in a number of astrophysical processes.

Finally, a simple calculation shows that the thermodynamic potential Φ of radiation is equal to zero:

$$\Phi = F + pV = 0.$$

This is in agreement with our requirement $\mu = 0$ for the photon gas.

§77. The properties of liquid helium II

A very interesting example of a macroscopic system in which quantum effects are displayed is liquid helium II, the only system which remains liquid down to absolute zero. All other liquids solidify at temperatures which are too high for quantum effects to be shown.

As shown by experiment, liquid helium can exist in two modifications which are called liquid helium I and liquid helium II and which differ sharply from each other in physical properties.

Fig. III.37 (see §62) shows the phase diagram of helium. It is seen that at pressures above 30 atm liquid helium I, which represents the high-temperature modification, goes over into the solid state as the temperature decreases. However, at pressures below 30 atm helium does not solidify at any temperature and remains liquid down to $T = 0$ K. On curve II the phase transition of helium I into the other modification takes place. The behaviour of the heat capacity (fig. III.46), density and a number of other properties of helium depending on the temperature is indicative of this transition. The heat capacity undergoes a jump at the transition point; on the density curve a break is observed at this point, and so on. Since the latent heat of the phase

Fig. III.46

transition helium I — helium II is zero, this phase transition is a typical phase transition of the second kind.

Liquid helium II possesses a number of remarkable properties which are due to its quantum nature. Some of these will be described below*.

L.D.Landau proposed a statistical theory of liquid helium II based on certain assumptions about the character of the energy spectrum of this system. New studies on the theory of helium II will be discussed in Part V. In these studies the assumptions which underlie the theory of Landau are derived from the general propositions of the quantum mechanics of a system of particles.

Consider a certain amount of liquid helium II confined in a container. The liquid as a whole represents a quantum system; its possible energy values form a certain energy spectrum. At very low temperatures the discrete character of the energy spectrum of the liquid cannot be disregarded, in spite of the fact that the liquid is a macroscopic system. We have to determine the character of the energy spectrum of the macroscopic quantum system for very small excitation energies, when the system can only be at energy levels close to the ground level which the system is in at absolute zero.

An accurate calculation of the energy levels of a system consisting of a large number of strongly interacting particles appears to be impossible at present. This holds equally for liquid helium II, crystals, mutually interacting electrons and all other systems of interacting particles. Nevertheless, it is possible to establish certain general properties of the energy spectrum of such systems for small excitation energies. In particular, such an energy spectrum will be possessed by liquid helium II, in which the smallness of the excitation energy is ensured by the temperature.

The basic property of the energy spectrum of any macroscopic system for small excitation energies is the fact that the excitation energy can be resolved into a set of independent "elementary excitations".

We shall consider for concreteness the energy spectrum of the elastic oscillations of a crystal or a liquid for small excitation energies. We have seen before that the motion of the atoms of a solid body can be resolved into independent elastic waves which do not interact with each other and are propagating over the entire volume of the body. The only difference between a crystal and a quantum liquid is the fact that in the former both longitudinal and transverse waves can propagate, whereas in the liquid only longitudinal waves (compression and expansion waves) can exist. Each of these waves

* See the book which we follow: W.H.Keesom, *Helium* (Elsevier Publ. Co., Amsterdam, 1942, repr. 1959).

carries a definite invariable energy which can be considered as an elementary excitation. The energy of the entire body can be considered as a set of elementary excitations, i.e. as the sum of the energies of all independent elastic waves propagating in the body. From the above it is clear that an elementary excitation corresponds to an excitation energy of the body as a whole and can in no way be referred to an individual atom with an excess energy over other atoms in the body. Each of the elementary excitations representing a sound wave moves in the body, undergoes reflections from its walls, moves in a new direction and so on. An elementary excitation possesses a definite momentum in addition to an energy.

The motion of all elementary excitations in a body can be likened to the motion of non-interacting quasi-particles, that is excitation quanta, which form an ideal gas inside the body. A complete analogy can be drawn between light waves and light quanta on the one hand, and between elastic waves and excitation quanta in a crystal on the other hand. Just as the light field can be treated as a set of light quanta (photons), the field of elastic waves which fill a crystal can be replaced by a gas of excitation quanta which are often called phonons.

However, an essential reservation should be made. This analogy, which is very convenient for carrying out a number of calculations, has only a formal character. Sound quanta have no direct physical reality and serve only for a mathematical expression of the properties of a discrete set of elastic waves in a crystal. Keeping in mind this reservation, we shall assume in what follows that the excitation energy of a body represents the energy of excitation quanta which fill its entire volume like an ideal gas. The energy of an excitation quantum ϵ has, in the general case, an unknown functional relationship with its momentum p .

We shall now consider the energy spectrum for the case of liquid helium * in more detail. The basic properties of liquid helium can be derived from certain simple assumptions about the form of the spectrum. That is, it should be assumed that in helium II there are two forms of excitation quanta: long-wave and short-wave ones. The first, which have a large wavelength λ , carry a small momentum $p = h/\lambda$ and a small energy $\epsilon(p)$. For small p the function $\epsilon(p)$ can be expanded in a series in powers of p , and one can write

$$\epsilon \approx \text{const} \cdot p. \quad (77.1)$$

* We shall return to the problem of the energy spectrum of helium II in Part V. The problem of collective excitations will be discussed in more detail in Part VI.

Long-wave excitations in liquid helium II represent elastic longitudinal compression and expansion waves. Therefore the constant in (77.1) is simply the velocity c of propagation of sound waves. Thus, for long-wave quanta one can write

$$\epsilon = cp. \quad (77.2)$$

In hydrodynamics it turns out that, when sound waves of a small amplitude arise in a liquid, then the liquid comes into a state of vortex-free (potential) motion. However, in the general case the flow of a non-ideal (viscous) liquid is a vortex motion. Hence in addition to longitudinal sound waves in liquid helium II there must exist other elementary excitations. We shall assume that besides long-wave sound excitation quanta there exist also in helium II short-wave excitation quanta whose wavelength is close to a certain wavelength λ_0 . The corresponding momentum of the short-wave quanta is close to $p_0 = h/\lambda_0$. We assume that the energy of quanta with momentum p_0 has a minimum value in comparison with the energy of all quanta whose momenta are close to p_0 . In other words, we assume that the energy of elementary excitations has the form of the curve shown in fig. III.47. It can then be said that in the liquid besides long-wave excitation quanta whose

Fig. III.47

momentum is close to zero there will also exist quanta with a momentum $p \approx p_0$. The energy of such quanta can be written in the form

$$\epsilon \approx \epsilon(p_0) + \frac{(p-p_0)^2}{2\mu}, \quad (77.3)$$

where $\epsilon(p_0)$ and μ are constants whose values must be determined experimentally. In expansion (77.3) in powers of $p - p_0$ the term proportional to the first power of this difference is absent, because, by the assumption, $\epsilon(p)$ has a minimum at the point $p = p_0$. The constant in the second term is denoted by μ , to stress that the energy of short-wave quanta formally looks the same as the energy of ordinary particles.

Of course, there are no grounds for assuming beforehand that in the excitation spectrum of the quantum liquid there exist mainly just quanta of the two types quoted. However, the introduction of such a spectrum is justified by the fact that by means of it, it turns out to be possible to give a quantitative explanation of all the peculiar phenomena which occur in helium II.

At the same time it should be kept in mind that in addition to short-wave and long-wave excitation quanta in the liquid there are also quanta of intermediate wavelengths, but that the number of such quanta is relatively small. As we have just stressed, excitation quanta move over the entire volume of the body without interacting with each other (for small excitations), like the particles of an ideal gas filling the volume of the body. Long-wave excitation quanta can be likened to photons, while short-wave quanta behave as ordinary particles of an ideal gas which have a mass μ .

To avoid any misunderstanding, we stress once more that this analogy has only a mathematical nature. In reality, each excitation represents a particular form of motion of all the atoms of the liquid. Hence a short-wave excitation cannot be represented as a real particle moving in the liquid. However, the mathematical analogy between a set of excitation quanta and an ideal gas allows one to find the thermodynamic functions of liquid helium easily.

§ 78. Statistical theory of liquid helium II

The presence of thermal excitation quanta in liquid helium II means, from the macroscopic point of view, that it has a free energy F which can be assumed to be made up of the free energy due to the existence of long-wave excitations and the free energy due to the existence of short-wave excitations:

$$F = F_{Lw} + F_{s.w} . \quad (78.1)$$

We shall write an expression for each of the terms separately.

The free energy of long-wave quanta F_{Lw} can immediately be written in analogy with the free energy of a solid body at low temperature, taking into account that now only longitudinal waves can exist, whereas transverse waves are absent. Thus,

$$3N = \frac{4\pi V \nu_{\max}^3}{3c^3} , \quad (78.2)$$

where N is the number of atoms of the liquid in a volume V , ν_{\max} is the maximum frequency of the sound waves, and c is the velocity of sound.

Hence, substituting the value $\theta_c = h\nu_{\max}/k$ into (53.7) and taking into account (78.2), we find for F_{Lw}

$$F_{Lw} = - \frac{4}{45} \frac{\pi^5 (kT)^4 V}{h^3 c^3} . \quad (78.3)$$

The calculation of $F_{s.w}$ is somewhat more complicated. Short-wave quanta behave like the particles of an ideal gas. Their energy, which is determined by formula (77.3) can be assumed to be large in comparison with kT at sufficiently low temperatures where it is still possible to speak of independent elementary excitations. For this the following inequality must in any case be fulfilled:

$$\epsilon(p_0) \gg kT .$$

We shall see below that this inequality is indeed fulfilled in liquid helium II. Hence the short-wave quantum distribution function has the form of the classical Boltzmann distribution. The free energy of a classical ideal gas (taking into account the identity of particles) has the form

$$F_{s.w} = -N_{s.w} kT \ln \left(\frac{eV}{N_{s.w}} \right) \int e^{-\epsilon/kT} \frac{d\gamma}{h^3} , \quad (78.4)$$

where $d\gamma = dp_x dp_y dp_z$ and $N_{s.w}$ is the number of short-wave excitation quanta. The value of $N_{s.w}$ is, however, not a fixed quantity, but depends on the temperature of the liquid. It increases with increasing excitation, i.e.

with increasing temperature of the liquid *. For a given temperature the number of short-wave excitation quanta is determined from the condition of the minimum free energy:

$$\frac{\partial F_{s.w}}{\partial N_{s.w}} = 0. \quad (78.5)$$

Substituting (78.4) into the condition (78.5), we find for the number of short-wave quanta the expression

$$N_{s.w} = V \int e^{-\epsilon/kT} \frac{d\gamma}{h^3}. \quad (78.6)$$

Substituting $N_{s.w}$ into (78.4), we find for the free energy

$$F_{s.w} = -kTV \int e^{-\epsilon/kT} \frac{d\gamma}{h^3}. \quad (78.7)$$

We calculate the integral contained in (78.7). Obviously, we have

$$\begin{aligned} \int e^{-\epsilon/kT} \frac{d\gamma}{h^3} &= 4\pi \int \exp\left(-\frac{\epsilon(p_0)}{kT}\right) \exp\left(-\frac{(p-p_0)^2}{2\mu kT}\right) \frac{p^2 dp}{h^3} = \\ &= 4\pi \exp\left(-\frac{\epsilon(p_0)}{kT}\right) \int \exp\left(-\frac{(p-p_0)^2}{2\mu kT}\right) \frac{p^2 dp}{h^3}. \end{aligned}$$

The range of integration with respect to the momentum of the excitation quanta is not accurately determined. Since, however, the integrand rapidly decreases with increasing difference $p - p_0$, and for $(p-p_0)^2/2\mu \gg kT$ practically reduces to zero, the range of integration can be extended to $\pm\infty$. Then we have

$$\int e^{-\epsilon/kT} \frac{d\gamma}{h^3} = 4\pi \exp\left(-\frac{\epsilon(p_0)}{kT}\right) \int_{-\infty}^{\infty} \exp\left(-\frac{(p-p_0)^2}{2\mu kT}\right) \frac{p^2 dp}{h^3}.$$

* The dependence of $N_{s.w}$ on the temperature allows us once again to convince ourselves that the treatment of elementary excitations as quasi-particles has a relative character.

Since the integrand reduces to zero when $(p-p_0)^2/2\mu \gg kT$, the slowly varying function p^2 can be brought out of the integral sign and taken at the point $p = p_0$. Then

$$\begin{aligned} \int e^{-\epsilon/kT} \frac{d\gamma}{h^3} &= 4\pi p_0^2 \exp\left(-\frac{\epsilon(p_0)}{kT}\right) \int_{-\infty}^{\infty} \exp\left(-\frac{(p-p_0)^2}{2\mu kT}\right) \frac{dp}{h^3} = \\ &= \frac{4\pi p_0^2 (2\mu kT)^{\frac{1}{2}}}{h^3} \exp\left(-\frac{\epsilon(p_0)}{kT}\right). \end{aligned} \quad (78.8)$$

Thus, we obtain finally

$$F_{s.w} = - \frac{4\pi (2\pi\mu)^{\frac{1}{2}} (kT)^{\frac{3}{2}} V p_0^2}{h^3} \exp\left(-\frac{\epsilon(p_0)}{kT}\right), \quad (78.9)$$

$$N_{s.w} = \frac{4\pi p_0^2 V (2\pi\mu kT)^{\frac{1}{2}}}{h^3} \exp\left(-\frac{\epsilon(p_0)}{kT}\right). \quad (78.10)$$

Substituting the values of $F_{l.w}$ and $F_{s.w}$ from (78.3) and (78.9) into (78.1), we find the expression for the free energy of liquid helium II:

$$F = - \frac{4}{45} \frac{\pi^5 (kT)^4 V}{h^3 c^3} - \frac{4\pi (2\pi\mu)^{\frac{1}{2}} (kT)^{\frac{3}{2}} V p_0^2}{h^3} \exp\left(-\frac{\epsilon(p_0)}{kT}\right). \quad (78.11)$$

Correspondingly, the entropy and heat capacity of helium II are equal to

$$S = \frac{16}{45} \frac{\pi^5 k^4 T^3 V}{h^3 c^3} + \frac{4\pi (2\pi\mu)^{\frac{1}{2}} p_0^2 k^{\frac{3}{2}} T^{\frac{1}{2}} V}{h^3} \left\{ \frac{3}{2} + \frac{\epsilon(p_0)}{kT} \right\} \exp\left(-\frac{\epsilon(p_0)}{kT}\right), \quad (78.12)$$

$$\begin{aligned} C_V &= \frac{16}{15} \frac{\pi^5 k^4 T^3 V}{h^3 c^3} \\ &+ \frac{4\pi (2\pi\mu)^{\frac{1}{2}} p_0^2 k^{\frac{3}{2}} T^{\frac{1}{2}} V}{h^3} \left\{ \frac{3}{4} - \frac{\epsilon}{2kT} + \frac{\epsilon^2}{k^2 T^2} \right\} \exp\left(-\frac{\epsilon(p_0)}{kT}\right). \end{aligned} \quad (78.13)$$

We see that all the thermodynamic quantities are made up of two parts which are due respectively to the long-wave and the short-wave excitations. The first part varies with temperature according to the same power law as in the case of crystals. The second part depends on the temperature exponentially, i.e. proportional to $\exp[-\epsilon(p_0)/kT]$. The values of the constants were

determined from the measurements of the entropy and heat capacity of helium II, and turned out to be equal to

$$\epsilon(p_0)/k = 9.6 \text{ K}, \quad p_0/h = 12.25 \times 10^8 \text{ cm}^{-1}, \quad \mu = 0.75 m_{\text{He}}.$$

For these values of the constants the power part of the heat capacity and entropy exceeds the exponential part at temperatures which are lower than about 1 K. On the contrary, at high temperatures the exponential (short-wave) part predominates. The temperature trend of the thermodynamic quantities is in complete agreement with experiment.

The most outstanding property of liquid helium II, which was discovered by P.L.Kapitza, is its "superfluidity". Namely, measurements of the viscosity of helium II flowing through fine slits and capillary tubes showed the viscosity to be negligibly small. Owing to this helium II flows practically without obstruction through the finest capillary tubes. A consequence of the superfluidity of helium II is its extraordinarily high thermal conductivity ("the thermal superconductivity"), which was discovered experimentally before the superfluidity. Owing to the negligibly small viscosity, characteristic convection streams arise in helium II, which make it possible to transfer considerable amounts of heat under conditions in which an ordinary viscous liquid devoid of convection agitation has a negligibly small thermal conductivity. The phenomenon of superfluidity finds a complete explanation in the theory given above. It turns out to be closely associated with the character of the energy spectrum of helium II.

Let us consider the flow of helium II along a solid wall. For convenience of the treatment we shall transform to the reference frame in which the helium is at rest and the solid wall is moving. From the point of view of excitation quanta any process of energy dissipation due to the viscosity can be considered in the following way. In the reference frame which we have chosen the energy of the helium is initially given and is determined by the number of elementary thermal excitations. The interaction between the wall and the liquid leads to the appearance of an additional internal motion in the liquid layer adjacent to the wall. This internal motion represents the thermal motion of the particles of the liquid. Thus, the energy dissipation consists in the appearance of excitation quanta (thermal motion) in the liquid. We shall assume in the beginning that in the helium II there were initially no excitation quanta, i.e. that its temperature T was equal to zero. Let an excitation quantum with a momentum p and an energy $\epsilon(p)$ arise in the helium. Then the internal energy of the helium will become equal to $\epsilon(p)$. In the reference frame in which the helium flows while the wall is at rest, its

energy, according to the rules for the transformation of energy in a relative motion, is equal to

$$E = \frac{1}{2}mv^2 + \epsilon(p) + \mathbf{p} \cdot \mathbf{v}, \quad (78.14)$$

where v is the velocity of flow, $\frac{1}{2}mv^2$ is the kinetic energy of the liquid, and $\epsilon(p) + \mathbf{p} \cdot \mathbf{v}$ is the change in its energy.

When energy is dissipated the kinetic energy of the flowing liquid can only decrease, i.e. $\epsilon + \mathbf{p} \cdot \mathbf{v} < 0$. The smallest value of the quantity $\epsilon + \mathbf{p} \cdot \mathbf{v}$ is reached when a quantum with momentum \mathbf{p} directed antiparallel to \mathbf{v} arises. It is equal to $\epsilon - pv$. Consequently, the inequality

$$\epsilon - pv < 0$$

or

$$v > \epsilon/p. \quad (78.15)$$

must be fulfilled. This means that, if $\epsilon/p \neq 0$, excitation quanta can arise in the flowing helium, and an energy dissipation can occur only for a sufficiently large velocity of flow. For a velocity of flow which does not satisfy the inequality (78.15) no interaction accompanied by the appearance of thermal excitation quanta can arise between the wall and the helium.

From the form of the energy spectrum of helium II shown in fig. III.47 (§77) it is clear that the quantity ϵ/p for helium II is always different from zero. Thus, at the temperature of absolute zero liquid helium II moves along a solid wall without any interaction and energy dissipation, provided its velocity of motion does not exceed $v_0 = (\epsilon/p)_{\min}$, where $(\epsilon/p)_{\min}$ is the minimum value of the ratio ϵ/p . It is in this that the phenomenon of superfluidity consists.

For $T \neq 0$ all previous reasoning remains valid, and no new excitation quanta can arise in helium II when $v \neq v_0$. However, the already existing thermal excitation quanta can interact with a solid wall.

It turns out that in helium II at $T \neq 0$ two forms of motion are possible, superfluid motion and normal motion, which can occur in the same portion of the liquid simultaneously and independently of each other. The superfluid motion is without viscosity and is not accompanied by any transfer of thermal excitation energy. The normal flow proceeds in the same way as an ordinary flow of a liquid with a viscosity different from zero. With each of the forms of motion is associated the transfer of a part of the mass of the helium. Because

of this helium II can, in an obvious although not strictly accurate way, be considered as a mixture of two liquids: a superfluid liquid and a normal liquid. The motion of the superfluid liquid, which carries a part of the helium II at $T \neq 0$, is the same as the motion of the entire helium II at $T = 0$. However, at $T \neq 0$ a part of the mass of the helium is in the normal state, flows with friction and carries heat. The properties of the superfluid part of the liquid are shown in experiments on the flow of helium through fine capillary tubes. It flows through the finest capillary tube unimpeded. In experiments on the motion of bodies, for example in experiments on the oscillations of a disc immersed in a container of liquid helium, an interaction with the normal part of the helium is observed. In this case the motion of the disc is the same as in a normal liquid possessing viscosity. However, the mass of normal liquid turns out to depend on the temperature. As $T \rightarrow 0$ the mass of the normal part of helium II also decreases to zero.

One of the remarkable thermal properties of helium II is the so-called thermomechanical effect. This effect consists of the fact that, as helium flows out of a container through a very fine capillary tube, the temperature of the helium which remains in the container increases. On the contrary, as helium flows into a container the temperature in the container decreases.

The origin of the thermomechanical effect is understandable from the above. The superfluid part of the helium which moves through the fine capillary tube carries no thermal energy. When a certain amount of the superfluid helium flows out of the container the thermal energy content which existed before is distributed through the remaining amount and its temperature increases. As helium flows into the container the reverse phenomenon occurs: the thermal energy content which existed initially in the helium in the container is distributed over the entire amount of helium. The magnitude of the effect increases with decreasing temperature. This allows one to make use of the thermomechanical effect in helium to obtain very low temperatures.

§ 79. The electron gas at absolute zero

We shall now consider the behaviour of a Fermi system, an electron gas, at low temperatures. In expounding the quantum theory of metals in Part VI we shall show that in a certain approximation the behaviour of the whole set of electrons in metals can be described as the behaviour of an ideal degenerate Fermi gas. Hence the properties of the Fermi gas are of very great interest.

We shall first of all discuss the behaviour of an electron gas at absolute

zero. For this we write the Fermi distribution which, according to (72.11), has the form

$$dn = 2 \times 2\pi \left(\frac{2m}{h^2} \right)^{\frac{3}{2}} \frac{\epsilon^{\frac{1}{2}} d\epsilon}{\exp[(\epsilon - \mu)/kT] + 1} = \bar{n} \frac{d\gamma}{h^3} \quad (79.1)$$

The factor 2 is introduced in order to take into account the fact that to each energy level there correspond two states in which the electrons can have spins with opposite orientations.

We pass in (79.1) to the limit $T \rightarrow 0$. Then the Fermi distribution shown (for $T \neq 0$) in fig. III.48 assumes the form shown in fig. III.49 and is expressed by the formulae

$$\bar{n} = \begin{cases} 1 & \epsilon \leq \mu(T=0) = \epsilon_{\max} \\ 0 & \epsilon > \mu(T=0) = \epsilon_{\max} \end{cases} \quad (79.2)$$

where $\mu(T=0)$ denotes the chemical potential at absolute zero. We call this quantity the maximum energy at absolute zero, ϵ_{\max} . This result has a simple

Fig. III.48

Fig. III.49

meaning: the energy levels of a system of a large number of electrons moving freely in a finite volume V , which is bounded by an impenetrable energy barrier (the walls), form an almost continuous spectrum. According to the exclusion principle, no more than two electrons with opposite spin orientations can simultaneously be in each energy level. Two electrons in a metal will occupy the lowest energy level with an energy equal to zero. The third and fourth electrons must be at the first excited level. Following electrons are distributed at higher energy levels, each successive electron pair occupying the corresponding level. If the total number of electrons in the system is equal to N , then the first $\frac{1}{2}N$ states with energies $0 \leq \epsilon \leq \epsilon_{\max}$ will be occupied at absolute zero. All other states with $\epsilon > \epsilon_{\max}$ will be free of electrons. This is schematically shown in fig. III.48.

Fig. III.49 shows the state distribution function for electrons at $T = 0$. The number of electrons in each occupied state is equal to two, and in unoccupied states it is equal to zero. It is obvious that, because of the exclusion principle, electrons must get into excited energy levels even at absolute zero.

Let us find the energy ϵ_{\max} of the highest of the occupied energy states of electrons at absolute zero. At each energy level there are two electrons, so that for the total number of occupied levels we have

$$4\pi \left(\frac{2m}{h^2} \right)^{\frac{3}{2}} V \int_0^{\epsilon_{\max}} \epsilon^{\frac{1}{2}} d\epsilon = N,$$

whence

$$N = \frac{8\pi}{3} V \left(\frac{2m\epsilon_{\max}}{h^2} \right)^{\frac{3}{2}} = \frac{8\pi V}{3h^3} p_{\max}^3$$

or

$$\epsilon_{\max} = \frac{h^2}{2m} \left(\frac{3N}{8\pi V} \right)^{\frac{2}{3}}. \quad (79.3)$$

The energy of all the electrons at absolute zero is obviously equal to

$$E_0 = 4\pi V \left(\frac{2m}{h^2} \right)^{\frac{3}{2}} \int_0^{\epsilon_{\max}} \epsilon^{\frac{3}{2}} d\epsilon = \frac{3}{5} N \epsilon_{\max}. \quad (79.4)$$

The mean energy of an individual electron in an electron gas at $T = 0$ amounts to $\frac{3}{5}$ of the maximum energy ϵ_{\max} .

The substitution of numerical values for the quantities contained in (79.3) gives, for example, for $N/V \sim 10^{19}$: $\epsilon_{\max} = 5$ eV or $\epsilon_{\max} = 6.0 \times 10^4$ degrees. One can also find the maximum velocity of electrons at absolute zero:

$$v_{\max} = P_{\max}/m = (2\epsilon_{\max}/m)^{\frac{1}{2}} = 1.39 \times 10^8 \text{ cm/sec} . \quad (79.3')$$

The velocities of electrons turn out to be very large even at absolute zero.

We see that the properties of an electron gas differ radically from those of a classical atomic gas.

The energy of an electron gas turns out to be proportional to the number of electrons N raised to the power $\frac{5}{3}$ and to the volume of the electron gas raised to the power $-\frac{2}{3}$. Electrons at absolute zero are not at rest, as is to be expected from classical concepts, but are moving with different velocities. The mean velocity of this motion is very large. In spite of this, the heat capacity of the electron gas at absolute zero turns out to be exactly equal to zero. Indeed,

$$C_V = \left(\frac{\partial E}{\partial T} \right)_{T=0} = 0 ,$$

since the energy of the gas does not depend on the temperature.

Electrons, as any other gas, exert a pressure on the walls of the container. For the gas pressure one can immediately write the expression (8.2):

$$p = \frac{2mN}{V} \int_0^\infty v_x^2 \rho(v_x) dv_x = \frac{Nm\overline{v^2}}{3V} , \quad (79.5)$$

since all directions of motion of electrons are equivalent and $\overline{v_x^2} = \frac{1}{3}\overline{v^2}$. For $\overline{v^2}$ it is necessary to substitute the expression

$$\overline{v^2} = 2E_0/mN , \quad (79.6)$$

where E_0/N is the mean energy per electron. Then we obtain

$$p = \frac{2}{3}E_0/V . \quad (79.7)$$

The same result can also be obtained by a thermodynamic method. The substitution of numerical values gives for $N/V \sim 10^{19}$: $p = 2 \times 10^5$ atm.

In the foregoing reasoning we have tacitly assumed that the electron gas is an ideal Fermi gas for which the interaction between particles can completely be disregarded. The validity of such an assumption may appear to be very questionable, particularly if it is taken into account that the density of the degenerate gas is very large and that it consists of charged particles for which the interaction decreases slowly with increasing distance.

The assumption that the gas is ideal is satisfied if the mean kinetic energy of an electron is very large in comparison with the mean energy of its interaction with other particles.

The mean kinetic energy of an electron is given by formula (79.4). The energy of interaction of two electrons is in order of magnitude equal to e^2/\bar{r} , where \bar{r} is the mean distance between them. If N/V is the number of electrons and ions per unit volume, then the mean distance \bar{r} is in order of magnitude equal to

$$\bar{r} \approx (V/N)^{1/3}.$$

The criterion of the smallness of the interaction energy can be written in the form

$$\frac{e^2}{(V/N)^{1/3}} \ll \epsilon_{\max}.$$

Since $\epsilon_{\max} \sim (N/V)^{2/3}$, then, upon performing simple transformations, we obtain

$$\frac{N}{V} \gg \left(\frac{e^2 m}{h^2} \right)^3.$$

For a large density of the electron gas the ratio of the interaction energy to the kinetic energy can turn out to be small.

Since the kinetic energy of the gas increases with increasing density more rapidly than the potential energy, we arrive at the following, at first sight paradoxical, result: for an electron gas to be considered as an ideal gas its density must be sufficiently great.

§80. The electron gas at low temperatures

We shall now consider the properties of an electron gas at temperatures which differ from zero but are still comparatively low. Namely, we shall

assume that the temperature of the metal is such that kT is considerably smaller than the maximum energy of electrons, ϵ_{\max} , at absolute zero. In this case the thermal excitation of the electron gas will be relatively negligible. This means that thermal excitation can bring electrons from energy levels occupied at $T=0$ only into nearby higher energy levels. It is clear, for example, that thermal excitation is insufficient to raise an electron from an energy level $\epsilon \ll \epsilon_{\max}$ to an energy level $\epsilon > \epsilon_{\max}$. It is only sufficient for the excitation of electrons which are at energy levels lying in a narrow interval of the order of magnitude of kT . Some of the electrons from these levels turn out to be raised to levels higher than the level $\epsilon = \epsilon_{\max}$ but above it by an amount which does not exceed kT .

Fig. III.50 shows schematically the thermal excitation at low temperature. Some of the levels lying below ϵ_{\max} turn out to be unoccupied for most of the time. Single electrons appear in levels lying above ϵ_{\max} . The state distribution function of electrons changes. At $T=0$ it is represented by the broken curve (fig. III.49) while at low temperatures above zero it assumes the form shown in fig. III.51. The distribution at $T=0$ is shown in fig. III.51 by a broken line. The fall of the curve for $\epsilon < \epsilon_{\max}$ means that the mean number of electrons in the corresponding levels turns out to be less than unity; electrons go into levels lying above ϵ_{\max} . The energy region in which the mean number of electrons at each level turns out to be smaller than unity but larger than zero is called the zone of diffuseness of the distribution function. From fig. III.51 and the above it is clear that the width of the zone of diffuseness is in order of magnitude equal to kT . The number of electrons appearing at levels lying above ϵ_{\max} is very small in comparison with the total number of electrons in the metal. Similarly the number of single electrons which are at various energy levels represents a small fraction of the total

Fig. III.50

Fig. III.51

number of electrons. The condition of degeneracy $kT \ll \epsilon_{\max}$ is the same as that for a Fermi gas.

We now pass on to the discussion of the quantitative theory of an electron gas at a low temperature.

We confine ourselves to the calculation of two thermodynamic quantities, the chemical potential μ and the mean energy E , as functions of the temperature. The chemical potential of the electron gas is usually called the Fermi level or the Fermi surface. The origin of this terminology will be clear from what follows.

To determine the chemical potential we make use of the normalization condition. Namely, on the basis of (79.1) we can write

$$N = 2 \times 2\pi \left(\frac{2m}{h^3} \right)^{\frac{3}{2}} \int_0^{\infty} \frac{\epsilon^{\frac{1}{2}} d\epsilon}{\exp[(\epsilon - \mu)/kT] + 1}. \quad (80.1)$$

The mean energy of an electron gas is given by the formula

$$E = 4\pi \left(\frac{2m}{h^2} \right)^{\frac{3}{2}} V \int_0^{\infty} \frac{\epsilon^{\frac{3}{2}} d\epsilon}{\exp[(\epsilon - \mu)/kT] + 1}. \quad (80.2)$$

The integrals contained in formulae (80.1) and (80.2) are not taken in the general form. To calculate them at low temperatures we make use of the following method. Let

$$f = \left[\exp \left(\frac{\epsilon - \mu}{kT} \right) + 1 \right]^{-1} \quad (80.3)$$

and

$$I = \int_0^{\infty} f \epsilon^n d\epsilon, \quad n > 0.$$

Integrating by parts, we obtain

$$I = f \frac{\epsilon^{n+1}}{n+1} \Big|_0^{\infty} - \frac{1}{n+1} \int_0^{\infty} \epsilon^{n+1} \frac{\partial f}{\partial \epsilon} d\epsilon. \quad (80.4)$$

When the limits are substituted the first term obviously reduces to zero. The function $\partial f / \partial \epsilon$ is shown in fig. III.52. We see that it is an even function of its argument and has such a sharp maximum for $\epsilon = \mu$ that one can consider it as one of the representations of the δ -function. We introduce a new variable

$$x = \frac{\epsilon - \mu}{kT}.$$

Then

$$I = -\frac{1}{n+1} \int_{-\mu/kT}^{\infty} (\mu + kTx)^{n+1} \frac{\partial f}{\partial x} dx.$$

Since we are considering the low temperature region, the lower limit can be replaced by minus infinity:

$$I = -\frac{1}{n+1} \int_{-\infty}^{\infty} (\mu + kTx)^{n+1} \frac{\partial f}{\partial x} dx.$$

In that region of variation of x in which $\partial f / \partial x$ has a value differing from zero, i.e. for $\epsilon \approx \mu$, the value of x is very small. Hence the first factor in the inte-

Fig. III.52

grand can be expanded in a series and one can restrict oneself to the first terms of the expansion. For large x , when this cannot be done, the integrand reduces to zero owing to the factor $\partial f/\partial x$ which is negligibly small everywhere except for $x = 0$. Thus,

$$I \approx -\frac{1}{n+1} \int_{-\infty}^{\infty} \mu^{n+1} \left[1 + (n+1) \frac{kTx}{\mu} + \frac{(n+1)n}{2} \left(\frac{kT}{\mu} \right)^2 x^2 + \dots \right] \frac{\partial f}{\partial x} dx. \quad (80.5)$$

Since $\partial f/\partial x$ is an even function, we have

$$\int_{-\infty}^{\infty} x \frac{\partial f}{\partial x} dx = 0, \quad \int_{-\infty}^{\infty} x^2 \frac{\partial f}{\partial x} dx = 2 \int_0^{\infty} x^2 \frac{\partial f}{\partial x} dx = 0.$$

Hence

$$I = -\frac{1}{n+1} \mu^{n+1} \left[\int_{-\infty}^{\infty} \frac{\partial f}{\partial x} dx + \frac{(n+1)n}{2} \left(\frac{kT}{\mu} \right)^2 \int_{-\infty}^{\infty} x^2 \frac{\partial f}{\partial x} dx + \dots \right]. \quad (80.6)$$

It is easily seen that

$$\int_{-\infty}^{\infty} \frac{\partial f}{\partial x} dx = f \Big|_{-\infty}^{\infty} = -1.$$

The second integral in (80.6) is calculated in Appendix IV. It is equal to $-\frac{1}{3}\pi^2$. Finally we have

$$I = \frac{\mu^{n+1}}{n+1} \left[1 + \frac{(n+1)n}{6} \pi^2 \left(\frac{kT}{\mu} \right)^2 \right]. \quad (80.7)$$

The discarded terms are proportional to higher powers of the ratio kT/μ .

Coming back to the normalization condition in which $n = \frac{1}{2}$, we have

$$\begin{aligned} N &= 4\pi \left(\frac{2m}{h^2} \right)^{\frac{3}{2}} V \int_0^{\infty} \frac{\epsilon^{\frac{1}{2}} d\epsilon}{\exp[(\epsilon - \mu)/kT] + 1} \approx \\ &\approx 4\pi \left(\frac{2m}{h^2} \right)^{\frac{3}{2}} \frac{2}{3} V \mu^{\frac{3}{2}} \left[1 + \frac{\pi^2}{8} \left(\frac{kT}{\mu} \right)^2 \right]. \end{aligned} \quad (80.8)$$

For $T = 0$ the second term in (80.8) reduces to zero, and

$$N = \frac{8\pi}{3} \left(\frac{2m}{h^2} \right)^{\frac{3}{2}} \mu_{T=0}^{\frac{3}{2}} V. \quad (80.9)$$

Comparing (80.9) with (79.3), we find that

$$\mu_{T=0} = \mu_0 = \epsilon_{\max}. \quad (80.10)$$

The chemical potential of the electron gas at absolute zero turns out to be equal to the maximum energy of an electron at absolute zero.

For temperatures close to absolute zero, (80.8) can be solved for μ by a method of successive approximations. In the small second term of (80.8) μ can be replaced by $\mu_0 = \epsilon_{\max}$. Then we have

$$\mu = \mu_0 \left[1 - \frac{\pi^2}{12} \frac{(kT)^2}{\mu_0^2} \right]. \quad (80.11)$$

Analogously, for the mean energy of the electron gas ($n = \frac{3}{2}$) we find

$$E \approx 4\pi \left(\frac{2m}{h^2} \right)^{\frac{3}{2}} V \left[\frac{2}{5} \mu^{\frac{5}{2}} + \frac{1}{3} \pi^2 \mu^{\frac{1}{2}} (kT)^2 \right]. \quad (80.12)$$

Substituting the value of μ from (80.11) into (80.12) and disregarding the higher powers of the ratio kT/μ , we obtain

$$E = \frac{3}{5} N \epsilon_{\max} \left[1 + \frac{5\pi^2}{12} \left(\frac{kT}{\epsilon_{\max}} \right)^2 \right]. \quad (80.13)$$

From (80.9) or (80.10) it can be seen that the conditions of degeneracy $kT \ll \epsilon_{\max}$ and (72.16) are completely identical. Hence the electron gas is degenerate at temperatures $T < \epsilon_{\max}/k$. We have pointed out that for $N/V \sim 10^{19}$ the maximum energy ϵ_{\max} expressed in units of temperature is equal to 6×10^4 .

From (80.13) one can find the heat capacity of the electron gas:

$$C_V = \frac{Nk\pi^2}{2} \frac{kT}{\epsilon_{\max}}. \quad (80.14)$$

The heat capacity of the electron gas turns out to be a linear function of the

temperature, and reduces to zero at $T = 0$. The factor of proportionality contains only known quantities: universal constants and the density of the electron gas N/V . For simple metals, for example, copper and silver, whose atoms have one weakly bound valence electron, the number of free electrons per atom can be considered to be equal to unity. Then, for example, for copper the theoretical expression for the electron heat capacity has the form

$$C_V = 0.9 \times 10^{-4} NkT. \quad (80.15)$$

Thus, the heat capacity of the electron gas, in agreement with experimental data, is very small and at normal temperature represents an immeasurably small fraction of the heat capacity of the crystal lattice.

The heat capacity of a lattice at temperatures which are lower than the characteristic temperature rapidly decreases and tends to zero as the cube of the temperature when $T \rightarrow 0$. The heat capacity of an electron gas also tends to zero as $T \rightarrow 0$, but much more slowly, as the first power of the temperature. The ratio of the heat capacity of the electron gas to that of the lattice is equal to

$$\frac{C_V^{\text{el}}}{C_V^{\text{lat}}} = \frac{5}{24\pi^2} \frac{kT}{\epsilon_{\text{max}}} \left(\frac{\theta}{T} \right)^3.$$

For copper $\epsilon_{\text{max}} = 5$ eV and the characteristic temperature is $\theta = 335$ K, so that

$$\frac{C_V^{\text{el}}}{C_V^{\text{lat}}} = 0.02 \frac{T}{7 \times 10^4} \left(\frac{335}{T} \right)^3.$$

The ratio between the heat capacities is of the order of unity at $T = 3.3$ K. At still lower temperatures the heat capacity of the electrons turns out to be larger than the heat capacity of the lattice.

Accurate measurements of the heat capacity confirmed the validity of the theoretical formulae. Thus for copper, for which the measurements are particularly accurate, the heat capacity at low temperatures turned out to be made up of two terms, one of which agreed very accurately with the theoretical formula for the heat capacity of the lattice. The second term agrees with an accuracy to within 2% with the theoretical formula (80.14). At temperatures which are lower than 3 K the electron heat capacity is larger than the heat capacity of the lattice and is superposed on the theoretical curve.

In conclusion we shall calculate the number of electrons in the zone of diffuseness of the Fermi distribution, which it is convenient to do for an obvious interpretation of a number of formulae in what follows.

The number of electrons in the zone of diffuseness, or the number of unpaired electrons, will also be called by us the number of effective electrons n_{eff} . It is these electrons which can change their state under the effect of external actions. Hence the heat capacity of the electron gas, its electric conductivity and so on depend on effective electrons.

The value of n_{eff} can be found from the following. The probability for an electron to be found in a given state with an energy ϵ is proportional to the value of the distribution function f . The probability that this state is not occupied is equal to $1 - f$. Since only electrons with antiparallel spins can be in one state, the product of the probabilities $f(1-f)$ represents the probability that in the state with energy ϵ there is one electron, while the second electron with the antiparallel spin is not in it. In other words, $f(1-f)$ represents the probability that the state with energy ϵ will be occupied by only one electron. The total number of such states or, what is the same, the total number of unpaired electrons is equal to the integral of the product of $f(1-f)$ and the number of states $d\Omega$ with given energy, the integral being taken over all values of the energy:

$$n_{\text{eff}} = 2 \int_0^{\infty} f(1-f) d\Omega = \frac{4\pi(2m)^{\frac{3}{2}}}{h^3} \int_0^{\infty} f(1-f) \epsilon^{\frac{1}{2}} d\epsilon. \quad (80.16)$$

In a strongly degenerate gas $\mu \gg kT$, so that

$$f = \left[\exp \frac{\epsilon - \mu}{kT} + 1 \right]^{-1} \approx 1, \quad 1 - f \approx \exp \frac{\epsilon - \mu}{kT}.$$

For $\epsilon - \mu \gg kT$ the integrand decreases exponentially. Hence, instead of integrating up to infinitely large values of the energy, one can confine oneself to an integration up to a value $\epsilon \approx \mu$. Then

$$n_{\text{eff}} \approx \frac{4\pi(2m)^{\frac{3}{2}}}{h^3} \int_0^{\mu} \left(\exp \frac{\epsilon - \mu}{kT} \right) \epsilon^{\frac{1}{2}} d\epsilon.$$

Since the exponential factor rapidly decreases, one can bring the slowly varying factor $\epsilon^{\frac{1}{2}}$ out of the sign of the integral, taking its value at the upper limit. This gives

$$\int_0^{\mu} \left(\exp \frac{\epsilon - \mu}{kT} \right) \epsilon^{\frac{1}{2}} d\epsilon \approx \mu^{\frac{1}{2}} \int_0^{\mu} \exp \frac{\epsilon - \mu}{kT} d\epsilon = kT\mu^{\frac{1}{2}} \left(1 - \exp -\frac{\mu}{kT} \right) \approx$$

$$\approx kT\mu^{\frac{1}{2}} \approx kT\mu_0^{\frac{1}{2}}$$

since $\mu \gg kT$, whence

$$n_{\text{eff}} \approx \frac{4\pi(2m)^{\frac{3}{2}} kT\mu_0^{\frac{1}{2}}}{h^3}. \quad (80.17)$$

By means of formulae (79.3) and (80.10) n_{eff} can be written in the form

$$n_{\text{eff}} = \frac{3NkT}{2V\epsilon_{\text{max}}}. \quad (80.18)$$

Thus, n_{eff} represents (with an accuracy to within the numerical coefficient) a small fraction of the total number of electrons per cm^3 which is equal approximately to kT/ϵ_{max} .

By means of n_{eff} the heat capacity of the electron gas in order of magnitude can be written in the form

$$C_V^{\text{el}} \sim \frac{3}{2} k n_{\text{eff}}, \quad (80.19)$$

where $\frac{3}{2}k$ is the classical value of the heat capacity.

Formula (80.19) shows that the properties of an electron gas can be approximately interpreted in the following way. In the gas there are n_{eff} effective particles which can change their state and absorb energy supplied from without. Every one of these particles possesses ordinary classical properties and, in particular, to every one of these there corresponds the usual value of the heat capacity.

PART IV

ELECTROMAGNETIC PROCESSES
IN MATTER

Electromagnetic Fields in Matter

§ 1. The derivation of the basic field equations

We have already considered electromagnetic processes occurring in a vacuum. The motion of electric charges in a vacuum and the electromagnetic field accompanying them were considered. We now pass on to the study of electromagnetic phenomena in matter (i.e. in a medium). The theory of electromagnetic processes in matter is often called macroscopic electrodynamics.

The character of electromagnetic processes in matter depends essentially on the properties of the matter. For example, the mechanisms of the passage of current through metal conductors and gaseous plasmas are essentially different in character and are accompanied by different phenomena; magnetic phenomena in ferromagnetics differ strongly from those in diamagnetics and paramagnetics, and so on. Nevertheless, it turns out to be possible to construct a phenomenological theory of electromagnetic phenomena in matter on the basis of certain very general assumptions. It is necessary, first of all, to find the general equations of the electromagnetic field in matter. For this, as we shall see below, it will be necessary to make certain very general assumptions about the concrete properties of the medium in which one or other electromagnetic process takes place.

We have seen that the basic equations of the theory of the electromagnetic field, the Maxwell–Lorentz equations, contain quantities referring to a given point and a given instant of time. We shall write these equations in a slightly different notation, replacing \mathbf{E} by \mathbf{e} and \mathbf{H} by \mathbf{h} . We write the Maxwell–Lorentz equations as well as the charge conservation law in this new notation:

$$\nabla \times \mathbf{e} = -\frac{1}{c} \frac{\partial \mathbf{h}}{\partial t}, \quad (1.1)$$

$$\nabla \cdot \mathbf{h} = 0, \quad (1.2)$$

$$\nabla \times \mathbf{h} = \frac{4\pi}{c} \rho \mathbf{v} + \frac{1}{c} \frac{\partial \mathbf{e}}{\partial t}, \quad (1.3)$$

$$\nabla \cdot \mathbf{e} = 4\pi\rho, \quad (1.4)$$

$$\nabla \cdot \rho \mathbf{v} + \frac{\partial \rho}{\partial t} = 0. \quad (1.5)$$

In matter, a medium consisting of atoms or molecules, the Maxwell–Lorentz equations characterizing the field at a given point and a given instant of time lose their meaning. Indeed, in matter all quantities, including also the electromagnetic field, vary very rapidly from point to point and at a given point also vary rapidly in time. For example, the electric field strength has a relatively small value outside any given atom, becomes very large inside the atom, and again decreases outside it. The increase of the field by a factor of several million and its subsequent decrease take place on a scale of the order of magnitude of atomic dimensions. A change in the field with time at a fixed point occurs, for example, because of the thermal motion of the atom in small fractions of a second. Hence, as in other macroscopic processes taking place in matter, only the mean values of the corresponding quantities are of interest and significant (see Part III).

Let us average the Maxwell–Lorentz equations over a volume v_0 large compared with atomic dimensions but macroscopically small and a time interval τ , introducing the mean values according to the formula

$$\bar{f} = \frac{1}{2\tau} \int_{-\tau}^{\tau} \frac{1}{v_0} \int f dV dt. \quad (1.6)$$

We then have

$$\nabla \times \bar{\mathbf{e}} = -\frac{1}{c} \frac{\partial \bar{\mathbf{h}}}{\partial t}, \quad (1.7)$$

$$\nabla \cdot \bar{\mathbf{h}} = 0, \quad (1.8)$$

$$\nabla \times \bar{\mathbf{h}} = \frac{4\pi}{c} \bar{\rho} \bar{\mathbf{v}} + \frac{1}{c} \frac{\partial \bar{\mathbf{e}}}{\partial t}, \quad (1.9)$$

$$\nabla \cdot \bar{\mathbf{e}} = 4\pi \bar{\rho}, \quad (1.10)$$

$$\nabla \cdot \bar{\rho} \bar{\mathbf{v}} + \frac{\partial \bar{\rho}}{\partial t} = 0. \quad (1.11)$$

We introduce the following notation:

$$\bar{\mathbf{e}} = \mathbf{E}, \quad (1.12)$$

$$\bar{\mathbf{h}} = \mathbf{B}. \quad (1.13)$$

The field strength \mathbf{E} denotes the mean value of the electric field strength in the medium, and the magnetic induction \mathbf{B} the mean value of the magnetic field strength in the medium (this name for the mean magnetic field is associated solely with historical tradition). Then eqs. (1.7) – (1.11) assume the form

$$\nabla \times \mathbf{E} = -\frac{1}{c} \frac{\partial \mathbf{B}}{\partial t}, \quad (1.14)$$

$$\nabla \cdot \mathbf{B} = 0, \quad (1.15)$$

$$\nabla \times \mathbf{B} = \frac{1}{c} \frac{\partial \mathbf{E}}{\partial t} + \frac{4\pi}{c} \bar{\rho} \bar{\mathbf{v}}, \quad (1.16)$$

$$\nabla \cdot \mathbf{E} = 4\pi \bar{\rho}, \quad (1.17)$$

$$\nabla \cdot \bar{\rho} \bar{\mathbf{v}} + \frac{\partial \bar{\rho}}{\partial t} = 0. \quad (1.18)$$

Further transformations of the equations are associated with the calculation of the mean values ρ and ρv . To find these mean values it is necessary to introduce certain assumptions about the structure of matter.

In the theory of the electromagnetic field in matter, the latter is considered as a continuous medium whose properties are described by means of a number of formal macroscopic characteristics, such as the dielectric constant, conductivity and so on. Some of these formal characteristics can be found by applying the methods of statistical physics and are connected with the molecular structure of matter.

However, we shall, from the very beginning, have to divide all matter into two groups; conductors and dielectrics. By conductors we shall understand bodies in which, under the action of an external static field, a displacement of charges occurs over the volume and an electric current arises corresponding to this motion of charges. In dielectrics an external field does not give rise to the motion of charges, although it can cause their displacement to new equilibrium positions.

It is clear from these definitions that the division of bodies into conductors and dielectrics is somewhat arbitrary. In practice, the external electric field gives rise to a finite, although very small, current in dielectrics. On the other hand, in some conductors also the current can be small. Semiconductors play a most important role in physics and technology. Under certain conditions the electric current in semiconductors is relatively large and approaches that in conductors. At other times the current in semiconductors is as small as in the best dielectrics.

Nevertheless, the schematic separation of all bodies into conductors and dielectrics appears to be a sufficiently good approximation on the basis of which it is possible to construct a phenomenological theory of electromagnetic phenomena in continuous media.

§2. The polarization of a medium in an electric field

In calculating ρ one has to distinguish between the cases of a body which is as a whole electrically neutral and one having a charge different from zero.

Let us consider the first case. If an electrically neutral body is placed in an external electric field, a displacement with respect to each other of the positive and negative charges occurs in the atoms and molecules. The body, remaining electrically neutral, acquires a dipole moment. We shall characterize the body by the total dipole moment of all its particles in unit volume. The total dipole moment per unit volume will be called the polariza-

tion vector or, briefly, polarization \mathbf{P} . The dipole moment acquired by the body is by definition equal to

$$\mathbf{d} = \int \mathbf{P} dV = \int \rho_{\text{bound}} \mathbf{r} dV. \quad (2.1)$$

In view of the arbitrariness of the volume of integration

$$\mathbf{P} = \rho_{\text{bound}} \mathbf{r}. \quad (2.1')$$

If the body is uniformly polarized, i.e. if \mathbf{P} is the same at all points of the body, then $\mathbf{P} = \mathbf{d}/V$. The appearance of polarization in a body can, under certain conditions which will be clear from what follows, be accompanied by the appearance of a mean charge density ρ_{bound} . The subscript "bound" means that the mean charge density is due to the displacement of charges which are bound in the atoms of the body. The appearance of the bound, or induced, charge is called electrostatic induction or polarization.

To find ρ_{bound} we shall make use of the definition (2.1) and shall transform the integral $\int \mathbf{P} dV$ into the form $\int f(\mathbf{P}) \mathbf{r} dV$, where $f(\mathbf{P})$ is a function of the polarization. Then, comparing $\int f(\mathbf{P}) \mathbf{r} dV$ with $\int \rho_{\text{bound}} \mathbf{r} dV$, one can find the value of ρ_{bound} . Making use of formula (1.53) and assuming in it that $\mathbf{a} = \mathbf{P}$, $\mathbf{b} = \mathbf{r}$, we find:

$$\int (\mathbf{P} \cdot \mathbf{n}) \mathbf{r} dS = \int \mathbf{r} (\nabla \cdot \mathbf{P}) dV + \int (\mathbf{P} \cdot \nabla) \mathbf{r} dV = \int \mathbf{r} (\nabla \cdot \mathbf{P}) dV + \int \mathbf{P} dV.$$

Choosing the surface of integration to be outside the volume occupied by the body, we have

$$(\mathbf{P} \cdot \mathbf{n}) \mathbf{r} dS = 0,$$

since outside the body the polarization is equal to zero. Hence

$$\int \mathbf{P} dV = - \int \mathbf{r} (\nabla \cdot \mathbf{P}) dV. \quad (2.2)$$

Comparing (2.2) with (2.1), we obtain

$$\rho_{\text{bound}} = - \nabla \cdot \mathbf{P}. \quad (2.3)$$

Thus, if the polarization of the body is not uniform and the vector \mathbf{P} varies from point to point in such a way that $\nabla \cdot \mathbf{P} \neq 0$, a charge density ρ_{bound} defined by formula (2.3) arises in the body.

Formula (2.3) can be given an obvious meaning. Let there be inside the body two imaginary planes S_1 and S_2 . In an external field the charges which are bound in the atoms confined in the space between the planes are displaced. If the polarization is not uniform in space, then, for example, the surface S_2 will be crossed by a larger number of charges going out of the volume than the surface S_1 . As a result, the number of charges going out of the volume confined between the planes is larger than that of charges coming in from the neighbouring volume. A charge density ρ_{bound} arises in the space between S_2 and S_1 .

In particular, when the surface is the boundary surface of the body, then the charges arising from polarization form a surface charge. Its density ω_{bound} is determined in the following simple calculation. We integrate (2.3) with respect to the volume confined between the two surfaces. We choose these surfaces in such a way that one of them is outside the body and the other inside it and that they are at a very small distance h from the external surface of the body.

Then we have

$$\begin{aligned} \int (\nabla \cdot \mathbf{P}) dV &= \oint \mathbf{P} \cdot d\mathbf{S} = \oint_{\substack{\text{outside} \\ \text{the body}}} P_n dS - \oint_{\substack{\text{inside} \\ \text{the body}}} P_n dS = \\ &= - \oint_{\substack{\text{inside} \\ \text{the body}}} P_n dS = - \int \rho_{\text{bound}} dV. \end{aligned} \quad (2.4)$$

Passing to the limit $h \rightarrow 0$, we can write

$$\begin{aligned} \lim_{h \rightarrow 0} \int \rho_{\text{bound}} dV &= \oint_{S'} \omega_S dS, \\ \oint_{\substack{\text{inside} \\ \text{the body}}} P_n dS &\rightarrow \int_{S'} P_n dS, \end{aligned}$$

where S denotes the surface of the body and the value of P_n is taken at the surface. In view of the arbitrary character of the surface of the body, it follows from the equality

$$\oint_S P_n dS = \int \omega_S dS,$$

that

$$\omega_S = P_n. \quad (2.5)$$

In this case it is clear that the total charge of an electrically neutral body placed in an external field remains equal to zero. Choosing the surface of integration in (2.4) to be outside the volume of the body, one can write

$$\int \rho_{\text{bound}} dV = - \int (\mathbf{V} \cdot \mathbf{P}) dV = - \int P_n dS = 0.$$

Thus, the total bound charge density arising within the body is equal to the total charge induced at its surface.

Up to now we have assumed the body to be electrically neutral. If the total free charge of the body is different from zero and is distributed in it with a volume density ρ , then the mean charge density is

$$\bar{\rho} = \rho_{\text{bound}} + \rho$$

and

$$\int \bar{\rho} dV = \int (\rho_{\text{bound}} + \rho) dV = \int \rho dV = e. \quad (2.6)$$

The charge of the body characterized by the density ρ is not bound to the atoms of the substance and is not induced by an external field. We shall see below that in a constant field the free charge ρ can exist only in dielectrics. In conductors free charges are mobile and move until they come to the surface of the conductor, forming a surface charge.

§3. The mean current density and mean charge density in a medium

The calculation of the mean current density $\overline{\rho \mathbf{v}}$ in a medium is a somewhat more complex problem. This calculation can be carried out either on the basis of certain model representations or, more formally, by proceeding from the general notions of the electromagnetic properties of a medium.

We choose the second method here, since the atomic and molecular models which are usually employed in expounding macroscopic electrodynamics are not only far from reality but also contain of necessity obviously incorrect assumptions. As will be explained below, quantum effects play a fundamental role in the magnetic properties of atoms. Hence the consideration of the electric and, in particular, the magnetic properties of atomic systems cannot be carried out on the basis of classical models. In a formal treatment we can

restrict ourselves to one physical assumption only: if a body is placed in an external electromagnetic field, then the mean field within the body is small in comparison with the intra-atomic fields. In other words, we shall assume that mean fields inside the body are weak. In addition, we shall confine ourselves to cases of homogeneous and isotropic bodies.

The mean current density, $\bar{\rho}\mathbf{v}$, at each point of the body is a function of the strengths of the electric and magnetic fields. In addition, if the fields vary in space and time, the mean current density will depend on the rate of change in time of the vectors \mathbf{E} and \mathbf{B} and on the spatial derivatives of these quantities, i.e.

$$\bar{\rho}\mathbf{v} = f\left(\mathbf{E}, \mathbf{B}, \frac{\partial \mathbf{E}}{\partial t}, \frac{\partial \mathbf{B}}{\partial t}, \frac{\partial E_i}{\partial x_k}, \frac{\partial H_i}{\partial x_k}\right). \quad (3.1)$$

Since the fields are weak, one can expand the function f in a series in powers of the variables and confine oneself to the first powers of the expansion*. This expansion is carried out in powers of a small ratio of the type $|\mathbf{E}|/|\mathbf{E}_{\text{int.at.}}|$, where $E_{\text{int.at.}}$ is the strength of the intra-atomic field.

Expanding f in a series in powers of the variables, we have to take into account that $\rho\mathbf{v}$ is a polar vector. Hence all terms of the series must also represent polar vectors. They can be neither scalars nor axial vectors.

We recall (see §6 of Part I) that the electric field strength \mathbf{e} and, consequently, also the mean electric field strength \mathbf{E} in a medium are polar vectors. On the contrary, the magnetic field strength \mathbf{h} and the mean magnetic field \mathbf{B} are axial vectors or pseudovectors. Hence the vector \mathbf{E} but not the vector \mathbf{B} can appear in the required expansion.

The derivative of the vector \mathbf{E} with respect to time, $\partial\mathbf{E}/\partial t$, is a polar vector and must be the first term of the expansion. The spatial derivatives $\partial E_i/\partial x_k$ can be grouped in the form of two combinations of the derivatives, $\nabla \times \mathbf{E}$ and $\nabla \cdot \mathbf{E}$. The first combination of the derivatives, $\nabla \times \mathbf{E}$, forms an axial vector, while the second forms a scalar. These two quantities cannot by themselves occur in the expansion. The first derivatives of \mathbf{B} are: $\partial\mathbf{B}/\partial t$, $\nabla \times \mathbf{B}$ and $\nabla \cdot \mathbf{B}$. The quantity $\partial\mathbf{B}/\partial t$ is an axial vector, $\nabla \cdot \mathbf{B} = 0$ by virtue of (1.15), while $\nabla \times \mathbf{B}$ is a polar vector. Hence the vector $\nabla \times \mathbf{B}$ must be retained in the expansion f . Thus, to the first order of small quantities, there are only three quantities which are polar vectors: \mathbf{E} , $\partial\mathbf{E}/\partial t$ and $\nabla \times \mathbf{B}$. Of course, in the next approximation one can form a number of polar vectors

* See I.E. Tamm, *Osnovy teorii elektrichestva (Introduction to the theory of electricity)* (Gostekhizdat, Moscow, 1954) p. 428.

from the scalars and axial vectors, but we shall not be interested in the expansion terms of the second order.

In expanding in powers of the ratio $|\mathbf{E}|/|\mathbf{E}_{\text{int.at.}}|$ one has, in general, to take into account the anisotropy of the body, because $\mathbf{E}_{\text{int.at.}}$ varies in different directions according to different laws. In isotropic bodies (such are gases, liquids and, to a certain extent, polycrystalline bodies) the ratio $|\mathbf{E}|/|\mathbf{E}_{\text{int.at.}}|$ has the same value in all directions. Then, with an accuracy to terms of the first order of small quantities,

$$\bar{\rho}\mathbf{v} = \sigma\mathbf{E} + \chi \frac{\partial \mathbf{E}}{\partial t} + \alpha c (\nabla \times \mathbf{B}), \quad (3.2)$$

where σ , χ and α are scalars depending on the properties of the medium. The reason why the factor c (the velocity of light) is introduced into the last term will be clear from what follows.

The zeroth order term (the term containing no field) is absent in expansion (3.2), since a mean current equal to zero must correspond to the absence of a field.

Before introducing this expression for $\rho\mathbf{v}$ into Maxwell's equations, we shall discuss the physical meaning of individual terms of the expansion.

The first term of the expansion, $\sigma\mathbf{E}$, has a very simple and obvious meaning. It shows that in the presence of an electric field a current arises in the medium whose mean density is proportional to the mean field strength \mathbf{E} . The quantity σ is called the conductivity or electrical conductivity of the body.

We shall make use of the notation

$$\mathbf{j} = \sigma\mathbf{E}. \quad (3.3)$$

The vector \mathbf{j} represents the mean charge passing per second through 1 cm^2 of surface inside the body perpendicular to \mathbf{j} . The vector \mathbf{j} is called the conduction current density. The relation (3.3) connects the current density at a given point of the body with the field strength at that point. We shall call the relation (3.3) Ohm's law in differential form. Below, in § 16, we shall establish the connection of (3.3) with the usual formulation of Ohm's law.

The properties of bodies are characterized by the value of the conductivity σ . For ideal dielectrics it should be assumed, in accordance with their definition, that $\sigma = 0$. For real dielectrics $\sigma \neq 0$, but is very small in comparison with its value in semiconductors and particularly in metals.

The problem of conductivity in bodies of different natures will be

considered below. Meanwhile we note only, that the conduction current is due to free charges: free electrons in metals, ions and electrons in gases, ions in liquids. They are called free because they are not bound to any atom and, under the action of a field, can move over the entire volume of the body.

We shall denote the mean density of free charges in a body by ρ . It is obviously connected with the current density \mathbf{j} by the equation of continuity

$$\nabla \cdot \mathbf{j} + \partial \rho / \partial t = 0. \quad (3.4)$$

It is here assumed that the free charges existing in a body do not become bound and do not arise from bound charges.

In order to explain the physical meaning of the second and third terms of the expansion (3.2) we transform (3.2) in such a way that the vectors \mathbf{E} and \mathbf{B} are separated from each other. We take, for example, the divergence of both sides of eq. (3.2). We then have, obviously,

$$\nabla \cdot (\bar{\rho} \mathbf{v}) = \nabla \cdot \mathbf{j} + \chi \frac{\partial}{\partial t} (\nabla \cdot \mathbf{E}).$$

By virtue of the equations of continuity for the total current $\rho \mathbf{v}$ and the free charge current \mathbf{j} , given by formulae (1.18) and (3.4),

$$-\frac{\partial}{\partial t} (\bar{\rho} - \rho) = \chi \frac{\partial}{\partial t} \nabla \cdot \mathbf{E}. \quad (3.5)$$

The difference $\bar{\rho} - \rho$ is obviously equal to the mean density of bound charges ρ_{bound} . Thus, for a homogeneous medium we have

$$\frac{\partial \rho_{\text{bound}}}{\partial t} = -\frac{\partial}{\partial t} \nabla \cdot (\chi \mathbf{E}).$$

Integrating, one can write

$$\rho_{\text{bound}} = -\nabla \cdot (\chi \mathbf{E}). \quad (3.6)$$

The integration constant may be set equal to zero, since in the absence of a field ρ_{bound} must be equal to zero.

Comparing (3.6) with (2.3), we verify, first of all, the formula

$$\mathbf{P} = \chi \mathbf{E}, \quad (3.7)$$

which relates the polarization in the body to the field strength \mathbf{E} . The polarization \mathbf{P} turns out to be proportional to the field \mathbf{E} . The factor of proportionality χ is called the polarization coefficient or dielectric susceptibility of the body. The value of the dielectric susceptibility for bodies consisting of simple molecules will be calculated in §12 and §13. There it will be shown that χ is an essentially positive quantity, so that the vector \mathbf{P} is always directed in the same direction as the vector \mathbf{E} .

By virtue of (3.7) the second term of (3.2) can be written in the form

$$\chi \frac{\partial \mathbf{E}}{\partial t} = \frac{\partial \mathbf{P}}{\partial t}. \quad (3.8)$$

Formula (3.8) shows that the variation of the polarization vector in time is equivalent to the appearance of a certain current. This current is called the polarization current, and its density is

$$\mathbf{j}_{\text{pol}} = \partial \mathbf{P} / \partial t, \quad (3.9)$$

i.e. is equal to the rate of change of the dipole moment per unit volume at a given point of the body.

Indeed, from the definition (2.1) of the vector \mathbf{P} it follows that

$$\int \frac{\partial \mathbf{P}}{\partial t} dV = \frac{\partial}{\partial t} \int \rho_{\text{bound}} \mathbf{r} dV = \int \mathbf{r} \frac{\partial \rho_{\text{bound}}}{\partial t} dV. \quad (3.10)$$

Here we have changed the order of differentiation and integration. The quantity \mathbf{r} represents the integration variable and does not depend on t .

Making use of (1.5) and applying the relation (2.2) to the vector $\rho_{\text{bound}} \mathbf{v}$, we find

$$\int \frac{\partial \mathbf{P}}{\partial t} dV = - \int \mathbf{r} [\nabla \cdot (\rho_{\text{bound}} \mathbf{v})] dV = \int \rho_{\text{bound}} \mathbf{v} dV. \quad (3.11)$$

The meaning of the density of the current of bound charges is very simple. The variation in time of the polarization of a given volume means that bound charges are going out of it (or coming into it). It is clear, however, that the displacement of bound charges, from the point of view of the electricity which they transport, is equivalent to the motion of free charges.

We now go on to the explanation of the meaning of the last term in (3.2). For this we form the vector product of formula (3.2) and \mathbf{r} and integrate the result with respect to the volume of the body:

$$\int \mathbf{r} \times (\overline{\rho \mathbf{v}}) dV = \int \mathbf{r} \times \mathbf{j} dV + \int \mathbf{r} \times \frac{\partial \mathbf{P}}{\partial t} dV + \alpha c \int \mathbf{r} \times (\nabla \times \mathbf{B}) dV.$$

By virtue of (3.10):

$$\begin{aligned} \int \mathbf{r} \times \frac{\partial \mathbf{P}}{\partial t} dV &= \int \mathbf{r} \times \left(\frac{\partial}{\partial t} (\rho_{\text{bound}} \mathbf{r}) \right) dV = \\ &= \frac{\partial}{\partial t} \int \mathbf{r} \times (\rho_{\text{bound}} \mathbf{r}) dV = \frac{\partial}{\partial t} \int \rho_{\text{bound}} (\mathbf{r} \times \mathbf{r}) dV = 0. \end{aligned}$$

Consequently,

$$\alpha c \int \mathbf{r} \times (\nabla \times \mathbf{B}) dV = \int \mathbf{r} \times (\overline{\rho \mathbf{v}} - \mathbf{j}) dV = \int \mathbf{r} \times (\rho_{\text{bound}} \mathbf{v}) dV, \quad (3.12)$$

where $\rho_{\text{bound}} \mathbf{v} = \overline{\rho \mathbf{v}} - \mathbf{j}$ is the current density carried by bound charges.

We introduce the notation

$$\mathbf{M} = \alpha \mathbf{B}. \quad (3.13)$$

Then (3.12) can be written in the form

$$\int \mathbf{r} \times (\nabla \times \mathbf{M}) dV = \frac{1}{c} \int \mathbf{r} \times (\rho_{\text{bound}} \mathbf{v}) dV. \quad (3.14)$$

By virtue of formula (1.54), in which $\mathbf{a} = \mathbf{M}$, $\mathbf{b} = \mathbf{r}$,

$$\int \mathbf{r} \times (\nabla \times \mathbf{M}) dV = - \int (\mathbf{M} \times \nabla) \times \mathbf{r} dV - \oint (\mathbf{n} \times \mathbf{M}) \times \mathbf{r} dV.$$

If the integration surface is outside the volume occupied by the body, then at this surface $\mathbf{M} = 0$ and, thus,

$$\int \mathbf{r} \times (\nabla \times \mathbf{M}) dV = - \int (\mathbf{M} \times \nabla) \times \mathbf{r} dV.$$

Here

$$(\mathbf{M} \times \nabla) \times \mathbf{r} = (\mathbf{M} \cdot \nabla) \mathbf{r} - \mathbf{M} (\nabla \cdot \mathbf{r}) = \mathbf{M} - 3\mathbf{M} = -2\mathbf{M}.$$

Hence, finally,

$$\int \mathbf{r} \times (\nabla \times \mathbf{M}) \, dV = 2 \int \mathbf{M} \, dV. \quad (3.15)$$

Comparing (3.15) with (3.14), we obtain

$$\int \mathbf{M} \, dV = \int \frac{\mathbf{r} \times (\rho_{\text{bound}} \mathbf{v})}{2c} \, dV. \quad (3.16)$$

Eq. (3.16) shows that the vector \mathbf{M} introduced by the relation (3.13) represents the mean magnetic moment per unit volume of the body produced by moving bound charges (see §22 of Part I).

The statistical theory of magnetic phenomena will be expounded in ch. 6.

By means of the quantities \mathbf{j} , \mathbf{P} and \mathbf{M} the mean current density in matter can finally be written in the form

$$\overline{\rho \mathbf{v}} = \mathbf{j} + \frac{\partial \mathbf{P}}{\partial t} + c(\nabla \times \mathbf{M}). \quad (3.17)$$

§4. The system of equations for the electromagnetic field in a medium

Having calculated the mean values of the quantity $\rho \mathbf{v}$, we can pass on to the final formulation of the equations for the electromagnetic field in a medium. Substituting (3.17) into (1.16), we find

$$\nabla \times \mathbf{B} = \frac{4\pi}{c} \mathbf{j} + \frac{1}{c} \frac{\partial \mathbf{E}}{\partial t} + \frac{4\pi}{c} \frac{\partial \mathbf{P}}{\partial t} + 4\pi(\nabla \times \mathbf{M}),$$

or

$$\nabla \times (\mathbf{B} - 4\pi \mathbf{M}) = \frac{4\pi}{c} \mathbf{j} + \frac{1}{c} \frac{\partial}{\partial t} (\mathbf{E} + 4\pi \mathbf{P}). \quad (4.1)$$

We now introduce a new notation, writing

$$\mathbf{H} = \mathbf{B} - 4\pi \mathbf{M} \quad (4.2)$$

and

$$\mathbf{E} = \mathbf{D} - 4\pi \mathbf{P}. \quad (4.3)$$

We rewrite (4.1) in the form

$$\nabla \times \mathbf{H} = \frac{4\pi}{c} \mathbf{j} + \frac{1}{c} \frac{\partial \mathbf{D}}{\partial t}. \quad (4.4)$$

We now consider eq. (1.17). By expressing the mean charge density according to formula (2.6) in terms of the mean density of the free charge ρ and the mean density of the bound charge ρ_{bound} , and making use of (2.6), we obtain

$$\nabla \cdot \mathbf{E} = 4\pi\rho + 4\pi\rho_{\text{bound}} = 4\pi\rho - 4\pi(\nabla \cdot \mathbf{P}).$$

Hence, by virtue of (4.3),

$$\nabla \cdot \mathbf{D} = 4\pi\rho. \quad (4.5)$$

The two remaining equations (1.14) and (1.15), as we have seen, are averaged without any difficulties:

$$\nabla \times \mathbf{E} = -\frac{1}{c} \frac{\partial \mathbf{B}}{\partial t}, \quad (4.6)$$

$$\nabla \cdot \mathbf{B} = 0. \quad (4.7)$$

In this case ρ and \mathbf{j} are related by the equation of continuity

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \mathbf{j} = 0. \quad (4.8)$$

Eqs. (4.4) – (4.8) form the system of equations for the field in a medium. This system of equations was established by Maxwell in 1873 and they are called Maxwell's equations (as distinct from the Maxwell–Lorentz equations (1.1) – (1.5) of Part I). It is clear that this system is still not complete, since it contains four unknown vectors: the mean fields \mathbf{E} and \mathbf{B} and the auxiliary quantities \mathbf{H} and \mathbf{D} . For historical reasons we call the vector \mathbf{H} the magnetic field in the medium, and the vector \mathbf{D} the electric displacement.

In order that the Maxwell system of equations may be complete, it is necessary to give certain additional relations connecting the basic and auxiliary field vectors. These relations are called constitutive equations. In the simplest (homogeneous and isotropic) medium which we have considered above, the form of the constitutive equations follows directly from (3.2).

By virtue of (3.13) and (4.2), we have

$$\mathbf{H} = \mathbf{B} - (4\pi\alpha)\mathbf{B} = [1 - (4\pi\alpha)]\mathbf{B}. \quad (4.9)$$

For historical reasons the constitutive equation (4.9) is written in the form

$$\mathbf{B} = \mu\mathbf{H}, \quad (4.10)$$

where the constant $\mu = [1 - (4\pi\alpha)]^{-1}$ is called the magnetic permeability of the medium. The induced magnetic moment per unit volume \mathbf{M} is expressed not in terms of \mathbf{B} but in terms of \mathbf{H} according to the formula

$$\mathbf{M} = (\mu\alpha)\mathbf{H} = \kappa\mathbf{H}, \quad (4.11)$$

where κ is called the magnetic susceptibility. It follows from (4.2) and (4.11) that

$$\mu = 1 + 4\pi\kappa. \quad (4.12)$$

Analogously, from (3.7) and (4.3) we obtain the constitutive equation

$$\mathbf{D} = \epsilon\mathbf{E}, \quad (4.13)$$

where the coefficient

$$\epsilon = 1 + 4\pi\chi \quad (4.14)$$

is called the dielectric permittivity or, according to an obsolete but frequently applied terminology, the dielectric constant. The relation (3.3) is also usually referred to as a constitutive equation. We would like to stress that, in contrast to the Maxwell–Lorentz equations, which are among the most accurate and universal of the known laws of nature, Maxwell's equations have limited applicability in consequence of the limited region of applicability of the constitutive equations. We shall dwell on this problem in more detail below.

In what follows it will be shown that for all bodies the electric susceptibility χ is larger than 0 and, consequently, the dielectric constant ϵ is larger than 1. On the contrary, the magnetic susceptibility can be either positive or negative.

Substances for which $\kappa > 0$ are called paramagnetic, while those for which

$\kappa < 0$ are called diamagnetic. For what follows we shall need the integral form of Maxwell's equations, which we can write as follows:

$$\oint \mathbf{E} \cdot d\mathbf{l} = -\frac{1}{c} \frac{\partial}{\partial t} \int \mathbf{B} \cdot d\mathbf{S}, \quad (4.15)$$

$$\oint \mathbf{B} \cdot d\mathbf{S} = 0, \quad (4.16)$$

$$\oint \mathbf{H} \cdot d\mathbf{l} = \frac{4\pi}{c} \int \mathbf{j} \cdot d\mathbf{S} + \frac{1}{c} \frac{\partial}{\partial t} \int \mathbf{D} \cdot d\mathbf{S}, \quad (4.17)$$

$$\oint \mathbf{D} \cdot d\mathbf{S} = 4\pi \int \rho \, dV. \quad (4.18)$$

In just the same way as has been done for the electromagnetic field in vacuum in §10 of Part I, one can introduce the electromagnetic potentials φ and \mathbf{A} in matter. We define them by the formulae

$$\mathbf{B} = \nabla \times \mathbf{A}, \quad (4.19)$$

$$\mathbf{E} = -\frac{1}{c} \frac{\partial \mathbf{A}}{\partial t} - \nabla \varphi. \quad (4.20)$$

In this case the Lorentz conditions assume the form

$$\nabla \cdot \mathbf{A} = -\frac{\epsilon\mu}{c} \frac{\partial \varphi}{\partial t}. \quad (4.21)$$

Reproducing the calculations of §10 of Part I, one can easily arrive at the equations for the potentials

$$\nabla^2 \mathbf{A} - \frac{\epsilon\mu}{c^2} \frac{\partial^2 \mathbf{A}}{\partial t^2} = -\frac{4\pi\mu}{c} \mathbf{j}, \quad (4.22)$$

$$\nabla^2 \varphi - \frac{\epsilon\mu}{c^2} \frac{\partial^2 \varphi}{\partial t^2} = -\frac{4\pi}{c} \rho. \quad (4.23)$$

§5. Boundary conditions

In what follows we shall usually have to consider electromagnetic phenomena in bodies which are limited in space. Hence it is necessary to find out how the vectors of the electromagnetic field change near the boundary of the body. In the most general case the boundary of the body is the interface of two media with different properties. We shall assume that with a sufficient degree of accuracy the interface can be considered as a surface, and we shall not be interested in the properties of the electromagnetic field in the transition layer near the boundary.

Let one medium be characterized by ϵ_1 and μ_1 , and the other by ϵ_2 and μ_2 . The behaviour of the vectors of the field at the interface can be established from Maxwell's equations written in integral form.

Let us consider eq. (4.15) and apply it to an infinitesimal contour L shown in fig. IV.1, assuming the length l_1 to be an infinitesimal quantity of the first order, and the length l_2 to be an infinitesimal quantity of the second order. Then we have

$$\oint \mathbf{E} \cdot d\mathbf{l} = E_{\text{tg}}^{(1)} l_1 - E_{\text{tg}}^{(2)} l_1 + \text{an infinitesimal quantity of the second order}.$$

Here E_{tg} denotes the component of the electric field strength vector tangent to the interface; the indices refer to the first and second media.

Eq. (4.15) gives:

$$(E_{\text{tg}}^{(1)} - E_{\text{tg}}^{(2)}) l_1 = -\frac{1}{c} \frac{\partial \Phi}{\partial t}, \quad (5.1)$$

where Φ is the flux of magnetic induction through the surface enclosed by the contour L . Obviously, $\Phi \sim l_1 l_2$ and is of a high order of small quantities. Hence, passing over to the limit $l_2 \rightarrow 0$, we find from (5.1)

$$E_{\text{tg}}^{(1)} = E_{\text{tg}}^{(2)}. \quad (5.2)$$

Fig. IV.1

The tangential component of the electric field strength remains continuous in passing through the interface of the media.

We apply an analogous method to formula (4.17), dropping at once the term of second order in small quantities $\oint \mathbf{D} \cdot d\mathbf{S}$. We then find

$$\oint \mathbf{H} \cdot d\mathbf{l} = (\mathbf{H}_2 - \mathbf{H}_1) \cdot \mathbf{l} dl_1 = \frac{4\pi}{c} \int \mathbf{j} \cdot d\mathbf{S},$$

where \mathbf{l} is the unit vector of the contour lying in the plane of the interface (fig. IV.1).

We denote the normal to the interface by \mathbf{n} , and the normal to the surface enclosed by the contour \mathbf{l} by \mathbf{n}_l . The vectors \mathbf{n} , \mathbf{n}_l and \mathbf{l} form a right-handed screw system

$$\mathbf{l} = \mathbf{n}_l \times \mathbf{n}.$$

Further, we introduce the concept of surface current density \mathbf{j}_S , by which is meant the amount of electricity passing per second through unit length on the surface

$$\lim_{dl_1 dl_2 \rightarrow 0} (\mathbf{j} \cdot \mathbf{n}_l) dl_1 dl_2 = (\mathbf{j}_S \cdot \mathbf{n}) dl_1.$$

Then (4.17) gives

$$\oint \mathbf{H} \cdot d\mathbf{l} = \frac{4\pi}{c} (\mathbf{j}_S \cdot \mathbf{n}_l) dl_1 = (\mathbf{H}_2 - \mathbf{H}_1) \cdot \mathbf{l} dl_1,$$

or

$$(\mathbf{H}_2 - \mathbf{H}_1) \cdot \mathbf{l} = \frac{4\pi}{c} (\mathbf{j}_S \cdot \mathbf{n}_l).$$

Expressing \mathbf{l} in terms of \mathbf{n}_l , we have

$$(\mathbf{H}_2 - \mathbf{H}_1) \cdot (\mathbf{n}_l \times \mathbf{n}) = \mathbf{n}_l \cdot [\mathbf{n} \times (\mathbf{H}_2 - \mathbf{H}_1)],$$

hence

$$\mathbf{n}_l \cdot [\mathbf{n} \times (\mathbf{H}_2 - \mathbf{H}_1)] = \frac{4\pi}{c} (\mathbf{j}_S \cdot \mathbf{n}_l).$$

Since the orientation of the vector \mathbf{n}_l in the plane of the interface can be arbitrary, the following equality must be fulfilled:

$$\mathbf{n} \times (\mathbf{H}_2 - \mathbf{H}_1) = \frac{4\pi}{c} \mathbf{j}_S. \quad (5.3)$$

In the presence of surface currents the tangential component of the field strength \mathbf{H} is discontinuous at the interface of the media. The value of the discontinuity ΔH_{tg} is equal to $(4\pi/c)j_S$.

If there is no surface current at the interface, $j_S = 0$, then

$$H_{tg}^{(1)} = H_{tg}^{(2)}. \quad (5.4)$$

The boundary conditions for the normal components of the induction vector \mathbf{B} and the displacement vector \mathbf{D} are obtained from (4.16) and (4.18), if the infinitesimal surface S shown in fig. IV.2 is chosen as the integration surface. The area S_1 of the bases is an infinitesimal quantity of the first order, while the area of the lateral faces is an infinitesimal quantity of the second order. From (4.16) we find

$$(B_n^{(1)} - B_n^{(2)}) + \text{an infinitesimal quantity of the second order} = 0,$$

or, passing over to the limit,

$$B_n^{(1)} = B_n^{(2)}. \quad (5.5)$$

The normal component of the magnetic induction vector is conserved in passing through the interface.

Fig. IV.2

Analogously, from (4.18) we find

$$D_n^{(1)} = D_n^{(2)} + 4\pi\omega_S, \quad (5.6)$$

where ω_S is the surface charge density defined, as above, by

$$\lim_{h \rightarrow 0} \int \rho \, dV = \int \omega_S \, dS.$$

If the surface charge density is $\omega_S = 0$, then

$$D_n^{(1)} = D_n^{(2)}. \quad (5.7)$$

Eqs. (5.2), (5.3), (5.5) and (5.6) are the boundary conditions which must be satisfied by the field vectors at the interface of the media. In particular, at the boundary with a vacuum one must assume in these formulae that $\epsilon_2 = \mu_2 = 1$.

§6. The limits of applicability of the system of constitutive equations

We have obtained Maxwell's equations (together with the constitutive equations) from the Maxwell-Lorentz equations by means of averaging, based on certain assumptions about the properties of the medium.

Although these assumptions have a rather general character, they are not always fulfilled. It turns out that the region of applicability of the constitutive equations and, consequently, Maxwell's equations in the simplest form (4.4) – (4.7) is rather limited. We have to stress these limitations particularly because nowadays one has to deal more and more often in physics with systems to which Maxwell's equations in the form we have written down are not applicable. Usually one of the terms on the right-hand side of eq. (4.4) is large while the other is small. Thus, in ideal dielectrics the conduction current is $\mathbf{j} = 0$, and in real dielectrics it is very small in comparison with the displacement current $\partial \mathbf{D} / \partial t$. On the other hand, in conductors the displacement current is usually small. Therefore eq. (4.17) should be considered as a general expression which includes limiting real cases but which is almost always simplified in actual use. However, they are presented in all the old and many new textbooks without adequate reservations.

We now go on to the discussion of the assumptions made in deriving Maxwell's equations. The basic assumption is the expansion (3.2). This ex-

pansion means, first of all, that the medium is isotropic, so that the connection between the vector $\bar{\rho}\bar{\mathbf{v}}$ and the vectors \mathbf{E} , $\partial\mathbf{E}/\partial t$ and $\mathbf{V} \times \mathbf{B}$ is characterized by the scalar constants σ , χ , μ . It is clear that this assumption is not applicable to anisotropic media, in particular to monocrystals. Hence in anisotropic media the relations (3.3), (4.13) and (4.10) do not hold and must be replaced by the tensor expressions

$$j_i = \sigma_{ik} E_k, \quad D_i = \epsilon_{ik} E_k, \quad B_i = \mu_{ik} H_k. \quad (6.1)$$

The quantities ϵ_{ik} and μ_{ik} are symmetric second-rank tensors. The proof of this statement will be given in §12.

Further, the very existence of a linear relation between \mathbf{M} and \mathbf{B} or, what is the same, between \mathbf{B} and \mathbf{H} , turns out not to be fulfilled for a relatively small but very important group of substances which are called ferromagnetics and antiferromagnetics. For these substances the functional relationship between \mathbf{B} and \mathbf{H} has a complex non-linear and ambiguous character. We shall dwell on the theory of ferromagnetism below, cf. §20.

Another group of substances, called ferroelectrics, possess electric properties which are analogous to the magnetic properties of ferromagnetics: the dependence of \mathbf{D} on \mathbf{E} is non-linear and ambiguous.

Thus, for ferromagnetics and ferroelectrics the expression (3.2), in which the first terms of the expansion are retained, loses its meaning.

A number of substances, called superconductors, show a profound change in their magnetic properties at low temperatures. The magnetic field does not penetrate inside superconductors, so that in the volume of a superconductor the following condition is fulfilled:

$$\mathbf{B} = 0.$$

It is obvious that Maxwell's equations in the form (4.4)–(4.7) do not describe the behaviour of superconductors. The properties of superconductors will be considered in §21, while the theory of superconductivity will be given in Part V.

The problem of the applicability of the expansion (3.2) in the case of high-frequency fields and for spatially non-uniform systems is more complex.

In considering high frequencies the division of the current into two parts, the current of free charges and the current of bound charges, ceases to have any meaning.

It is clear that in a high-frequency field the free charges as well as the bound charges perform practically the same oscillatory motion. Reasoning

further quantitatively, one can say that the expansion (3.2) assumes that the variation of fields in space must be rather smooth and occur over distances which are large in comparison with molecular dimensions. Otherwise the macroscopic averaging over the volume, which must include a sufficiently large number of molecules, would be meaningless. Since the variation in space takes place over a wavelength, the inequality $\lambda \gg a$ must be fulfilled and, consequently, we are confined to frequencies which are much lower than $\omega_0 \ll c/a$.

However, this restriction is still not the strongest one. In the range $\omega \ll \omega_0$ there is a wide interval of frequencies in which the constitutive equation (4.13) turns out to be inapplicable. This equation, as well as (3.2), assumes that the frequency of the field is small compared with the inverse of the relaxation time τ^{-1} which is characteristic of the given substance. In this case the polarization \mathbf{P} at a given point of space at a particular time t is determined by the displacement (mean field) at the same point and at the same instant of time. But if the frequency is comparable with the inverse of the relaxation time τ^{-1} , then the polarization will lag behind the field and will become dependent on the history of the process. Then instead of (4.13) we shall have to write the more general relation

$$\mathbf{D}(\mathbf{r}, t) = \int_{-\infty}^t \epsilon(t, t') \mathbf{E}(\mathbf{r}, t') dt', \quad (6.2)$$

where the integration is carried out with respect to past times ($t' < t$) and the function $\epsilon(t, t')$ determines the production of polarization as a result of the action of the field at preceding instants of time. Since time flows uniformly, there is no unique instant of time. This means that the function $\epsilon(t, t')$ can depend only on the time which passed between the instant t' and the instant t , in other words, on the argument $t - t'$. Thus

$$\mathbf{D}(\mathbf{r}, t) = \int_{-\infty}^t \epsilon(t - t') \mathbf{E}(\mathbf{r}, t') dt'. \quad (6.3)$$

We note that the frequencies for which eq. (4.13) is inapplicable are very small in comparison with ω_0 . Indeed, relaxation times τ are always in order of magnitude equal to characteristics atomic times $\tau_{at} \sim a/v$, where v is the velocity of electrons in atoms. Hence

$$\omega \sim \frac{1}{\tau_{at}} \sim \frac{v}{a} \sim \frac{v}{c} \omega_0 \ll \omega_0. \quad (6.4)$$

In §32 we will show that in the frequency range approaching characteristic atomic frequencies the dielectric constant is dependent on the frequency. This phenomenon is therefore called frequency dispersion or time dispersion.

Another phenomenon, called spatial dispersion, also occurs at high frequencies. In order that eq. (4.13) may apply the wavelength must be large not only in comparison with the size of the atom but also in comparison with the size of any region of spatial non-uniformity in the substance.

If the size of a region of non-uniformity is denoted by l , then it is necessary that the inequality $\lambda > l$ be satisfied. If $\lambda \approx l$, then the polarization at a given point of space will depend on the value of the field at neighbouring points of space at preceding instants of time, i.e.

$$\mathbf{D}(\mathbf{r}, t) = \int_{-\infty}^t dt' \int \epsilon(\mathbf{r}, \mathbf{r}', t-t') \mathbf{E}(\mathbf{r}', t') dV'. \quad (6.5)$$

Formula (6.5) means that a contribution to the polarization at a given point at a given instant of time is produced by charges which have earlier been at neighbouring points of space. This phenomenon is called spatial dispersion. Media with a spatial dispersion are encountered in a number of important cases (e.g.: plasma, metals). All that has been said about the time dispersion and spatial dispersion of dielectric permittivity also holds for magnetic permeability.

We thus see that the way of writing the constitutive equations and, consequently, Maxwell's equations as presented in §4 is the simplest form and is applicable only to the case of isotropic media which do not display a time dispersion or spatial dispersion and are neither ferromagnetic nor ferroelectric.

§7. The law of conservation of energy in a medium

The derivation of the law of conservation of energy for a non-absorbing, isotropic and non-ferromagnetic medium does not differ from the analogous calculations carried out in §12 of Part I. Namely, if all bodies (conductors and dielectrics) which are placed in a field are at rest, then the work done by the electric field on the charges per unit time is equal to

$$\begin{aligned} \frac{dW}{dt} &= \int \mathbf{j} \cdot \mathbf{E} dV = \frac{c}{4\pi} \int \mathbf{E} \cdot (\nabla \times \mathbf{H}) dV - \frac{1}{4\pi} \int \mathbf{E} \cdot \frac{\partial \mathbf{D}}{\partial t} dV = \\ &= \frac{c}{4\pi} \int [\mathbf{E} \cdot (\nabla \times \mathbf{H}) - \mathbf{H} \cdot (\nabla \times \mathbf{E})] dV - \frac{1}{4\pi} \int \left(\mathbf{E} \cdot \frac{\partial \mathbf{D}}{\partial t} + \mathbf{H} \cdot \frac{\partial \mathbf{B}}{\partial t} \right) dV = \end{aligned}$$

$$= - \oint \boldsymbol{\sigma} \cdot d\mathbf{S} - \int \frac{\partial}{\partial t} u_0 dV.$$

Here we have added an expression equal to zero to the integral to be calculated by virtue of (1.14), and have denoted the energy density of the electromagnetic field in the medium by u_0

$$u_0 = \frac{\epsilon E^2 + \mu H^2}{8\pi} \quad (7.1)$$

and the Poynting vector by $\boldsymbol{\sigma}$

$$\boldsymbol{\sigma} = \frac{c}{4\pi} \mathbf{E} \times \mathbf{H} = \frac{c}{4\pi\mu} \mathbf{E} \times \mathbf{B}. \quad (7.2)$$

It is convenient to write the energy conservation law in the form

$$- \frac{\partial}{\partial t} \int u_0 dV = \oint \boldsymbol{\sigma} \cdot d\mathbf{S} + \frac{dW}{dt}. \quad (7.3)$$

In differential form the energy conservation law is expressed by the relation

$$- \frac{\partial}{\partial t} \frac{\epsilon E^2 + \mu H^2}{8\pi} = \mathbf{j} \cdot \mathbf{E} + \nabla \cdot \boldsymbol{\sigma}. \quad (7.4)$$

The interpretation of the conservation law for a medium does not, in principle, differ from that given in ch. 1 for a vacuum. All one should note is the fact that (7.4) contains only the free charge current density \mathbf{j} . As free charges are moving in a conductor at rest the entire mechanical work of the field is transformed completely into heat, called the Joule heat. The mechanism of this process depends on the actual properties of the conductor. We shall touch upon this problem later. Denoting the Joule heat released in unit volume per second by Q_0 equal to

$$Q_0 = \mathbf{j} \cdot \mathbf{E} = j^2/\sigma,$$

we can write the law of energy conservation in the form

$$- \frac{\partial}{\partial t} \int u_0 dV = \int Q_0 dV + \oint \boldsymbol{\sigma} \cdot d\mathbf{S}.$$

The quantities

$$\frac{\epsilon E^2}{8\pi} = \frac{\mathbf{D} \cdot \mathbf{E}}{8\pi} \quad \text{and} \quad \frac{\mu H^2}{8\pi} = \frac{\mathbf{B} \cdot \mathbf{H}}{8\pi}$$

represent respectively the densities of the electric and magnetic energies.

Since, however, the quantities ϵ and μ in matter are functions of temperature (see ch. 6), our overall treatment assumes the constancy of the temperature of the medium. Hence the quantity $(\mathbf{E} \cdot \mathbf{D} + \mathbf{B} \cdot \mathbf{H})/8\pi$ must be interpreted as the free energy per unit volume of the medium.

Electrostatics

§8. The electrostatic field

The equations of the electromagnetic field are greatly simplified in the case of electrostatics.

Assuming that the fields do not depend on time and that the current is equal to zero, one can write Maxwell's equations in the form

$$\nabla \times \mathbf{E} = 0, \quad \nabla \cdot \mathbf{D} = 4\pi\rho, \quad (8.1)$$

$$\nabla \cdot \mathbf{B} = 0, \quad \nabla \times \mathbf{H} = 0. \quad (8.2)$$

We shall not consider constant magnetic fields in matter *.

Eqs. (8.1) and (8.2) determine the electrostatic field in a medium completely.

It should be noted that ρ denotes the mean density of free charges which are introduced into the dielectric from outside. In contrast to conductors, free charges in a dielectric are at rest and fixed in definite positions.

* See I.E. Tamm, *Osnovy teorii elektrichestva (Introduction to the theory of electricity)* (Gostekhizdat, Moscow, 1954).

If a dielectric is placed in an external electric field, the bound charges contained in the molecules, or ions forming the ion lattice, are displaced with respect to each other in such a way that the dielectric becomes polarized. For non-uniform polarization, a bound volume charge arises in the dielectric whose mean density is determined by formula (3.6). We recall that the total bound charge which appears in the polarized dielectric is always equal to zero.

In addition to the volume density of bound charges, a surface charge density $\omega_S = P_n$ arises at the surface of a polarized dielectric.

The field inside a dielectric is, according to (8.1), irrotational. The electrostatic field potential, defined by (6.2), satisfies the equation

$$\nabla \cdot (\epsilon \nabla \varphi) = -4\pi\rho. \quad (8.3)$$

In a homogeneous dielectric $\epsilon = \text{const}$, and the last equation becomes the Poisson equation

$$\nabla^2 \varphi = -4\pi\rho/\epsilon. \quad (8.4)$$

From this equation it follows that for a homogeneous dielectric the potential of the field produced by the free charge volume density ρ can be written in the form

$$\varphi = \frac{1}{\epsilon} \int \frac{\rho \, dV}{r}. \quad (8.5)$$

Formula (8.5) shows that the potential of the field and the field itself in a dielectric medium are decreased by a factor of ϵ in comparison with the field produced by the same charges in vacuum. In particular, the field of a point charge in a dielectric medium is equal to

$$\mathbf{E} = \frac{e\mathbf{R}}{\epsilon R^3}.$$

The corresponding force of interaction of charges according to the Coulomb law is smaller in a homogeneous dielectric medium than in vacuum by a factor ϵ . This result has a simple meaning: the electric field produced by free charges which are put in a dielectric medium gives rise to its polarization. As a result of the polarization the bound charges are displaced and produce in the medium a field which decreases the field of the free charges.

It should be stressed that this refers only to the field of charges which are put inside a homogeneous and isotropic dielectric. From examples which will be discussed below it will be clear that this conclusion is quite inapplicable to an inhomogeneous dielectric.

At the interface of two dielectrics the potential must satisfy the following boundary conditions:

$$\varphi_1 = \varphi_2, \quad (8.6)$$

$$\epsilon_1 \left(\frac{\partial \varphi}{\partial n} \right)_1 = \epsilon_2 \left(\frac{\partial \varphi}{\partial n} \right)_2. \quad (8.7)$$

The first of these is equivalent to (5.2), while the second follows directly from (5.6) if the surface density of free charges is assumed to be $\omega_s = 0$.

Representing the field distribution in an obvious way by means of lines of force, we see from the boundary conditions (8.6) and (8.7) that the lines of force are broken at the interface of two dielectrics and that

$$\frac{\operatorname{tg} \alpha_1}{\operatorname{tg} \alpha_2} = \frac{\epsilon_1}{\epsilon_2}. \quad (8.8)$$

The meaning of the angles α_1 and α_2 is shown in fig. IV.3.

Let us now consider the electrostatic field in conductors. As we have already stressed, a distinctive feature of conductors is the presence of a large number of mobile charges in them. The presence of a mean field \mathbf{E} inside a conductor always produces an electric current in it, representing the motion of free charges under the action of the field. If current is absent in a conduc-

Fig. IV.3

tor, and this is just the requirement of electrostatics, then inevitably the field strength in the conductor is also equal to zero.

$$\mathbf{E} = 0.$$

From the equality of the field to zero in the entire region of space occupied by the conductor it follows that the volume charge density inside the conductor is also equal to zero.

The reduction to zero of the electrostatic field strength vector in the conductor can be presented in the following obvious way. When a conductor is placed in an external field, free charges in it begin to move towards the surface, and this displacement continues until the field of the surface charges completely compensates for the field inside the conductor due to external sources.

The process proceeds as though the conductor possesses an infinitely large polarizability for any value of the field strength or, as is seen from (8.7), an infinitely large dielectric constant $\epsilon_2 \rightarrow \infty$. As is seen from (8.8), the lines of the electrostatic field are normal to the surface of the conductor. Although the identification of the conductor with a dielectric having an infinitely large permittivity has a formal character, the concept of polarization is not applicable to free charges in conductors and is only useful for an obvious interpretation of the relations of electrostatics.

The value of the surface charge density for conductors is obtained from the boundary condition (5.6), if the field strength inside the metal is assumed to be equal to zero. Then we find

$$\omega_S = \epsilon E_n / 4\pi, \quad (8.9)$$

where ϵ is the dielectric constant of the medium surrounding the conductor, and E_n is the normal component of the external field at its surface. The boundary condition (5.2) gives for the tangential component of the external field at the surface of the conductor

$$E_{tg} = 0, \quad (8.10)$$

since in the conductor itself it is equal to zero.

Thus, the field external to the conductor is directed perpendicularly to its surface and $E_n = E$. Formulae (8.9) and (8.10) can be rewritten by introducing the external field potential φ in the form

$$\left. \begin{aligned} \omega_S &= -\frac{\epsilon}{4\pi} \frac{\partial \varphi}{\partial n}, \\ \varphi &= \varphi_m = \text{const} \end{aligned} \right\} \text{ at the surface of the conductor.} \quad (8.11)$$

In particular, if the metal is in vacuum, the value of ϵ must be set equal to unity.

The total charge at the surface of the conductor is

$$e = -\frac{\epsilon}{4\pi} \oint_S \left(\frac{\partial \varphi}{\partial n} \right) dS, \quad (8.12)$$

where the integration is carried out over the entire surface S of the conductor. Formula (8.12) establishes the relation between the surface potential φ_m of the conductor and its charge e . It is easy to verify that this relation has a linear character: if φ is increased by a factor k , then by virtue of (8.12) and the constancy of the potential along the surface of the metal its charge e will increase by the same factor.

The ratio of the charge of a conductor to its potential is called its capacitance:

$$C = \frac{e}{\varphi_m} = \frac{\epsilon}{4\pi} \oint_S \frac{1}{\varphi_m} \left(\frac{\partial \varphi}{\partial n} \right) dS. \quad (8.13)$$

The capacitance is proportional to the dielectric constant ϵ of the medium, and in other respects is determined solely by the form of the conductor.

As is seen from (8.13), the capacitance has the dimensions of length, and in order of magnitude is the same as the linear dimension of the conductor. In the case where there is not one but several conductors in the electrostatic field, the boundary conditions (8.13) must be fulfilled for each of these.

In this case the charges on the conductors and their potentials are not arbitrary. There is a certain relation between them which follows from the uniqueness of the solution of the Laplace equation with boundary conditions of the type (8.11). From the mathematical standpoint finding the influence of one conductor on the others is a complex problem, and we shall not touch upon it *.

* See, for example, W.R.Smythe, *Static and dynamic electricity* (McGraw-Hill, New York, 1950).

§9. The solution of electrostatic problems

We can now formulate the problem of electrostatics in a general way.

Let a system of conductors and dielectrics of different natures be given in a finite region of space. Let the volume charge density ρ at all points of space also be given (in the volume occupied by the conductors $\rho = 0$). Then the equation for the potential has the form

$$\nabla^2 \varphi = -4\pi\rho/\epsilon_i$$

(i corresponds to the medium; in vacuum $\epsilon = 1$).

At the interfaces vacuum–dielectric, vacuum–conductor and dielectric–conductor of the media the system of boundary conditions which have been discussed is fulfilled. The potential at infinity satisfies the condition

$$\varphi \sim O\left(\frac{1}{r^{1+\alpha}}\right) \quad (\alpha > 0). \quad (9.1)$$

We wish to find the potential distribution and electric field distribution over all space. This problem is often called the direct problem of electrostatics. The inverse problem is to find the charge distribution from the known potential distribution. The direct problem of electrostatics is one of the basic problems of mathematical physics. The electrostatic problem can be solved by elementary methods only for particular simple cases. A number of methods for its solution have been devised, and solutions for a great number of actual systems have been calculated. In these an important role is played by approximate and numerical methods. Our purpose does not include the analysis of different cases of electrostatic fields. We shall consider only some simple examples of general interest.

The solution of Poisson's or Laplace's equations for given boundary conditions represents one of the most important problems of mathematical physics.

Standard methods, exact as well as approximate, have been devised for the solution of these problems. The solution of the boundary value problems of electrostatics is of great practical importance, but is of no great interest from the point of view of theoretical physics. Hence, we refer the reader to handbooks of mathematical physics and we shall confine ourselves only to the briefest exposition.

First of all, we point out the existence of two types of boundary conditions. If the region in which the potential is to be found is bounded by

metal conductors at the surface of which the potential (i.e. the function sought for) is defined, then it is said that Dirichlet's boundary conditions are defined. But if the boundary surface is a conductor with a given surface charge density, then according to (8.11) the derivative of the potential with respect to the normal is defined. In this case the boundary conditions are called Neumann's conditions.

The definition of the Laplace (or Poisson) equation together with the boundary conditions at all boundary surfaces and at infinity defines the boundary value problem.

It can easily be shown that the boundary value problem with Dirichlet's or Neumann's conditions has a unique solution.

We shall dwell very briefly on the solution of boundary value problems for Laplace's equation, when volume charges are absent.

There are a number of methods for the solution of such equations. We shall mention only some of these.

If the boundary value problem has a particular simple symmetry, then the Laplace operator is most conveniently written in coordinates which express the symmetry of the system. Thus, for example, to find fields with a spherical or cylindrical symmetry one has to express the Laplace operator in spherical or cylindrical coordinates.

In such cases the variables are separable and the solution of the equation with partial derivatives reduces to the solution of equations in total derivatives. There are eleven different coordinate systems in which the Laplace operator in three dimensions allows one to separate the variables. They are given in the book of P.M.Morse and H.Feshbach *.

As the simplest examples we shall consider the solutions of Laplace's equations in Cartesian coordinates. In these coordinates Laplace's equation has the form:

$$\frac{\partial^2 \varphi}{\partial x^2} + \frac{\partial^2 \varphi}{\partial y^2} + \frac{\partial^2 \varphi}{\partial z^2} = 0. \quad (9.2)$$

Assume that the boundary conditions are given at surfaces which have in Cartesian coordinates a simple form, for example,

* P.M.Morse and H.Feshbach, *Methods of theoretical physics* (McGraw-Hill, New York, 1953).

$$\begin{array}{lll}
 \varphi = \varphi_1(x, y) & \text{for} & z = 0, \quad x, y \leq L, \\
 \varphi \rightarrow 0 & & z \rightarrow \infty, \\
 \varphi = 0 & & x = \pm L, \quad y = \pm L.
 \end{array} \quad (9.3)$$

These conditions mean that at the surface of an open parallelepiped the potential is equal to zero at the lateral walls and is defined at the base.

Then eq. (9.2) is easily solved by the method of separation of variables. We shall seek the solution of (9.2) in the form of the product

$$\varphi = X(x)Y(y)Z(z), \quad (9.4)$$

where X , Y , Z are functions of one variable. The substitution of (9.4) leads to the equation

$$X \frac{d^2 X}{dx^2} + \frac{1}{Y} \frac{d^2 Y}{dy^2} + \frac{1}{Z} \frac{d^2 Z}{dz^2} = 0. \quad (9.5)$$

Since each of the terms depends on its argument the equality (9.5) is fulfilled if they all are equal to constants, i.e.

$$\frac{1}{X} \frac{d^2 X}{dx^2} = -\alpha^2, \quad \frac{1}{Y} \frac{d^2 Y}{dy^2} = -\beta^2, \quad \frac{1}{Z} \frac{d^2 Z}{dz^2} = \gamma^2,$$

$$\alpha^2 + \beta^2 = \gamma^2.$$

Consequently, the solution of (9.4) has the form

$$\varphi = A (\sin \alpha x \sin \beta y) e^{-\gamma z}.$$

The boundary conditions (9.3) are fulfilled if

$$\alpha = \frac{n\pi}{L}, \quad \beta = \frac{m\pi}{L}, \quad \gamma = \frac{\pi}{L} (n^2 + m^2)^{\frac{1}{2}}; \quad n, m = 1, 2, 3, \dots,$$

so that

$$\varphi = \sum A_{nm} \sin\left(\frac{n\pi}{L} x\right) \sin\left(\frac{m\pi}{L} y\right) \exp\left[-\frac{\pi}{L} (n^2 + m^2)^{\frac{1}{2}} z\right]. \quad (9.6)$$

The coefficients A_{nm} must now be chosen in such a way that the following condition be satisfied:

$$\varphi_1(x, y) = \sum A_{nm} \sin\left(\frac{n\pi}{L} x\right) \sin\left(\frac{m\pi}{L} y\right). \quad (9.7)$$

This can always be done, since the sines form a system of orthonormal functions and by multiplying (9.7) through by $\sin(n\pi x/L) \sin(m\pi y/L)$ and integrating with respect to x and y one can write

$$A_{nm} = \frac{1}{L^2} \int_{-L}^{+L} dx \int_{-L}^{+L} \varphi_1(x, y) \sin\left(\frac{n\pi}{L} x\right) \sin\left(\frac{m\pi}{L} y\right) dy.$$

§ 10. The method of images and method of inversion

In solving a number of electrostatic problems it is useful to employ the uniqueness theorem. Indeed, suppose that for a given system we managed to choose potentials or electric fields which satisfy the differential equations and boundary conditions. By virtue of the uniqueness theorem the solution found can be considered as correct irrespective of the way in which it is obtained. As an example we consider the following problem.

Let an infinite plane $x = 0$ be the surface of a metal which occupies a half-space $x < 0$. In vacuum, at a distance a from the metal-vacuum boundary, let there be a charge e . We require to find the field strength over all space. It is obvious that the electric field inside the metal (region $x < 0$) is equal to zero.

Poisson's equation for the potential in the region $x > 0$ has the form

$$\nabla^2 \varphi = -4\pi e \delta(\mathbf{r} - \mathbf{a}). \quad (10.1)$$

The boundary conditions for our problem have the following form:

$$\varphi = 0 \quad \text{as} \quad r \rightarrow \infty.$$

In the plane $x = 0$ the following relations must be satisfied:

$$\left. \begin{aligned} D_n^{(2)} &= D_n^{(1)} + 4\pi\omega_S = 4\pi\omega_S, \\ E_{tg}^{(1)} &= E_{tg}^{(2)}. \end{aligned} \right\} \quad (10.2)$$

Here the fact that $D_n^{(1)} = 0$ in the metal and at its surface is taken into account. The condition for E_{tg} is equivalent to the requirement of the constancy of the potential at the surface of the metal. If we find the electric field outside the metal, then the boundary condition (10.2) will allow us to determine the surface charge.

To obtain the solution we note that eq. (10.1) and the condition of the constancy of the potential at the surface $x = 0$ are satisfied by the field potential of two charges, one of which (e) is located at the point $x = +a$ and the other ($-e$) at the point $x = -a$:

$$\varphi = \frac{e}{r} - \frac{e}{r_1}, \quad (10.3)$$

where r and r_1 are the distances from the charges to the point of observation. By virtue of the uniqueness of the solutions of Maxwell's equations, formula (10.3) gives the distribution to be determined.

The calculation of the gradient of φ allows one to determine the electric field E .

We now pass on to the treatment of the more complex case where the plane $x = 0$ is the interface of two dielectrics. The half-space $x > 0$ and $x < 0$ are occupied by dielectrics with dielectric constants ϵ_1 and ϵ_2 respectively. At the point $x = a$ there is a charge e . We have to find the distribution of the field over all space produced by the charge located at the point $x = a$.

The differential equation for the potential in the region $x > 0$ has the form

$$\nabla^2 \varphi = -\frac{4\pi e}{\epsilon_1} \delta(\mathbf{r}-\mathbf{a}).$$

We assume that there are no free charges at the interface, so that the boundary conditions can be written in the form

$$\varphi = 0 \quad \text{as} \quad r \rightarrow \infty,$$

$$D_n^{(2)} = D_n^{(1)}, \quad (10.4)$$

$$E_{tg}^{(2)} = E_{tg}^{(1)}. \quad (10.5)$$

We shall try to solve this problem by analogy with the preceding one, assuming that the field potential is the same as the potential of the field of equivalent charges at the points $x = a$ and $x = -a$.

We assume that the field in the region $x > 0$ is equivalent to the field of the two charges: charge e located at the point $x = a$ and an unknown charge e_1 located at the point $x = -a$. In this case the field potential in the region $x > 0$ has the form (fig. IV.4)

$$\varphi_1 = \frac{e_1}{r_1} + \frac{e}{\epsilon_1 r} \quad (x > 0). \quad (10.6)$$

Further we assume that the potential in the region $x < 0$ is also represented in the form of the field potential of a point charge

$$\varphi_2 = e_2/r, \quad (10.7)$$

where e_2 is a certain unknown charge located at the point $x = a$.

It is obvious that the potentials φ_1 and φ_2 are the solutions of the equations of electrostatics for the corresponding point charges. The electric fields in the two regions have the form

$$E_1 = \frac{e_1 \mathbf{r}_1}{r_1^3} + \frac{e \mathbf{r}}{\epsilon_1 r^3},$$

$$E_2 = \frac{e_2 \mathbf{r}}{r^3}.$$

Fig. IV.4

Substituting these values into the boundary conditions (10.4) and (10.5), we find

$$\epsilon_2 \frac{e_2(\mathbf{r})_n}{r^3} = \epsilon_1 \left[\frac{e(\mathbf{r})_n}{\epsilon_1 r^3} + \frac{e_1(\mathbf{r}_1)_n}{r_1^3} \right],$$

$$\frac{e_1(\mathbf{r}_1)_{tg}}{r_1^3} + \frac{e(\mathbf{r})_{tg}}{\epsilon_1 r^3} = \frac{e_2(\mathbf{r})_{tg}}{r^3}.$$

Here $(\mathbf{r})_n$, $(\mathbf{r})_{tg}$ and $(\mathbf{r}_1)_n$, $(\mathbf{r}_1)_{tg}$ are respectively the normal and tangential projections of the vectors \mathbf{r} and \mathbf{r}_1 .

In the plane $x = 0$ the following obvious relations hold:

$$|\mathbf{r}| = |\mathbf{r}_1|, \quad (\mathbf{r}_1)_{tg} = (\mathbf{r})_{tg}, \quad (\mathbf{r}_1)_n = -(\mathbf{r})_n.$$

Hence we obtain two equations for the determination of the charges e_1 and e_2 :

$$e_2 = e_1 + (e/\epsilon_1),$$

$$e_1 \epsilon_1 = e - \epsilon_2 e_1,$$

from which it follows that

$$e_2 = \frac{2e}{\epsilon_1 + \epsilon_2},$$

$$e_1 = \frac{(\epsilon_1 - \epsilon_2)e}{\epsilon_1(\epsilon_1 + \epsilon_2)}.$$

Thus, the field potential is expressed by the formulae

$$\varphi = \frac{e}{\epsilon_1 r} + \frac{(\epsilon_1 - \epsilon_2)}{\epsilon_1(\epsilon_1 + \epsilon_2)} \frac{e}{r_1} \quad (x > 0),$$

$$\varphi = \frac{2}{\epsilon_1 + \epsilon_2} \frac{e}{r} \quad (x < 0).$$

The method of images is applied in an analogous way to obtain the solution of problems which are more complex from the geometrical point of view.

Another useful method of solving electrostatic problems is the method of inversion.

If $\varphi(r, \theta, \psi)$ is a potential satisfying the Laplace equation, then a simple calculation shows that the function

$$\varphi_1 = -\frac{R}{r} \varphi\left(\frac{R^2}{r}, \theta, \psi\right),$$

also satisfies this equation. The relation

$$\varphi_1 + \varphi = 0$$

is satisfied on a sphere of radius $r = R$. From the geometrical point of view the transformation $r \rightarrow R^2/r$ represents the mirror reflection in a sphere of radius R .

As a simple example of the application of the method of inversion we give the problem of the potential distribution in a system of a point charge and a grounded sphere of radius R . We assume the potential of the sphere to be equal to zero. If the charge e_1 is located at a distance p_1 from the centre of the sphere, then the potential of the field produced by this charge and by the charge induced on the sphere must be zero at the surface $r = R$. This condition is satisfied by the potential outside the sphere, given by the formula

$$\varphi = \frac{e_1}{r_1} - \frac{e_2}{r_2},$$

if the unknown quantities, the charge e_2 and its position, are chosen properly.

We assume that a fictitious charge is placed at a point a distance p_2 from the centre of the sphere and that

$$p_1 p_2 = R^2.$$

If the absolute value of this charge is equal to

$$e_2 = e_1 (p_1/p_2)^{\frac{1}{2}},$$

then the two charges produce a potential equal to zero at the surface of the sphere. Thus,

$$\varphi = \frac{e_1}{r_1} - \frac{R e_1}{p_2 r_2}.$$

§11. The energy of a system of conductors

We now pass on to the consideration of energy relations in the electrostatic field. The energy relations have their simplest form for conductors.

Since the field does not penetrate inside conductors, their thermodynamic properties do not change. However, the field in the space surrounding a conductor depends on the presence of the conductor, its size and so on.

We shall call the energy of the electromagnetic field surrounding a conductor the electromagnetic energy of the conductor. The total energy of a conductor is equal to the sum of its internal and electromagnetic energies.

We shall only be interested below in the latter, and for brevity we shall speak simply of the energy of the conductor.

We assume first that the conductors are in vacuum. The total energy of the electrostatic field is

$$U = \frac{1}{8\pi} \int E^2 dV.$$

We transform the integral, writing it in the form

$$\begin{aligned} U &= -\frac{1}{8\pi} \int \mathbf{E} \cdot (\nabla \varphi) dV = -\frac{1}{8\pi} \int \nabla \cdot (\varphi \mathbf{E}) dV + \frac{1}{8\pi} \int \varphi (\nabla \cdot \mathbf{E}) dV = \\ &= -\frac{1}{8\pi} \int_{R \rightarrow \infty} \varphi \mathbf{E} \cdot d\mathbf{S} + \frac{1}{8\pi} \sum_i \oint \varphi_i \mathbf{E}_i \cdot d\mathbf{S}_i. \end{aligned}$$

The integration is carried out with respect to all surfaces bounding the integration volume. These are the external surface of radius $R \rightarrow \infty$ and the surfaces of the conductors. Since the external normals of these surfaces are oriented in opposite directions, different signs occur in front of the surface integrals. We have also made use of the fact that in vacuum

$$\nabla \cdot \mathbf{E} = 0.$$

The integral with respect to the infinitely distant surface is equal to zero by virtue of (9.1). At metal surfaces $\varphi_{m_i} = \text{const}$, hence

$$\begin{aligned}
 U &= \frac{1}{8\pi} \sum_i \oint \varphi_i \mathbf{E}_i \cdot d\mathbf{S}_i = \frac{1}{8\pi} \sum_i \varphi_i \oint \mathbf{E}_i \cdot d\mathbf{S}_i = \\
 &= -\frac{1}{8\pi} \sum_i \varphi_{m_i} \oint \left(\frac{\partial \varphi_{m_i}}{\partial n} \right) dS_i = \frac{1}{2} \sum_i e_i \varphi_{m_i}.
 \end{aligned}$$

The energy of a system of conductors is formally the same as the energy of a system of charges.

We now assume that the space between the conductors is filled with a dielectric. Then two cases are, in principle, possible:

(a) the conductors are insulated, so that the charges of all the conductors have a constant value,

(b) the conductors are connected to devices which maintain their potentials constant.

In the first case, as is seen from formula (8.12), we have

$$e = -\frac{1}{4\pi} \oint \frac{\partial \varphi}{\partial n} dS = -\frac{\epsilon}{4\pi} \oint \frac{\partial \varphi'}{\partial n} dS,$$

so that

$$\varphi' = \varphi/\epsilon.$$

Correspondingly

$$U' = \frac{1}{2} \sum_i e_i \varphi_{m_i} = U/\epsilon.$$

The fields and energy are decreased by a factor of ϵ . The energy is used in the work done in filling the space with the dielectric.

In the second case, after filling the interspace with the dielectric the charge of each of the conductors will be equal to

$$e' = \frac{\epsilon}{4\pi} \oint \frac{\partial \varphi}{\partial n} dS = \epsilon e,$$

and the energy to

$$U' = \epsilon U.$$

The increase in the energy and the work done on the dielectric arise from the devices which maintain the potentials of the conductors constant.

§ 12. Dielectrics and conductors in an external electrostatic field

If an uncharged conductor or dielectric is placed in an external field $E_0^{(e)}$, the configuration of the field near the body will change. This change depends essentially on the form of the body and the character of the external field, as is clearly seen from the examples which are discussed below.

We shall consider first the case of a dielectric.

In what follows we shall assume the external field to be uniform over the extent of the body. We indicate by the index i all quantities which refer to the region of space inside the body.

As the simplest examples we shall consider a long cylinder whose axis is oriented along the field and a thin parallel-sided plate situated perpendicularly to the field.

In the first case the polarization of the dielectric will give rise to surface charges at the bases of the cylinder. However, since the length of the cylinder is large, these charges will produce only a weak field which does not distort the field due to external sources inside the cylinder. This is seen from the boundary condition (5.2) which gives

$$E_{tg}^{(i)} = E_{tg}^{(e)}$$

and, since E is, by symmetry, parallel to the axis of the cylinder,

$$E^{(i)} = E_0^{(e)}. \quad (12.1)$$

In the second example, surface charges produce an appreciable weakening of the field inside the plate. The boundary condition (5.7) gives

$$\begin{array}{l} D^{(i)} = E_0^{(e)}, \\ \text{or} \quad E^{(i)} = E_0^{(e)} - 4\pi P. \end{array} \quad (12.2)$$

The field inside the plate is reduced by an amount $4\pi P$. This inference, as is shown by calculation, is preserved qualitatively for bodies of a more complicated form.

As the next example we consider a dielectric sphere placed in a uniform

external field $E_0^{(e)}$. The potential distribution will be determined from the solution of Laplace's equation

$$\nabla^2 \varphi = 0,$$

which satisfies the requirement

$$\varphi = -E_0^{(e)} \cdot \mathbf{r} \quad (12.3)$$

at a large distance from the sphere ($r \gg R$) and satisfies the boundary conditions (8.6) – (8.7) at its surface. We seek the solution in the form

$$\varphi^{(e)} = \varphi_0 + \varphi_1^{(e)}(r, \theta, E_0^{(e)}),$$

where $\varphi_0 = -E_0^{(e)} \cdot \mathbf{r}$, and $\varphi_1^{(e)}$ represents the change in the potential near the sphere.

The function $\varphi_1^{(e)}$ must decrease for $r \gg R$. Since $\varphi_1^{(e)}$ depends only on the vector $E_0^{(e)}$ and on the scalars r and θ and must itself be a scalar, one can write it in the form of a combination of the vectors $E_0^{(e)}$ and \mathbf{r} or $E_0^{(e)}$ and the gradient of r^{-1} . In the first case $\varphi_1^{(e)}$ would not satisfy the requirement of decrease at infinity, so that the only possible form of $\varphi_1^{(e)}$ is the following:

$$\varphi_1^{(e)} = \alpha E_0^{(e)} \cdot (\nabla r^{-1}),$$

where α is a constant. Hence

$$\varphi^{(e)} = -E_0^{(e)} \cdot \mathbf{r} + \alpha E_0^{(e)} \cdot (\nabla r^{-1}). \quad (12.4)$$

On the contrary, inside the sphere the potential $\varphi^{(i)}$ at all points must remain finite and hence must be written in the form

$$\varphi^{(i)} = \beta(E_0^{(e)} \cdot \mathbf{r}). \quad (12.5)$$

It is obvious that both (12.4) and (12.5) satisfy Laplace's equation, and that φ_0 behaves at infinity in accordance with (12.3).

To find the two unknown quantities α and β one can make use of two boundary conditions:

$$\left. \begin{aligned} \varphi^{(i)} &= \varphi^{(e)} , \\ \epsilon^{(i)} \frac{\partial \varphi^{(i)}}{\partial r} &= \epsilon^{(e)} \frac{\partial \varphi^{(e)}}{\partial r} \end{aligned} \right| \quad \text{for } r = R .$$

Elementary calculations, which are most conveniently carried out in spherical coordinates, give

$$\alpha = \frac{\epsilon^{(e)} - \epsilon^{(i)}}{\epsilon^{(i)} + 2\epsilon^{(e)}} R^3 ,$$

$$\beta = - \left(1 - \frac{\epsilon^{(i)} - \epsilon^{(e)}}{\epsilon^{(i)} + 2\epsilon^{(e)}} \right) = - \frac{3\epsilon^{(i)}}{\epsilon^{(i)} + 2\epsilon^{(e)}} ,$$

so that finally

$$\varphi^{(e)} = - (\mathbf{E}_0^{(e)} \cdot \mathbf{r}) + \frac{(\mathbf{P} \cdot \mathbf{r})}{r^3} , \quad (12.6)$$

$$\varphi^{(i)} = - (\mathbf{E}_0^{(e)} \cdot \mathbf{r}) + \frac{4\pi}{3} (\mathbf{P} \cdot \mathbf{r}) , \quad (12.7)$$

where

$$\mathbf{P} = \frac{3}{4\pi} \frac{\epsilon^{(i)} - \epsilon^{(e)}}{\epsilon^{(i)} + 2\epsilon^{(e)}} \mathbf{E}_0^{(e)} , \quad (12.8)$$

$$V = \frac{4\pi}{3} R^3 .$$

In particular, in vacuum $\epsilon^{(e)} = 1$ and

$$\mathbf{P} = \frac{3}{4\pi} \frac{\epsilon^{(i)} - 1}{\epsilon^{(i)} + 2} \mathbf{E}_0^{(e)} = \frac{3\kappa}{\epsilon^{(i)} + 2} \mathbf{E}_0^{(e)} . \quad (12.9)$$

If the susceptibility κ of the body is small, so that $\epsilon^{(i)} \approx 1$, then

$$\mathbf{P} \approx \kappa \mathbf{E}_0^{(e)} .$$

Hence the field strength outside the sphere is

$$\mathbf{E}^{(e)} = -\nabla\varphi^{(e)} = \mathbf{E}_0^{(e)} + V \frac{3\mathbf{r}(\mathbf{P}\cdot\mathbf{r}) - r^2\mathbf{P}}{r^5} \quad (r < R); \quad (12.10)$$

$$\mathbf{E}^{(i)} = -\nabla\varphi^{(i)} = -\frac{4}{3}\pi\mathbf{P} + \mathbf{E}_0^{(e)} \quad (r < R). \quad (12.11)$$

In calculating the gradient according to (1.47) we have taken into account the constancy of the vector \mathbf{P} .

From formulae (12.6) – (12.11) it follows that

(1) in a uniform external field a sphere becomes polarized, acquires a dipole moment $(\mathbf{P}\cdot\mathbf{V})$, and produces an additional field identical with the field of a dipole placed at the centre of the sphere.

(2) inside the sphere the field has a constant value and is weakened by a factor of $3\epsilon^{(i)}/(\epsilon^{(i)}+2\epsilon^{(e)})$ in comparison with the external field.

Let us now consider an uncharged metal sphere placed in a uniform external field E_0 . The field outside the sphere will be found from the solution of Laplace's equation satisfying the condition (12.3) at infinity and the condition

$$\varphi = \varphi_m = 0 \quad (12.12)$$

at the surface of the metal (the potential φ_m can be assumed to be zero).

One can, however, simply assume that in the formulae for $\varphi^{(e)}$, $\mathbf{E}^{(e)}$ and \mathbf{P} , which have been obtained above for a dielectric sphere, the dielectric permittivity inside the sphere $\epsilon^{(i)}$ tends to infinity. One then obtains immediately the expression

$$\varphi^{(e)} = -E_0^{(e)}r \left(1 - \frac{R^3}{r^3}\right) \cos\theta = -\mathbf{E}_0^{(e)}\cdot\mathbf{r} + \frac{(\mathbf{r}\cdot\mathbf{P})}{r^3} V,$$

where it is assumed that

$$\mathbf{P} = \frac{3}{4\pi} \mathbf{E}_0^{(e)}.$$

The field inside the sphere is

$$\mathbf{E}^{(i)} = 0.$$

The surface charge density at the surface of the sphere is equal to

$$\omega_S = -\frac{1}{4\pi} \left(\frac{\partial \varphi}{\partial r} \right)_{r=R}^{(e)} = \frac{3E_0}{4\pi} \cos \theta .$$

The total charge of the uncharged sphere obviously remains equal to zero.

§ 13. The thermodynamic potentials of a dielectric and the dielectric susceptibility

We have seen in the preceding section that the field inside a dielectric is essentially different from the external field, and that the value of the field strength inside the dielectric depends on its shape.

Let a dielectric be placed in an external electric field of strength E_0 . For simplicity we shall restrict ourselves to the case of a uniform and isotropic dielectric. From the statistical point of view a dielectric can be considered as a quasi-closed subsystem placed in an external field of force.

The energy of such a subsystem will differ from the energy of the same subsystem without a field. The field strength is an external parameter with which the energy levels of the system change.

According to the results of § 22 of Part III, the energy of the i th level changes with the change of the parameter according to formula (22.1). In our case the external parameter is the vector E_0 . Hence its change by an amount δE_0 leads to a change in the energy of the i th level by an amount

$$\delta \epsilon_i = - \mathcal{P}_i \delta E_0 , \quad (13.1)$$

where \mathcal{P}_i represents the generalized force corresponding to the external parameter E^* :

$$\mathcal{P}_i = - \partial \epsilon_i / \partial E_0 .$$

Since we shall be interested in mean values, then, averaging (13.1), we have

$$\delta U = \overline{\delta \epsilon_i} = \overline{\mathcal{P}_i} \cdot \delta E_0 = - \overline{\mathcal{P}} \cdot \delta E_0 , \quad (13.2)$$

* The derivative with respect to the vector has the usual meaning of the abbreviated notation of the relations for vector components.

where

$$\mathcal{P} = \overline{\mathcal{P}}_i = -\partial U / \partial E_0 \quad (13.3)$$

and U is the mean energy of the system in the external field (for convenience we do not write the averaging bar and simply drop the index i).

Comparing (13.2) with (17.8) of Part I, it is easily seen that \mathcal{P} represents the mean dipole moment of the entire dielectric.

From the definition of the mean, we find

$$\begin{aligned} \mathcal{P} &= \frac{\sum P_i e^{-\epsilon_i/kT} \Omega(\epsilon_i)}{\sum e^{-\epsilon_i/kT} \Omega(\epsilon_i)} = - \frac{\sum (\partial \epsilon_i / \partial E_0) e^{-\epsilon_i/kT} \Omega(\epsilon_i)}{\sum e^{-\epsilon_i/kT} \Omega(\epsilon_i)} = \\ &= kT \frac{\partial}{\partial E_0} \ln \sum e^{-\epsilon_i/kT} \Omega(\epsilon_i) = kT \frac{\partial \ln Z}{\partial E_0} = - \frac{\partial F}{\partial E_0}, \end{aligned} \quad (13.4)$$

where F is the free energy.

The derivatives with respect to the projections of the external parameter E_0 are taken for constant values of the temperature and all other external parameters characterizing the state of the system. Formula (13.4) shows that the mean dipole moment \mathcal{P} of the body and its polarization $\mathbf{P} = \mathcal{P}/V$ can be calculated if the partition function of the system and its dependence on the strength of the external field are known. On the basis of (13.4) we can establish the relation between the change in the free energy with the field, dF , and without the field, dF_0 , in the form

$$dF = dF_0 - \mathcal{P} \cdot dE_0. \quad (13.5)$$

Integrating (13.5), we find

$$F = F_0 - \int \mathcal{P} \cdot dE_0 = F_0 - V \int \mathbf{P} \cdot d\mathbf{E}_0 = F_0 - \frac{1}{2} (\mathbf{P} \cdot \mathbf{E}_0) V. \quad (13.6)$$

We have assumed that in a uniform field and uniform dielectric medium the polarization vector $\mathbf{P} \sim \mathbf{E}_0$. This always holds for uniformly polarized bodies (in particular, bodies of ellipsoidal form).

The polarization \mathbf{P} of the body is connected with the field \mathbf{E} by the relation (3.7). Generally speaking, the field \mathbf{E} differs from the external field \mathbf{E}_0 ,

since the dielectric distorts the external field in the space surrounding it. If, however, its dielectric constant ϵ is close to unity, then $\mathbf{E}_0 \approx \mathbf{E}$ and $\mathbf{P} = \kappa \mathbf{E} \approx \kappa \mathbf{E}_0$, and

$$dF = dF_0 - V\mathbf{P} \cdot d\mathbf{E}, \quad (13.7)$$

or

$$F = F_0 - \frac{1}{2}\kappa V E^2 = F_0 - \frac{1}{2}(\mathbf{P} \cdot \mathbf{E}) V. \quad (13.8)$$

As well as the free energy F of a dielectric in an external field one often considers the total free energy of the dielectric allowing for its potential energy in the external field

$$dF' = dF_0 + V\mathbf{E}_0 \cdot d\mathbf{P} = dF_0 + V\mathbf{E} \cdot d\mathbf{P}, \quad (13.9)$$

$$F' = F_0 + V\mathbf{P} \cdot \mathbf{E}_0. \quad (13.10)$$

Sometimes free energy is used for the quantity

$$F'' = F' + \frac{E_0^2 V}{8\pi} = F_0 + \frac{E_0^2 V}{8\pi} + V\mathbf{P} \cdot \mathbf{E}_0, \quad (13.11)$$

which represents the free energy of the dielectric (allowing for its potential energy in the external field) plus the energy of the external electric field in the volume occupied by the dielectric.

Making use of (13.8), it can easily be shown that

$$\begin{aligned} dF'' &= dF_0 + V\mathbf{E} \cdot d\mathbf{P} + \frac{1}{4\pi} V\mathbf{E} \cdot d\mathbf{E} = \\ &= dF_0 + V\mathbf{E} \cdot \left(d\mathbf{P} + \frac{d\mathbf{E}}{4\pi} \right) = dF_0 + \frac{V\mathbf{E}}{4\pi} \cdot d\mathbf{D}. \end{aligned} \quad (13.12)$$

Thus, F'' represents the energy of the dielectric without field plus the energy of the field in the volume occupied by the dielectric.

It follows from (13.12) that

$$E_i = \frac{4\pi}{V} \frac{\partial F''}{\partial D_i}, \quad (13.13a)$$

$$\frac{\partial E_i}{\partial D_k} = \frac{4\pi}{V} \frac{\partial^2 F''}{\partial D_i \partial D_k} \quad (13.13b)$$

In an anisotropic medium the relation between \mathbf{D} and \mathbf{E} is given by formula (6.1) which we shall write in the form

$$E_i = \epsilon_{ik}^{-1} D_k,$$

where ϵ_{ik}^{-1} is the tensor inverse to ϵ_{ik} . Then (13.13) gives

$$\frac{V}{4\pi} \epsilon_{ik}^{-1} = \frac{\partial^2 F''}{\partial D_i \partial D_k} = \frac{\partial^2 F''}{\partial D_k \partial D_i} = \frac{V}{4\pi} \epsilon_{ki}^{-1}.$$

Thus ϵ_{ik} is a symmetric tensor.

For practical purposes it is convenient to use the thermodynamic potential instead of the free energy. Then instead of (13.8) we obtain

$$G = G_0 - \frac{1}{2}(\mathbf{P} \cdot \mathbf{E}_0) V. \quad (13.14)$$

The volume of the dielectric in the field is

$$V = \left(\frac{\partial G}{\partial p} \right)_T = V_0 - \frac{\mathbf{E}_0}{2} \cdot \left(\frac{\partial(\mathbf{P}V)}{\partial p} \right)_T.$$

The change in the volume of the dielectric when the external field is applied isothermally is called electrostriction. As can be seen from the last formula, the sign and magnitude of the effect depend on the polarizability of the body as well as on its compressibility.

When the field is applied, a change in the entropy of the dielectric occurs in addition to the change in the volume. Namely:

$$S = - \left(\frac{\partial G}{\partial T} \right)_p = S_0 + \frac{\mathbf{E}_0}{2} \cdot \left(\frac{\partial(\mathbf{P}V)}{\partial T} \right)_p. \quad (13.15)$$

The change in the entropy when the field is applied isothermally is accompanied by the release of heat $Q = T\Delta S$ (the so-called electro-caloric effect at constant pressure). When the field is applied adiabatically, a change in the temperature of the dielectric occurs.

As an example we shall find the electrostriction and electro-caloric effect for a sphere in a uniform field.

According to (12.9) we have

$$G = G_0 - \frac{1}{2}(\mathbf{P} \cdot \mathbf{E}_0) \quad V \approx G_0 - \frac{3}{8\pi} \frac{\epsilon_1 - 1}{\epsilon_1 + 2} V E_0^2,$$

whence

$$V = \left(\frac{\partial G}{\partial p} \right)_T = V_0 - \frac{3}{8\pi} \frac{\epsilon_1 - 1}{\epsilon_1 + 2} E_0^2 \left(\frac{\partial V}{\partial p} \right)_T - \frac{9E_0^2 V}{8\pi} \frac{1}{(\epsilon_1 + 2)^2} \left(\frac{\partial \epsilon_1}{\partial p} \right)_T. \quad (13.16)$$

Analogously

$$Q = T\Delta S = \frac{3TE_0^2}{8\pi} \frac{\epsilon_1 - 1}{\epsilon_2 + 2} \left(\frac{\partial V}{\partial T} \right)_p + \frac{9TE_0^2 V}{8\pi} \frac{1}{(\epsilon_1 + 2)^2} \left(\frac{\partial \epsilon_1}{\partial T} \right)_p. \quad (13.17)$$

It is easily shown that if ϵ decreases with increasing temperature (as is the case for most substances), $Q < 0$, i.e. as the polarization increases heat is released.

The next problem which naturally arises is the calculation of the electric susceptibility κ of the dielectric.

In contrast to the preceding relations which have a very general character and do not require the knowledge of the actual form of the partition function Z , to find the electric susceptibility it is necessary to obtain the partition function for the body.

Let us first consider the electric susceptibility of ideal gases. To find the value of the susceptibility per molecule it is necessary to find the corresponding partition function of the molecule in the electric field. One has to distinguish between two cases:

- (a) the molecules possess an intrinsic constant dipole moment,
- (b) the molecules possess no intrinsic dipole moment.

The dipole moment is defined by the expression

$$\mathbf{d} = \sum e_i \mathbf{r}_i,$$

where the summation is carried out over all charges in the molecule. In atoms and molecules of symmetric form positive and negative charges are distributed symmetrically. Because of this the summation over the negative and positive charges gives zero. All atoms and such symmetric molecules as H_2 , O_2 , CH_4 etc. have no intrinsic dipole moment. On the contrary, for strongly asym-

metric molecules, for example molecules made up of two different ions, such as HCl, HBr and so on, or molecules having an asymmetric form, such as CH_3Cl , CH_3COOH , H_2O , the dipole moment is different from zero. Such molecules are called polar molecules.

Let us first consider the properties of a gas with polar molecules having an intrinsic moment \mathbf{d}_0 . If $\epsilon^{(0)}$ is the energy of the molecule in the absence of a field, then, when it is placed in an electric field of strength \mathbf{E} , its energy will be equal to

$$\epsilon = \epsilon^{(0)} - \mathbf{d}_0 \cdot \mathbf{E} = \epsilon^{(0)} - d_0 |\mathbf{E}| \cos \theta, \quad (13.18)$$

where θ is the angle between the direction of the applied field and the axis of the molecule.

From formula (13.18) it follows that the change in the energy of a polar molecule in an electric field leads to the appearance of a potential energy equal to $(-d_0 |\mathbf{E}| \cos \theta)$ for the molecule. This energy in a uniform electric field does not depend on the position of the molecule and is determined solely by its orientation. The potential energy has a minimum value for a molecule oriented along the field, and a maximum value for a molecule oriented in the opposite direction. In the absence of a field, molecules are oriented completely at random; all orientations are equally probable. The electric field has an orienting effect and tends to arrange all the molecular dipoles along the field, where their potential energy is a minimum. The orientation of molecules along the field becomes more probable than against the field. The extent to which the field manages to orient all the dipoles is determined by the ratio of the energy $\mathbf{d}_0 \cdot \mathbf{E}$ acquired by the dipole molecules in the electric field to their thermal energy kT . If the latter is large, i.e. if $kT \gg \mathbf{d}_0 \cdot \mathbf{E}$, then the orienting effect of the field is relatively weak. On the contrary, if $kT \ll \mathbf{d}_0 \cdot \mathbf{E}$ all the dipoles will be oriented along the field.

The values of the dipole moments of the molecules of certain gases are given in table 1. In order of magnitude they are equal to the product of the charge of the electron and the size of the molecule.

Table 1

Gas	HCl	HBr	H ₂ O	SO ₂	CO ₂	CO	CHCl ₃	CH ₂ Cl ₂	CH ₃ Cl
Dipole moment (10^{-18} esu·cm)	1.03	0.79	1.84	1.61	0.00	0.12	0.95	1.59	1.89

By means of the data of table 1 the order of magnitude of $\mathbf{d}_0 \cdot \mathbf{E}/kT$ can be estimated. Because of the smallness of the dipole moment \mathbf{d}_0 it turns out that this quantity is very small for all temperatures at which the gases are still not condensed and in all practically attainable fields. In order that $\mathbf{d}_0 \cdot \mathbf{E}$ may be of the order of magnitude of kT it is necessary that $|\mathbf{E}|$ be of the order of magnitude of $kT/d_0 \approx 10^4 T$ V/cm. For $T \approx 300$ K we obtain $|\mathbf{E}| \approx 3 \times 10^6$ V/cm, which is obviously impractical. Thus, the orienting effect of the field is weak. Nevertheless, the appearance of a preferential orientation of molecular dipoles gives rise to a mean dipole moment \mathcal{P} of the entire gas different from zero.

We shall calculate the mean dipole moment of the gas according to formula (13.4). In this case, since the ratio $(\mathbf{d}_0 \cdot \mathbf{E})/kT$ is very small, the temperature can practically always be considered as high and the summation can be replaced by integration. The partition function of a gas of dipole molecules in an electric field has the form

$$Z = Z_0 \left(\int_0^\pi \exp \left(\frac{d_0 |\mathbf{E}| \cos \theta}{kT} \right) \sin \theta \, d\theta \int_0^{2\pi} d\varphi \right)^N. \quad (13.19)$$

Here N is the number of molecules in the gas, and Z_0 denotes the partition function of the gas in the absence of a field. The integration is carried out with respect to all states of the molecule, which are determined by the angles θ, φ . Since $d_0 |\mathbf{E}|/kT \ll 1$, we have

$$\begin{aligned} \int_0^\pi \exp \left(\frac{d_0 |\mathbf{E}| \cos \theta}{kT} \right) \sin \theta \, d\theta &\approx \\ &\approx \int_0^\pi \left\{ 1 + \frac{d_0 |\mathbf{E}|}{kT} \cos \theta + \left(\frac{d_0 |\mathbf{E}|}{kT} \right)^2 \frac{\cos^2 \theta}{2} \right\} \sin \theta \, d\theta = 2 + \frac{1}{3} \left(\frac{d_0 |\mathbf{E}|}{kT} \right)^2, \end{aligned}$$

so that

$$Z = Z_0 (4\pi)^N \left\{ 1 + \frac{1}{6} \left(\frac{d_0 |\mathbf{E}|}{kT} \right)^2 \right\}^N$$

On taking the logarithm we have

$$\ln Z \approx \ln Z_0 + N \ln 4\pi + \frac{N}{6} \left(\frac{d_0 |\mathbf{E}|}{kT} \right)^2. \quad (13.20)$$

Substituting (13.20) into (13.4), we find

$$\mathcal{P} = \frac{Nd_0^2|\mathbf{E}|}{3kT}. \quad (13.21)$$

This formula has a very simple meaning. If it is written in the form of the product of two factors

$$\mathcal{P} = \frac{d_0|\mathbf{E}|}{3kT} (d_0N),$$

then it is clear that the first factor characterizes the degree of orientation of the molecular dipoles, which is higher the stronger the applied field $|\mathbf{E}|$, and lower the stronger the disorienting effect of the thermal motion which is characterized by the value of kT . The second factor is the total dipole moment of the molecules in the gas. If all the dipoles were oriented along the field, the resulting polarization of the gas would be equal to d_0N . In the presence of thermal motion the polarization represents only a small fraction of this limiting polarization. One can picture the smallness of the orientation factor $d_0|\mathbf{E}|/kT$ in an obvious way as follows. Most of the polar molecules are moving and, in particular, are rotating in the gas with an energy which is considerably larger than the potential energy in the field d_0E . Hence the applied field cannot stop their rotation. As the molecules are rotating the dipole moment is averaged over all directions, and the mean contribution of a rotating molecule to the total dipole moment of the gas turns out to be equal to zero. However, there is in the gas a small percentage of molecules for which the kinetic energy of rotary motion is smaller than d_0E . Such molecules cannot be oriented against the field, and in the field their rotary motion is replaced by torsional oscillations about the direction of the field. It is only these molecules which contribute to the mean dipole moment of the gas.

From (13.21) one can find the electric susceptibility of a polar gas related to unit volume:

$$\kappa = \frac{\mathcal{P}}{|\mathbf{E}|V} = \frac{Nd_0^2}{3VkT}. \quad (13.22)$$

Formula (13.22) is called the Langevin formula, since it was first obtained by Langevin.

The electric susceptibility of the gas is connected with the directly measured dielectric constant by the relation (4.14):

$$\epsilon = 1 + 4\pi\kappa.$$

From the measurements of ϵ as a function of the temperature one can find the dipole moment d_0 of the molecules. The values of d_0 found in such a way are given in table 1. Their numerical value is small in comparison with unity, so that in gases ϵ is always of the order of unity.

The dipole moment is an important characteristic of molecules. In particular, it allows one to estimate the structure and geometrical form of the molecules. The more asymmetric the molecule, the larger is its dipole moment. This is seen, in particular, in the example of the molecules CCl_4 , CHCl_3 , CH_2Cl_2 , CH_3Cl and CH_4 , whose susceptibilities are shown in fig. IV.5. The value of d_0^2 is determined from the slope of the corresponding straight line.

Carbon tetrachloride and methane are symmetric molecules having the form of a tetrahedron; their dipole moments are nearly equal to zero. The slope of the corresponding straight line is connected with the induced dipole moment. For the chlorine derivatives of methane, which represent asymmetric molecules, the dipole moments differ from zero. The largest value occurs for the asymmetric molecule CH_3Cl .

The behaviour of molecules which possess no intrinsic dipole moment is of less interest. Under the action of an applied electric field they become polarized. The electron shells of the atoms or molecules are displaced with

Fig. IV.5

respect to the nuclei, and an induced dipole moment arises in them. The value of the induced dipole moment is proportional to the strength of the applied field, so that

$$\mathbf{d} = \alpha \mathbf{E}$$

and the energy is

$$\epsilon = \epsilon^{(0)} - \frac{1}{2} \alpha |\mathbf{E}|^2. \quad (13.23)$$

Hence

$$Z = Z_0 \exp\left(\frac{N\alpha |\mathbf{E}|^2}{2kT}\right)$$

and

$$P = N\alpha |\mathbf{E}|. \quad (13.24)$$

The polarization turns out to be independent of the temperature. In other words, the thermal motion has no effect on the polarization of the electron shells of atoms and molecules.

The theory given here is valid only for very rarefied gases. For more dense gases and particularly for liquids the interaction between molecules plays an essential role in their electric properties. In such systems one can no longer consider the orienting effect of the field on an individual dipole. The orientation of the dipoles will be determined not only by the external but also by the internal electric field which is produced by all the polar molecules.

The theory of polar liquids turns out to be very complex, and we cannot develop it here. We note only that in this field things are not as clear as in the case of rarefied gases.

The dielectric polarization of most solid dielectrics is due to the induced polarization of the molecules of the dielectric. Even in crystals made up of polar molecules no orientation polarization occurs, since the molecules in the crystal interact strongly with their neighbours and the electric field is too weak to overcome the forces of interaction and to turn the molecules. One of a few typical exceptions is the solid HCl. The measurements of I.V. Kurchatov have shown that the molecules of HCl are turned under the action of an electric field and an orientation polarization takes place in the crystal. The values of the susceptibility and dielectric constant for solid dielectrics are

much larger than for gases. The dielectric constants of solid dielectrics have values several times unity, and in a number of cases reach as much as 100.

In view of the large value of the dielectric constant in a dense medium it is necessary to take into account that a molecule in the medium is acted upon not by the external field E_0 but by the effective internal field made up of the external field and the field which arises in the medium because of the polarization of its molecules.

The dielectric constant of solid dielectrics varies relatively weakly with the temperature. This means that the dielectric properties of solid bodies are associated with the change of the charge distribution inside the molecules but do not depend on their thermal motion.

Direct Electric Current and the Magnetic Properties of Matter

§ 14. Ohm's law

Having considered the basic properties of the electrostatic field of charges at rest, we can pass on to the study of the more complex case of the electromagnetic field arising when there is a steady motion of free charges, i.e. in the presence of a current in conductors constant in time. This problem has two aspects which are to a considerable degree independent:

- (1) to find the electromagnetic field of direct currents,
- (2) the consideration of the mechanism of passage of the current in different media, i.e. the mechanism of electrical conductivity.

Without going into a study of the mechanism of electrical conductivity, we shall restrict ourselves to the assumption that the current density in a homogeneous conductor is related to the field strength by Ohm's law ($\mathbf{j} = \sigma \mathbf{E}$).

The value of the electrical conductivity σ is closely associated with the mechanism of the passage of the current and varies over a very wide range for different conductors.

In Part V we shall consider the microscopic meaning of the electrical conductivity and shall estimate its value for some important conductors.

We shall further assume that the constancy of the electric current in time is maintained by devices called current sources. Examples of such sources are

constant-current generators of various types, i.e. galvanic cells, accumulators, thermocouples etc. Indeed, it is physically obvious that no combination of charged or neutral conductors can ensure the passage of a constant current in a system. By bringing conductors at different potentials into contact we can cause a transient motion of free charges which will continue until the potentials of all the conductors become the same.

The sources of a constant electric current must always have a non-electrostatic character. They can, for example, have an electrochemical character. In what follows we shall not go into details of the current sources. For us, only the fact that the current sources ensure the maintainance of a constant current is of importance.

Formally, without considering the mechanism of the current sources, we can include them in the composition of the system of conductors considered by changing the form of Ohm's law. That is, observing that the current sources produce a current in the conductors independent of the direct action of the electric field, we write Ohm's law in the generalized form

$$\mathbf{j} = \sigma(\mathbf{E} + \mathbf{E}^{\text{imp}}). \quad (14.1)$$

The vector \mathbf{E}^{imp} (where imp stands for "impressed"), which depends on the coordinates, formally characterizes the action of the current sources. In those parts of the conductor where the current source acts, for $\mathbf{E} = 0$, $\mathbf{j} \neq 0$. Thus, for example, if the system is made up of a conductor connected to the plates of a galvanic cell, then in the region of space occupied by the cell $\mathbf{E}^{\text{imp}} \neq 0$. The processes occurring inside the galvanic cell make it possible to maintain its plates, which are connected to the conductor, at different potentials. This in its turn ensures the existence of an electric field constant in time inside the cell and, in correspondence with Ohm's law, the existence of a constant current in the conductor.

The quantity \mathbf{E}^{imp} is for historical reasons called, not quite correctly, the impressed electromotive force (\mathbf{E}^{imp} does not have the dimensions of a force and is not, in essence, the analogue of a force). The electromotive force is a quantitative characteristic of the device which maintains the passage of a constant current in conductors. We shall return to the interpretation of the notation of the electromotive force in later sections.

Maxwell's equations for a constant current in the presence of electromotive forces has the form

$$\left. \begin{aligned} \nabla \times \mathbf{E} &= 0, \\ \nabla \cdot \mathbf{D} &= 4\pi\rho; \end{aligned} \right\} \quad (14.2)$$

$$\left. \begin{aligned} \nabla \times \mathbf{H} &= \frac{4\pi}{c} \mathbf{j}, \\ \nabla \cdot \mathbf{B} &= 0. \end{aligned} \right| \quad (14.3)$$

The equation of continuity for the passage of steady currents can be written in the form

$$\nabla \cdot \mathbf{j} = 0. \quad (14.4)$$

It is easily seen that the system of equations written above is complete. We see, first of all, that the electric field distribution does not depend on the magnetic field distribution. The latter is determined by defining the current density \mathbf{j} over all space.

At the interface of conducting media the following boundary conditions must be fulfilled:

$$E_{\text{tg}}^{(1)} = E_{\text{tg}}^{(2)}, \quad (14.5)$$

or

$$\frac{j_{\text{tg}}^{(1)}}{\sigma^{(1)}} = \frac{j_{\text{tg}}^{(2)}}{\sigma^{(2)}} \quad (14.6)$$

and

$$j_n^{(1)} = j_n^{(2)}. \quad (14.7)$$

The first of these is the same as (5.2), and the second is obtained from the equation of continuity in the same way as, for example, the condition (5.5).

The boundary conditions (14.6) – (14.7) can be interpreted in an obvious way as the refraction of lines of flow at the interface according to the law

$$\frac{\text{tg } \alpha_1}{\text{tg } \alpha_2} = \frac{\sigma^{(1)}}{\sigma^{(2)}}, \quad (14.8)$$

where α is the angle between the line of flow and the normal to the surface in the corresponding media.

At the interface conductor–dielectric the following boundary condition is satisfied:

$$j_n = 0. \quad (14.9)$$

Magnetic vectors satisfy the boundary conditions which have been considered in § 5.

§ 15. A linear conductor carrying a constant current

We shall first consider the very important case of a linear conductor with constant current. By a linear conductor we shall mean one whose length is very large compared with its transverse dimensions. Linear conductors are also often called wires. The current density vector in a linear conductor can, by virtue of the boundary condition (14.9) at its surface, be considered with a high degree of accuracy to be parallel to the vector $d\mathbf{l}$ which is tangential to the axis of the conductor. Thus, for each point of a linear conductor one can write

$$\mathbf{j} d\mathbf{l} = j d\mathbf{l}. \quad (15.1)$$

We bring into consideration the total current I flowing through the cross-section of the linear conductor normal to the axis of the conductor (or, what is the same, normal to the flow lines). By definition

$$I = \int \mathbf{j} \cdot d\mathbf{S} = \int \sigma(\mathbf{E} + \mathbf{E}^{\text{imp}}) \cdot d\mathbf{S}, \quad (15.2)$$

where the integration is carried out over a cross-section of the contour carrying the current.

From the equation of continuity (14.4) and the boundary condition one can write

$$\oint \mathbf{j} \cdot d\mathbf{S} = 0,$$

or

$$I = \int \mathbf{j} \cdot d\mathbf{S} = jS = \text{const}, \quad (15.3)$$

where S is the cross-section of the conductor at a given position.

The equation of continuity in integral form shows that the same current I flows through any section of the linear conductor.

We integrate the formula of the generalized Ohm's law (14.1) along the conductor carrying the current. We have

$$\int_1^2 \mathbf{j} \cdot \frac{d\mathbf{l}}{\sigma} = \int_1^2 \mathbf{E} \cdot d\mathbf{l} + \int_1^2 \mathbf{E}^{\text{imp}} \cdot d\mathbf{l}.$$

We transform the first integral, writing

$$\int_1^2 \mathbf{j} \cdot \frac{d\mathbf{l}}{\sigma} = \int_1^2 j \frac{dS}{\sigma S} = I \int_1^2 \frac{dl}{\sigma S} = IR_{12}, \quad (15.4)$$

where R_{12} represents the ohmic resistance of the conductor along the segment (1, 2). Then we have

$$IR_{12} = \varphi_1 - \varphi_2 + \mathcal{E}_{12}^{\text{imp}}, \quad (15.5)$$

where $\varphi_1 - \varphi_2$ is the potential difference between the points 1 and 2, and

$$\mathcal{E}_{12}^{\text{imp}} = \int_1^2 \mathbf{E}^{\text{imp}} \cdot d\mathbf{l} \quad (15.6)$$

is called the impressed electromotive force (e.m.f.) over the segment (1, 2).

If there is no electromotive force in a given segment of the conductor, i.e. $\mathbf{E}^{\text{imp}} = 0$ then (15.5) goes over into the simple Ohm's law.

If the path is closed and the points 1 and 2 coincide, since by virtue of (14.2) the field \mathbf{E} has the character of potential, the integral $\oint \mathbf{E} \cdot d\mathbf{l} = 0$ and

$$IR = \mathcal{E}^{\text{imp}}, \quad (15.7)$$

where R is the resistance of the entire linear contour and

$$\mathcal{E}^{\text{imp}} = \oint \mathbf{E}^{\text{imp}} \cdot d\mathbf{l}. \quad (15.8)$$

The product of the current and the resistance of the current carrying filament is equal to the e.m.f. round the closed circuit.

Let us now consider the energy relations for a current carrying filament.

As we have stressed, the entire work done by the current in a direct current circuit goes into heat. Hence the total heat released in the linear conductor is

$$\begin{aligned}
 Q &= \frac{j^2}{\sigma} dV = \int j \cdot (E + E^{\text{imp}}) dV = \\
 &= - \int j \cdot \nabla \varphi dV + \int j \cdot E^{\text{imp}} dV = \\
 &= \int j \cdot E^{\text{imp}} dV - \int (\nabla \cdot j \varphi) dV + \int \varphi (\nabla \cdot j) dV = \\
 &= \int j \cdot E^{\text{imp}} dV - \oint \varphi j_n dS = \int j \cdot E^{\text{imp}} dV
 \end{aligned}$$

by virtue of (14.2), (14.4) and (14.9).

The total heat released in the circuit turns out to be equal to the work done by the electromotive forces.

§ 16. Direct current in a conducting medium

Another limiting case is the passage of current in a system of good conductors (for example, metal electrodes) immersed into a conducting medium. If it is assumed that electromotive forces are absent in the conducting medium, the equations for the electric field can be written in the form

$$\nabla \times E = 0,$$

$$\nabla \cdot j = \nabla \cdot \sigma E = 0.$$

In a homogeneous medium, for $\sigma = \text{const}$, the last expression assumes the form

$$\nabla \cdot E = 0.$$

Introducing the field potential φ , we find that it satisfies the equation

$$\nabla^2 \varphi = 0. \quad (16.1)$$

At the surface of the conductors the boundary conditions (14.5) and (14.7) are satisfied. They can be written in terms of the potential φ . The condition (14.5) for the continuity of the tangential component of the field goes over directly into the condition of the continuity of the potential at the interface:

$$\varphi_1 = \varphi_2 . \quad (16.2)$$

The equality of the normal components of the current density $j_n = \sigma E_n$ gives

$$\sigma^{(1)} \left(\frac{\partial \varphi}{\partial n} \right)_1 = \sigma^{(2)} \left(\frac{\partial \varphi}{\partial n} \right)_2 , \quad (16.3)$$

where n is the normal to the interface.

We see that the equation for the potential and the whole set of boundary conditions, which determine the current distribution in a conducting medium, are identical with the corresponding expressions of §8 which determine the electrostatic field distribution in two dielectric media. The only difference lies in the fact that the electric conductivities $\sigma^{(1)}$ and $\sigma^{(2)}$ of the media appear in the boundary condition (16.3) instead of the dielectric constants ϵ_1 and ϵ_2 .

Hence the potential in a conducting medium is determined by the formulae of electrostatics with the substitution of σ for ϵ .

Let us consider the case of two electrodes in an infinite medium. We write the current flowing from an electrode in the form

$$I = \oint \mathbf{j} \cdot d\mathbf{S} = \oint j_n dS = \sigma \oint \left(\frac{\partial \varphi}{\partial n} \right)_S dS .$$

Introducing the electrostatic capacitance according to formula (8.13), we find

$$I = \frac{4\pi\sigma}{\epsilon_1} \left[\frac{\epsilon_1}{4\pi} \oint \left(\frac{\partial \varphi}{\partial n} \right)_S dS \right] = \frac{4\pi\sigma}{\epsilon_1} C\varphi_1 .$$

The resistance is equal to

$$R = \frac{\varphi_1 - \varphi_2}{I} = \frac{\varphi_1}{I} = \frac{\epsilon_1}{4\pi\sigma} \frac{1}{C} . \quad (16.4)$$

This last formula allows one to express the resistance of the system formally in terms of the capacities of an electrostatic system of conductors with analogous geometric characteristics.

As an example a system of two spherical electrodes immersed into an infinite medium can be considered. We assume that the radii of the electrodes a and b are small in comparison to the distance between their centres.

The solution of Laplace's equation for the two spheres has the form

$$\varphi = \frac{a}{r_1} \varphi_a - \frac{b}{r_2} \varphi_b,$$

where φ_a and φ_b are the potentials at the surfaces of the spheres, and r_1 and r_2 are the distances to the centres of the spheres.

The total current from the surface of the first sphere is equal to

$$I = \oint \sigma \left(\frac{\partial \varphi}{\partial r} \right)_{r=a} dS \approx 4\pi a \sigma \varphi_a,$$

if the second term of φ , which for $r = a$ is small in comparison with the first term, is disregarded. Analogously, the total current to the second sphere turns out to be equal to

$$I = -4\pi b \sigma \varphi_b.$$

The resistance is

$$R = \frac{\varphi_a - \varphi_b}{I} \approx \frac{1}{4\pi\sigma} \left(\frac{1}{a} + \frac{1}{b} \right).$$

Thus the solution of the problem of the spatial current distribution reduces to the solution of the corresponding electrostatic problem.

However, an important reservation should be made. If the conductor is partially contiguous to a conducting medium and partially to a non-conducting medium, the formal analogy with electrostatics is meaningless. Indeed, in a non-conducting medium $\sigma = 0$, whereas in electrostatics there are no bodies with a dielectric constant equal to zero.

We shall find one more useful relation between the current density and total current in a conductor in the general case. Let the current density flowing along a conductor be distributed non-uniformly over the cross-section. We divide the conductor into arbitrarily fine current tubes. The solenoidal character of direct current always allows one to make such a division. Each current tube can be considered a linear conductor, and we can write

$$dI = \mathbf{j}_\alpha \cdot d\mathbf{S}_\alpha, \quad (16.5)$$

where the index α denotes the ordinal number of the tube.

This equation has a simple meaning: although the current density distribution is determined by the physical properties of the conductor and by its geometry, the current density is proportional to the total current, other things being equal.

If the current density were distributed uniformly over the cross-section, one could obviously write

$$\frac{dI_\alpha}{I} = \frac{dS_\alpha}{S}, \quad (16.6)$$

where I and S are the total current and the cross-section of the conductor respectively. For a non-uniform current distribution one can always assume that

$$\frac{dI_\alpha}{I} = \frac{dS_\alpha}{S} \psi = \text{const} \quad (\text{along the length of the conductor}), \quad (16.7)$$

where the function ψ characterizes the non-uniformity of the current distribution. Hence for any current distribution we have

$$\mathbf{j} = I \frac{\psi}{S} \mathbf{l}, \quad (16.8)$$

where \mathbf{l} is the unit vector directed along the flow line.

§ 17. The magnetic fields of direct currents. The Biot—Savart law

Knowing the current density distribution one can find the magnetic field distribution by integrating eqs. (14.3). Introducing the vector potential A into (14.3), according to formula (4.19) we obtain the equation

$$\nabla \times \left(\frac{1}{\mu} \nabla \times A \right) = \frac{4\pi}{c} \mathbf{j}. \quad (17.1)$$

For an infinite homogeneous and isotropic medium characterized by a constant magnetic permeability μ one can write

$$\nabla^2 A = - \frac{4\pi\mu}{c} \mathbf{j}. \quad (17.2)$$

The solution of this last equation

$$\mathbf{A} = \frac{\mu}{c} \int \mathbf{j} \frac{dV}{r} \quad (17.3)$$

differs only by the factor μ from the solution of eq. (19.13) of Part I for the vector potential in vacuum.

Since outside the conductors the current density \mathbf{j} is equal to zero, the integration can actually be carried out only with respect to the volume of the conductors. However, we assume that μ has one and the same value both in the conductors and in the medium which surrounds them. If the system contains no ferromagnetic bodies, then the actual value of μ differs little from unity. Hence μ can be assumed to have approximately the same value over all space. In the presence of ferromagnetics the formula (17.3) becomes meaningless.

For linear conductors one can essentially simplify formula (17.3), writing, by virtue of the constancy of the total current I over the cross-section of the linear conductor,

$$\mathbf{A} = \frac{\mu}{c} \int \mathbf{j} \frac{dV}{r} = \frac{\mu}{c} \int \frac{j dS dl}{r} = \frac{\mu I}{c} \int \frac{dl}{r}. \quad (17.4)$$

In formula (17.4) μ denotes the magnetic permeability of the medium, which is external to the conductor carrying the current. We see that all characteristics of the linear conductor itself, for example the current density distribution in it, are eliminated in (17.4), and the conductor is considered as a purely geometric object. Hence the properties of the linear conductor, including also the magnetic properties of the material of which the wire is made, do not affect the value of the magnetic field. Formula (17.4) is valid for all conductors, including ferromagnetic ones.

From the definition of the vector potential it follows that the magnetic induction of a linear conductor carrying a current I is equal to (see (19.15) of Part I)

$$\begin{aligned} \mathbf{B} &= \nabla \times \mathbf{A} = \frac{\mu I}{c} \nabla \times \int \frac{dl}{r} = \frac{\mu I}{c} \int \nabla \times \frac{dl}{r} = \\ &= \frac{\mu I}{c} \int (\nabla r^{-1}) \times dl = \frac{\mu I}{c} \int \frac{dl \times \mathbf{r}}{r^3}. \end{aligned} \quad (17.5)$$

Formula (17.5) expresses the Biot-Savart law for a homogeneous and isotropic medium. The induction (mean field) \mathbf{B} turns out to be larger by a factor of μ than the field of the same current in vacuum. Correspondingly the field strength in the medium $\mathbf{H} = \mu^{-1}\mathbf{B}$ is the same as the field in a vacuum.

The Biot-Savart law is often written in differential form

$$d\mathbf{B} = \frac{\mu I}{c} \frac{d\mathbf{l} \times \mathbf{r}}{r^3}, \quad (17.6)$$

where $d\mathbf{B}$ is the contribution to the induction of the current element $d\mathbf{l}$. It should be kept in mind that (17.5) cannot be resolved unambiguously into the elements (17.6). One can always add to (17.6) a vector function which reduces to zero in integrating over a closed contour carrying a direct current.

As an example of the application of the formulae obtained, we shall calculate the magnetic field produced in the surrounding space by a current flowing in an infinite straight linear conductor.

From considerations of symmetry it is clear that the field is directed along tangents to circles which are concentric about the conductor. The Biot-Savart law applied to the case considered gives

$$\mathbf{B} = \frac{\mu I}{c} \int \frac{d\mathbf{l} \times \mathbf{n}}{r^2},$$

where $\mathbf{n} = \mathbf{r}/r$. Introducing the shortest distance ρ from the point of observation to the conductor, we have for the field component B_ψ directed along a tangent to the circle of radius ρ concentric with respect to the conductor

$$B_\psi = \frac{\mu I}{c} \int \frac{\cos^2 \alpha}{\rho^2} \sin(90^\circ - \alpha) dl = \frac{\mu I}{c\rho} \int_{-\frac{1}{2}\pi}^{+\frac{1}{2}\pi} \cos \alpha d\alpha = \frac{2\mu I}{c\rho}, \quad (17.7)$$

where we have set (fig. IV.6)

$$r \cos \alpha = \rho,$$

$$\sin(90^\circ - \alpha) dl = r d\alpha = \frac{\rho d\alpha}{\cos \alpha}.$$

Further, we calculate the magnetic field on the central axis, z , perpendicular to the plane of a flat circular current carrying conductor of radius a with centre on the axis z (fig. IV.7). In this case one can write for the field component

Fig. IV.6

Fig. IV.7

$$B_z = \frac{\mu I}{c} \oint \frac{[d\mathbf{l} \times \mathbf{r}]_z}{r^3} = \frac{\mu I}{c} \int \frac{dl \sin \alpha}{r^2} = \frac{\mu I \cos^2 \alpha \sin \alpha}{cz^2} 2\pi a.$$

Since (fig. IV.7)

$$\cos \alpha = z(z^2 + a^2)^{-\frac{1}{2}}, \quad \sin \alpha = a(z^2 + a^2)^{-\frac{1}{2}},$$

we find finally

$$B_z = \frac{2\mu I}{c} \frac{S}{(z^2 + a^2)^{\frac{3}{2}}}, \quad (17.8)$$

where S is the area of the circle formed by the current.

In particular, at a large distance from the conductor ($z \gg a$)

$$B_z = \frac{2\mu IS}{cz^3} = \frac{2\mu M_z}{z^3}, \quad (17.9)$$

where the projection M_z of the magnetic moment of the current is equal to IS/c (see §22 of Part I).

At the centre of the circle in the plane $z = 0$

$$B_z = \frac{2\mu I}{ca^3}. \quad (17.10)$$

The field component B_{\perp} perpendicular to the z -axis is equal to zero, as is clear from considerations of symmetry: to opposite segments of the current carrying conductor there will correspond values of B_{\perp} with opposite signs.

Finding the magnetic field in non-linear conductors carrying direct currents presents a problem which is complex from the mathematical standpoint. The calculation of the vector potential according to the general formula (17.3) can be carried out only for individual cases. We shall therefore confine ourselves to examples.

A very simple example is the magnetic field of an infinite current carrying linear conductor of circular cross-section of radius a . In this case the integration of eq. (14.3) can be carried out directly. Owing to the cylindrical symmetry the magnetic field inside as well as outside the conductor has only one component, H_ψ . The integration of (14.3) over the area of a circle of a radius $\rho < a$ gives

$$2\pi\rho H_\psi = \frac{4\pi}{c} jS,$$

where $S = \pi\rho^2$. This last formula can be written in the form

$$H_\psi = \frac{2I}{c} \frac{\rho}{a^2} \quad (\rho < a), \quad (17.11)$$

or, in the vector form,

$$\mathbf{H} = \frac{2I}{ca^2} [\mathbf{l} \times \boldsymbol{\rho}] = \frac{2\pi j}{c} [\mathbf{l} \times \boldsymbol{\rho}], \quad (17.12)$$

where \mathbf{l} is a unit vector along the axis of the cylinder. Analogously, outside the conductor

$$H_\psi = \frac{2I}{c\rho} \quad (\rho > a). \quad (17.13)$$

If the cross-section of the conductor is more complex, then the principle of superposition of fields sometimes proves useful.

§18. The magnetization of magnetic materials and the magnetic moment

We now pass on to the consideration of the magnetic properties of matter.

If a system of particles is placed in an external magnetic field, then the system will be magnetized. The mean magnetic moment of the system can be determined by the same relation as the mean dipole moment:

$$\mathbf{M} = kT \frac{\partial}{\partial \mathbf{H}} \ln Z = - \frac{\partial F}{\partial \mathbf{H}}, \quad (18.1)$$

where \mathbf{H} is the strength of the external magnetic field.

Correspondingly one can write the expression for the change in the free energy:

$$dF = dF_0 - \mathbf{M}V \cdot d\mathbf{H}.$$

One can also introduce the Gibbs thermodynamic potential

$$dG = dG_0 - \mathbf{M}V \cdot d\mathbf{H} \quad (18.2)$$

Their meanings are analogous to those of the corresponding quantities for the electric field.

We shall not dwell on the analysis of the phenomena of magnetostriction and the magnetocaloric effect. They are also analogous to the electric effects which have been considered in § 13.

The magnetic susceptibility can be calculated according to the formula

$$\chi = \frac{|\mathbf{M}|}{|\mathbf{H}|} = \frac{kT}{V} \frac{1}{|\mathbf{H}|} \frac{\partial \ln Z}{\partial H}. \quad (18.3)$$

Depending on the sign of χ one distinguishes between diamagnetic ($\chi < 0$) and paramagnetic ($\chi > 0$) substances. In addition to diamagnetic and paramagnetic substances there is a special group of ferromagnetic bodies, for which the magnetic susceptibility is extremely large and depends strongly on the magnetic field.

For diamagnetic substances the magnetic susceptibility is usually very small in absolute value ($\chi \approx 10^{-6}$) per gram-mole and does not depend on the temperature. All inert gases, many gases whose molecules represent saturated chemical compounds, almost all organic compounds, all simple insulators and about one half of all metals (Cu, Ag, Au, Hg, Zn for instance) are diamagnetic. Among the latter one encounters the so-called anomalous diamagnetics, for which the susceptibility exceeds the normal value quoted above by a factor of 10–100 and which have a number of other anomalous properties (for example, χ depends on the temperature and on the field, as in the case of Bi and Sb).

For normal paramagnetics the magnetic susceptibility depends on the temperature according to the law

$$\chi = \frac{\text{const}}{T}.$$

In order of magnitude χ is about 10^{-4} – 10^{-6} per gram-mole. Among such paramagnetic substances there are certain gases (O_2 , NO , CO_2 for instance), the crystalline hydrates of rare earth salts (for example, $\text{Gd}_2\text{SO}_4 \cdot 8\text{H}_2\text{O}$), the salts of the metals of the group of platinum, iron etc. For many normal paramagnetics the dependence of χ on the temperature has the form

$$\chi = \frac{\text{const}}{T \pm \Delta},$$

where Δ is a constant. Another group of paramagnetic substances is made up of paramagnetic metals possessing a small paramagnetic susceptibility ($\chi = 10^{-6}$ – 10^{-7} per gram-mole) which does not depend on the temperature. There also exist the so-called anomalous paramagnetics, for which the paramagnetic susceptibility depends on the field (metamagnetics) or has a maximum value at a certain temperature (antiferromagnetics).

Finally, substances with a very large positive susceptibility (in order of magnitude reaching 10^3) which depends in a complex way on the magnetic field strength and on the temperature and a number of other factors make up the group of ferromagnetics.

We cannot here discuss in detail all aspects of the modern theory of the magnetic properties of matter. We shall confine ourselves only to certain general observations and to the exposition of the theory of the paramagnetism of normal paramagnetics. The theory of the diamagnetic properties of atoms will be substantiated in ch. 9 of Part V.

Before passing on to the exposition of the modern theory of the magnetic properties of matter it is necessary to dwell briefly on a statement which seems at first sight to be paradoxical. Namely, one can in the most general form prove that the magnetic moment of any body calculated by means of the laws of classical statistics is identically equal to zero. We shall present the simplest proof of this theorem.

Any system in an external field can be looked on as a set of moving charged particles. As is known from electrodynamics, when a charged particle is moving in a uniform magnetic field directed along the z -axis the generalized momentum of the particle has the form (§41 of Part I)

$$p_x = p_x^{(0)} - \frac{eHy}{2c}, \quad p_y = p_y^{(0)} + \frac{eHx}{2c}, \quad p_z = p_z^{(0)},$$

where $p_x^{(0)}$, $p_y^{(0)}$, $p_z^{(0)}$ are the components of the momentum in the absence of field.

The Hamilton function is given by the expression (41.8) of Part I:

$$H = \frac{[p_x + (eHy/2c)]^2 + [p_y - (eHx/2c)]^2 + p_z^2}{2m}.$$

The partition function of the system in the magnetic field has the form

$$Z = \left\{ \int e^{-H/kT} \frac{d\mathbf{p} dV}{h^3} \right\}^N.$$

Introducing instead of p_x a new variable

$$p'_x = p_x^{(0)} = p_x + \frac{eHy}{2c},$$

we see that upon integration with respect to p'_x from minus infinity to plus infinity the partition function turns out to be independent of the external field \mathbf{H} . The same holds also for p_y . By virtue of (18.3) the mean magnetic moment is identically equal to zero.

This seems to be particularly paradoxical because most books give the classical interpretation of diamagnetism and paramagnetism. The diamagnetic properties of matter are associated with the change in the orbital motion of electrons in the atom caused by the magnetic field. As is well known, the magnetic field induces a current flowing in a closed path in such a direction that the additional magnetic field of the current weakens the applied field. The induced magnetic moment of the current is directed against the field and is proportional to the strength of the latter as well as to the area embraced by the contour. Assuming the electron moving in the atom to be a current filament, one can obtain the following purely electrodynamic expression for the magnetic moment of the particle moving in an orbit of radius r_0 :

$$\mu = -\frac{e^2}{6mc^2} r_0^2 H.$$

As to paramagnetism, it is associated in classical electrodynamics with the presence of a magnetic moment of the electron moving in orbit and having an angular momentum different from zero. If L denotes the angular momentum of the system, then in classical electrodynamics it turns out that the system possesses the magnetic moment

$$\mu = \frac{e}{2mc} L. \quad (18.4)$$

The magnetic moment defined by formula (18.4) is the analogue of the electric dipole moment. Every atom is a sort of a small magnet. Hence the above considerations and formula (18.1) are completely applicable to it. In an atomic gas whose atoms possess magnetic moment μ there must arise a mean magnetic moment owing to the appearance of the preferential orientation of magnetic moments along the field.

The inconsistency of these arguments lies in the fact that one assumes beforehand the existence of stable electron orbits. However, it is well known that the existence of stable orbits cannot be conceived on the basis of classical concepts. The absence of a magnetic moment in classical physics is an expression of the fact of the absence of stable motion in a system of elementary charges. The assumption of the existence of stationary electron orbits in atoms or fixed moments of atoms, which is used in the "classical" theory of magnetism, represents in essence the assumption of the quantization of states, in an implicit form.

It is proved in quantum mechanics that the energy levels of an atomic system change in a magnetic field. In the case of atoms or ions, for which the mean value of the angular momentum L of the system is equal to zero, for the energy of the ground state one obtains the following expression (see ch. 9 of Part V):

$$\epsilon = \epsilon_0 + \frac{e^2 H^2}{12mc^2} \sum (r_i^2)_{\text{mean}}, \quad (18.5)$$

where ϵ_0 is the value of the energy in the ground state, and $(r_i^2)_{\text{mean}}$ is the quantum-mechanical mean of the radius vector of the i th electron in the ground state. The summation is carried out over all electrons in the atom. To this energy there corresponds a mean magnetic moment

$$\mu_{\text{mean}} = -\frac{\partial \epsilon}{\partial H} = -\frac{e^2 H}{6mc^2} \sum (r_i^2)_{\text{mean}}. \quad (18.6)$$

Formula (18.6) is in form the same as the classical formula given above, but has a different meaning: the quantity $(r^2)_{\text{mean}}$ represents the quantum-mechanical mean (see ch. 3 of Part V).

The atom or ion in the ground state has a diamagnetic susceptibility

$$\chi_0 = -\frac{e^2}{6mc^2} \sum (r_i^2)_{\text{mean}}. \quad (18.7)$$

We stress that in (18.7) no averaging over different states is carried out, and the averaging has nothing in common with statistical averaging.

A system representing a set of N independent atoms or ions will, in the ground state, possess an induced magnetic moment

$$M = -\frac{Ne^2H}{6mc^2} \sum (r_i^2)_{\text{mean}}$$

and a diamagnetic susceptibility

$$\chi = -\frac{Ne^2}{6mc^2} \sum (r_i^2)_{\text{mean}}. \quad (18.8)$$

If one substitutes values for $(r^2)_{\text{mean}}$ calculated by different methods (for these methods see Part V) or the mean radii of atoms obtained from the kinetic theory of gases, then one obtains for χ a value which agrees with those found from measurements.

If a system (an atom or an ion) in the ground state possesses an angular momentum different from zero, then the energy in a magnetic field will have a different form.

It turns out that in quantum mechanics, if a molecular system possesses an orbital angular momentum L , then its energy in a state i is equal to

$$\epsilon_i = \epsilon_i^{(0)} - \frac{eh}{4\pi mc} L_z H + \frac{e^2 H^2}{6mc^2} \sum (r_i^2)_{\text{mean}}, \quad (18.9)$$

where L_z is the projection of the angular momentum onto the direction of the magnetic field (the z -axis is chosen to be along the field). For the derivation of (18.9) see ch. 9 of Part V.

Simple estimates show that the last term of formula (18.9) for all values of the field strength H is small in comparison with the second term. Exceptions are for very large organic molecules, for which $\sum (r_i^2)_{\text{mean}}$ is very large.

In what follows we shall drop the last term of (18.9) and write the energy in the form

$$\epsilon_i = \epsilon_i^{(0)} - \frac{eh}{4\pi mc} L_z H. \quad (18.10)$$

It is shown in quantum mechanics (see ch. 3 of Part V) that the projection of the angular momentum onto the z -axis takes on discrete values:

$$L_z = -L, \quad -L+1, \dots, 0, \quad 1, \dots, L-1, \quad L$$

(all together $2L+1$ values). Hence in a magnetic field the i th energy level splits into $2L+1$ levels which possess the energies

$$\begin{aligned} \epsilon_i &= \epsilon_i^{(0)} + \frac{eh}{4\pi mc} LH; \\ \epsilon_i^{(0)} + \frac{eh}{4\pi mc} (L-1)H; \\ &\dots \dots \dots; \\ \epsilon_i^{(0)} - \frac{eh}{4\pi mc} (L-1)H; \\ \epsilon_i^{(0)} - \frac{eh}{4\pi mc} LH. \end{aligned}$$

The presence of an intrinsic angular momentum (spin) as well as the angular momentum due to the orbital motion in a system of electrons leads to the appearance of a spin magnetic moment in the system. If the resulting spin S of the system is different from zero, while the resulting orbital momentum L is equal to zero, the energy of the system in a magnetic field turns out to be equal to (see ch. 8 of Part V)

$$\epsilon_i = \epsilon_i^{(0)} - \frac{eh}{2\pi mc} S_z H, \quad (18.11)$$

where S_z is the projection of the intrinsic angular momentum onto the direction of the field taking on a discrete series of values:

$$S_z = -S, \quad -S+1, \dots, S-1, \quad S.$$

For such a system the i th level splits into $2S+1$ sublevels:

$$\epsilon_i = \epsilon_i^{(0)} + \frac{eh}{2\pi mc} SH, \dots, \epsilon_i^{(0)} - \frac{eh}{2\pi mc} SH. \quad (18.12)$$

We shall not consider the general case where L and S simultaneously differ from zero.

In a magnetic field the system in the i th state will possess a mean (in the quantum-mechanical sense) magnetic moment

$$(\mu_i)_{\text{mean}} = - \frac{\partial \epsilon_i}{\partial H} = \frac{eh}{4\pi mc} L_z, \quad (18.13)$$

or

$$(\mu_i)_{\text{mean}} = - \frac{\partial \epsilon_i}{\partial H} = \frac{eh}{2\pi mc} S_z. \quad (18.14)$$

We see that the magnetic moment of the system has a positive sign, i.e. that the system having an intrinsic angular momentum is paramagnetic. The ratio of the magnetic moment to the orbital momentum is equal to $eh/4\pi mc$. For the spin moment this ratio is twice as large.

§ 19. Paramagnetic susceptibility

Let us now consider the behaviour of a system containing a large number of atoms or molecules in an external magnetic field. The magnetic field has an orienting effect on the magnetic moments of the atoms, tending to set them along the field. The thermal motion disturbs such a regular arrangement of the moments. As a result of the competition of these processes a certain mean arrangement of the directions of the magnetic moments with respect to the direction of the field is established. To this mean arrangement of the elementary magnetic moments there corresponds the mean magnetic moment of the entire system.

Let us find the resulting magnetic moment of a system of atoms according to the general formula. We assume that any interaction between the magnetic moments is absent and each magnetic moment turns freely in the external field. In order that this assumption may be valid it is necessary that the mean distance between the atom is sufficiently large. Examples of such systems will be given below. If the initial assumption is fulfilled, then each particle can be considered as an individual subsystem having an energy in the

field given by formula (18.9). The mean value of the magnetic moment of the particle can be found by means of formula (18.1).

For the partition function we have

$$z = \sum \exp \left[-\frac{\epsilon_i^{(0)} - (eh/4\pi mc)L_z H}{kT} \right] \Omega(\epsilon_i). \quad (19.1)$$

The summation is to be carried out over all values of the energy of the sub-system. Since in the magnetic field $2L + 1$ adjacent energy levels arise in place of one energy level, the summation in (19.1) is carried out over all energy levels i and, within the limits of a given level, also over all sub-levels which are defined by formula (18.9) and which differ from each other by the discrete values of the magnetic energy $ehL_z H/4\pi mc$, since L_z takes on a discrete series of values. The expression (19.1) can essentially be simplified if it is taken into account that in atomic systems the spacing between levels is very large in comparison with the thermal energy kT . Because of this the terms of the sum will decrease rapidly and one can confine oneself to the first term which refers to the ground state energy ϵ_0 . In the magnetic field the latter level splits into $2L + 1$ or $2S + 1$ sub-levels, depending on which of the quantities, L or S , differs from zero in the ground state. In the first case one can write

$$z = \exp \left[-\frac{\epsilon_0}{kT} \right] \sum \exp \left[\frac{eh}{4\pi mc} \frac{L_z H}{kT} \right] \Omega(\epsilon_0), \quad (19.2)$$

where the sum is taken over the sub-levels mentioned.

In what follows we shall consider two limiting cases:

$$\frac{eh}{4\pi mc} L_z H \gg kT \quad (19.3)$$

and

$$\frac{eh}{4\pi mc} L_z H \ll kT. \quad (19.4)$$

Because of the smallness of the magnetic moment, the condition (19.4) is fulfilled for available fields at a not too low temperature. If condition (19.4) is fulfilled, then the exponent in (19.2) can be expanded in a series and one can restrict oneself to terms which are of low order in the field:

$$z = \exp \left[-\frac{\epsilon_0}{kT} \right] \Omega(\epsilon_0) \sum_{L_z = -L}^{L_z = L} \left(1 + \frac{eh}{4\pi mc} \frac{L_z H}{kT} + \frac{1}{2} \left(\frac{eh}{4\pi mc} \right)^2 \left(\frac{L_z H}{kT} \right)^2 + \dots \right).$$

Upon summing, we have

$$\sum 1 = 2L + 1,$$

$$\sum L_z = 0,$$

$$\sum L_z^2 = \frac{1}{3} L(L+1)(2L+1).$$

We then obtain

$$z = \exp \left[-\frac{\epsilon_0}{kT} \right] (2L+1) \Omega(\epsilon_0) \left[1 + \frac{1}{6} \left(\frac{eh}{4\pi mc} \right)^2 \frac{L(L+1)H^2}{(kT)^2} \right]. \quad (19.5)$$

The partition function of an entire system consisting of mutually independent particles is obviously equal to $Z = z^N$.

According to (18.1) the mean magnetic moment of the entire system is

$$M = kT \frac{\partial \ln Z}{\partial H} = NkT \frac{\partial \ln z}{\partial H} \approx \frac{1}{3} \left(\frac{eh}{4\pi mc} \right)^2 \frac{L(L+1)NH}{kT}. \quad (19.6)$$

The paramagnetic susceptibility referred to N molecules has the form

$$\chi = \frac{M}{H} = \frac{1}{3} \left(\frac{eh}{4\pi mc} \right)^2 \frac{L(L+1)N}{kT}. \quad (19.7)$$

If the magnetic moment is due not to the orbital momentum but to the spin, the instead of (19.6) we have by virtue of (18.14)

$$M = \frac{1}{3} \left(\frac{eh}{2\pi mc} \right)^2 \frac{S(S+1)NH}{kT}, \quad (19.8)$$

while instead of (19.7) we obtain

$$\chi = \frac{1}{3} \left(\frac{eh}{2\pi mc} \right)^2 \frac{S(S+1)N}{kT} \quad (19.9)$$

If, finally, the system has both orbital momentum and spin, then one obtains for χ an analogous expression but with the coefficient in the numerator having a value which is intermediate between (19.7) and (19.9).

In all the cases considered the paramagnetic susceptibility turns out to be inversely proportional to the temperature T . Besides the temperature, the magnetic susceptibilities (19.7) and (19.9) contain only a constant factor made up of universal constants and the value of the orbital momentum or spin respectively.

Passing on to the second limiting case where the condition (19.3) is satisfied, we see that of all the terms of the sum in (19.1) it is necessary to retain only one term corresponding to the value of the magnetic part of the energy $ehLH/4\pi mc$. Other terms of the sum which contain the components $eh(L-1)H/4\pi mc$, $eh(L-2)H/4\pi mc$ and so on will be much smaller than the first. The reason for this is clear: the inequality (19.3) means that the energy of orientation in the magnetic field is large in comparison with the thermal energy and that all magnetic moments will be oriented along the field, so that their projection L_z will be equal to L , i.e. a total saturation will ensue.

Dropping all terms except the first in the sum (19.2), we find

$$z = \exp \left[-\frac{\epsilon_0}{kT} \right] \exp \left[\frac{eh}{4\pi mc} \frac{LH}{kT} \right], \quad (19.10)$$

whence

$$M = NkT \frac{\partial \ln z}{\partial H} = \frac{ehN}{4\pi mc} LH, \quad (19.11)$$

or

$$M = \frac{ehN}{2\pi mc} SH \quad (19.12)$$

(depending on the nature of the magnetic moment). Thus total saturation ensues, and all moments are set up along the field. In the intermediate case one can obtain a general formula for the dependence of the magnetic moment on the field.

Considering now comparison with experiment, we note that all quantities

in formulae (19.7) and (19.9) are known. Hence calculated susceptibilities can be compared directly with experimental values for systems for which the initial assumption (the absence of interaction between particles possessing a magnetic moment) is fulfilled. It should be noted that the number of such systems is rather small. Most atoms and molecules in the ground state have an orbital momentum and spin equal to zero ($L=S=0$). Substances which in the ground state possess a magnetic moment and a paramagnetic susceptibility also have a diamagnetic susceptibility. However, the latter constitutes a relatively small (although sometimes quite appreciable) part of the paramagnetic susceptibility. To obtain the true value of the paramagnetic susceptibility it is necessary to add to its measured value the value of the diamagnetic susceptibility. It is not a simple problem to obtain atomic paramagnetic substances in the gaseous state and measure their susceptibilities. Nevertheless, the susceptibility of the vapour of K has been measured, and these measurements led to a value of the paramagnetic susceptibility of $0.38T^{-1}$, which is in agreement with the theoretical value of $0.37T^{-1}$. The accuracy of the measurements is not high, and they cannot be used for a complete verification of formula (19.9).

The most suitable objects for the verification of the theory of paramagnetic susceptibility described above are:

(1) Aqueous solutions or the solid crystalline hydrates of salts containing ions with an orbital angular momentum or spin differing from zero. Such ions are those of the elements of the rare-earth group and the transition elements of the iron group in solutions or crystalline hydrates. In aqueous solutions and crystalline hydrates paramagnetic ions are separated from each other by a large number of water molecules. Hence the energy of interaction between them is very small. The agreement of theory with experiment turns out to be excellent. This is confirmed in the example of gadolinium Gd^{3+} . For this ion $L=0$ and $S=\frac{7}{2}$. Its magnetic moment and susceptibility are expressed by formulae (19.8) and (19.9). The theoretical dependence of the magnetic moment on the quantity $\mu H/kT$ is shown in fig. IV.8 by a solid line. The measured values of M are shown by dots.

(2) The molecules of paramagnetic gases (O_2 , NO etc.). The electric fields of molecules have not spherical symmetry; their angular momentum has no fixed value and the mean value is equal to zero. If, however, a molecule possesses a spin different from zero, then it has a magnetic moment which is connected with the spin by the relation (18.14). The number of molecules having a spin different from zero is relatively small. As an example one can quote the oxygen molecule O_2 whose spin is $S=1$. For the magnetic susceptibility of 1 cm^3 of oxygen in normal conditions we obtain from formula

Fig. IV.8

(19.9) the value $\chi = 0.142 \times 10^{-6}$. The measured value is equal to $\chi = 0.143 \times 10^{-6}$. This agreement is excellent.

We cannot go into a discussion here of more complex cases of molecules having a non-zero projection of the angular momentum onto the symmetry axis, and cases where one cannot consider the spin of the molecule to be oriented freely in space *.

§20. Ferromagnetism. Spontaneous magnetization and hysteresis

Ferromagnetism represents a specific phenomenon which occurs only in the solid phase and for a relatively limited range of substances.

As we have stressed earlier, the magnetic properties of ferromagnetics differ essentially from those of other bodies. For ferromagnetics not only is there no proportionality between the vectors \mathbf{B} and \mathbf{H} but the induction is a complex and ambiguous function of the field,

$$\mathbf{B} = f(\mathbf{H}) .$$

The value of $f(\mathbf{H})$ depends on the history of magnetization.

As the external field \mathbf{H} increases the induction of the ferromagnetic sample increases according to a curve whose characteristic shape is shown

* See, for example, E.Bloch, *Molekularnaya teoriya magnetizma* (Molecular theory of magnetism) (GTTI, 1936); S.V.Vonsovskii, *Sovremenoe uchenie o magnetizme* (Contemporary teaching on magnetism) (Gostekhizdat, Moscow, 1952); D.H.Martin, *Magnetism in solids* (Iliffe, London, 1967).

Fig. IV.9

in fig. IV.9. When the field is switched off the induction decreases but does not reach zero, so that a residual magnetization remains in the body, which exists even in the absence of the external field. This magnetization can be reduced to zero by changing the direction of the external field. The repetition of the process proceeds according to a characteristic cycle which is also shown in fig. IV.9 and which is called the hysteresis cycle.

The existence of such a connection between \mathbf{B} and \mathbf{H} means that in the relation

$$\mathbf{B} = \mathbf{H} + 4\pi\mathbf{M},$$

the mean magnetic moment (magnetization) of the body must be considered as a quantity determined by the state of the body as a whole. This means that the relation between \mathbf{M} and \mathbf{H} for a ferromagnetic body has a complex character and that the definition of \mathbf{H} does not in itself determine the magnitude of the magnetization. We shall discuss below the properties of magnetization for ferromagnetics and its dependence on the field \mathbf{H} and on the temperature. However, it should first of all be stressed that, in contrast to diamagnetic and paramagnetic substances, the magnetization in ferromagnetic substances is not determined by the external field but is an internal parameter of the system.

A spontaneous magnetization can exist in a ferromagnetic body in a state

of statistical equilibrium. The state of the body will be completely characterized by the definition of its internal parameters, for example, the temperature, pressure and spontaneous magnetization. In the equilibrium state the thermodynamic potential $G(p, T, \mathbf{M})$ must be a minimum.

In the presence of an external magnetic field the magnetization of the body will be a function of the applied field. The form of this function, for given properties of the body, is determined by equilibrium conditions in such a way that

$$G(p, T, \mathbf{M}(\mathbf{H})) \rightarrow \min. \quad (20.1)$$

The numerical value of the magnetization in ferromagnetic bodies is very large. If the magnetic susceptibility is formally defined as

$$\kappa = (\partial \mathbf{M} / \partial \mathbf{H})_{\mathbf{H} \rightarrow 0}, \quad (20.2)$$

then it turns out that its values reach orders of magnitude of $10^5 - 10^6$.

As we have already stressed, the phenomenon of ferromagnetism can occur only in solid bodies. It turns out that the magnetization in single crystals possesses an important property of anisotropy. The magnetization has different values in different directions in the crystal. In the so-called directions of easy magnetization it has a large value, while in other directions it has a smaller value for a given value of the strength of the magnetizing field.

The ferromagnetic properties of matter depend strongly on the temperature. As the temperature increases the spontaneous magnetization decreases and at a certain temperature, which is characteristic of a given substance, it reduces to zero. This temperature is called the magnetic transition temperature or the Curie point θ . At the Curie point the substance loses its ferromagnetic properties. At temperatures lying above the corresponding temperature θ all ferromagnetics become paramagnetics. At $T > \theta$ the paramagnetic susceptibility depends on the temperature according to the law

$$\kappa \sim \frac{1}{T - \theta},$$

which is called the Curie-Weiss law.

Finally, the most important property of ferromagnetic bodies is the following: even if it is homogeneous from the macroscopic point of view, a ferromagnetic body is usually divided into regions of spontaneous magnetization or domains. The size of the domains is very large in comparison with

the size of molecules and each domain consists of a very large number of particles. Within the limits of each domain there is a magnetization different from zero. This means that the magnetic moments of all atoms within the domain are spontaneously oriented preferentially in one direction, forming a macroscopic region of spontaneous magnetization.

If the body were not exposed to the action of a field, then the magnetization of individual domains in the entire body would, on the average, be balanced, and the vector \mathbf{M} for the body as a whole would be equal to zero.

The action of the external field amounts to a re-orientation of the magnetization vectors of individual domains such that a magnetization of the entire body different from zero is produced. When the field is removed the moments of a part of the domains preserve the preferential orientation, "remember" the action of the field, and additional work by a field is needed to reform a system of domains with a random orientation of magnetic moments.

It should be emphasized that the existence of domains is not a hypothesis but represents a phenomenon which has been well investigated experimentally in detail.

All the properties of ferromagnetic bodies mentioned above fit well into the framework of the thermodynamic theory of ferromagnetism described below. However, the basic problem, the essence of the phenomenon of spontaneous magnetization, cannot of course find any explanation within the framework of the macroscopic theory.

The microscopic quantum theory of the phenomenon of spontaneous magnetization is described in Part VI of this book.

Passing on to the discussion of the thermodynamic theory * we have, first of all, to write an explicit expression for the thermodynamic potential of the system — the ferromagnetic single crystal in a state of statistical equilibrium in an external field \mathbf{H} .

We shall consider the behaviour of ferromagnetism near the Curie point, when the magnetization is relatively small.

Let $G_0(p, T, \mathbf{M})$ be the thermodynamic potential of the body in the presence of an external field. The basic equality for the thermodynamic potential in a field reads

$$dG = dG_0 - \mathbf{H} \cdot d\mathbf{M}. \quad (20.3)$$

* In the subsequent exposition in this section we follow L.D. Landau and E.M. Lifshitz, *Electrodynamics of continuous media* (Pergamon Press, Oxford, 1960). Our potential φ corresponds to the quantity $\varphi + (H^2/8\pi)$ in the book quoted.

The difference between this relation and the analogous expression (18.2) lies in the fact that the independent variable is the mean magnetic moment of the ferromagnetic body, \mathbf{M} . Hence, integrating (20.3) with respect to \mathbf{M} for a given external field, one can write

$$G(p, T, \mathbf{M}) = G_0(p, T, \mathbf{M}) - \mathbf{M} \cdot \mathbf{H}. \quad (20.4)$$

The thermodynamic potential G_0 depends on the magnitude as well as on the orientation of the vector \mathbf{M} with respect to the axis of the single crystal.

The effect of anisotropy is relatively small. Hence $G_0(p, T, \mathbf{M})$ can be written in the form

$$G_0(p, T, \mathbf{M}) = G_1(p, T, M) + G_2(p, T, M), \quad (20.5)$$

where the second term takes into account the effect of anisotropy. The first, basic, term depends only on the absolute value of the magnetization vector.

We shall confine ourselves to the simplest case where the crystal has only one symmetry axis which is the axis of easy magnetization. We choose for this the z -axis. For the magnetization along the z -axis, i.e. $M_z = M$, the thermodynamic potential G_0 must have its smallest value. In this case the dependence of G_2 on M can be written in the form

$$G_2(p, T, \mathbf{M}) = \text{const} \cdot (M_x^2 + M_y^2) = \text{const} \cdot (M^2 - M_z^2) = \beta M_z^2 = \beta M^2 \sin^2 \theta. \quad (20.6)$$

where βM_z^2 which does not depend on angle can always be included in G_1 . In the small quantity G_2 we have written out only the first terms of the expansion in powers of M . Here β is a positive constant, and θ is the angle between the z -axis and the vector \mathbf{M} . The linear term in this expansion must drop out. Indeed, the magnetic moment, which is proportional to the velocity of the particles, changes sign under the substitution $t \rightarrow -t$. The thermodynamic potential of a system in an equilibrium state is obviously invariant under this substitution. Hence the expansion must contain a combination of the quadratic terms M_x^2 , M_y^2 , M_z^2 . This combination must be chosen in such a way that G_0 should have a minimum for the magnetization along the z -axis. Since the z -axis is the symmetry axis, the components M_x^2 and M_y^2 must figure symmetrically in the expansion. The expression (20.6) satisfies all these requirements. Since $\beta > 0$, the z -axis is indeed the axis of easy magnetization. The potential G_0 has its minimum value ($G_0 = 0$) if the vector \mathbf{M} is directed along the z -axis ($\theta = 0$).

The total thermodynamic potential in the external field has the form

$$G = G_1 - \mathbf{M} \cdot \mathbf{H} + \beta M^2 \sin^2 \theta. \quad (20.7)$$

This formula shows that the magnetization \mathbf{M} will be oriented by the external field on the one hand, and by the natural direction of easy magnetization on the other hand. As a result, the vector \mathbf{M} will set at a certain angle θ_{\min} with respect to the z -axis for which the thermodynamic potential has a minimum. If the plane in which \mathbf{H} and the axis of easy magnetization lie is chosen as the (xz) -plane, then the vector \mathbf{M} will obviously lie in this plane.

We write (20.7) in components

$$G = G_0 - MH_x \sin \theta - MH_z \cos \theta + \beta M^2 \sin^2 \theta.$$

We shall find the equilibrium orientation, determined by the condition of the minimum of G , from the condition

$$\partial G / \partial \theta = 2\beta M^2 \sin \theta \cos \theta - MH_x \cos \theta + MH_z \sin \theta = 0.$$

Hence we easily obtain

$$(2\beta M \sin \theta - H_x)^2 (1 - \sin^2 \theta) = H_z^2 \sin^2 \theta. \quad (20.8)$$

This is an equation of the fourth power with respect to the quantity $\sin \theta$. It has either two or four real roots, depending on the values of H_x and H_z (for given M and β).

In the first case one value of the root corresponds to the angle θ_{\min} for which G has its minimum value. This is the equilibrium orientation of \mathbf{M} . The second value of the root leads to the maximum value of G , i.e. to a thermodynamically unstable orientation of the magnetization.

In the second case there are two minimum and two maximum values of the angle θ .

One of these minima θ_{\min} leads to the smallest value of the thermodynamic potential. The corresponding orientation of the vector \mathbf{M} is the equilibrium orientation. The second minimum corresponds to a metastable state of the crystal. For this orientation the thermodynamic potential is smaller than for any neighbouring orientations but larger than that for the orientation at the angle θ_{\min} .

The existence of metastable states allows one to understand qualitatively the origin of residual magnetization and hysteresis.

The equilibrium state corresponds to a total magnetization of the crystal equal to zero in the absence of an external field. On the contrary, in the metastable state the magnetic moment of the body as a whole is different from zero in the absence of a field. If in the process of magnetization the crystal is brought into the metastable state with a certain total magnetization $\int \mathbf{M}(\mathbf{H})dV$ and thereupon the external field is removed, then the system will remain for a very long time (practically indefinitely) in the state with the total magnetization $\int \mathbf{M}(\mathbf{H} \rightarrow 0)dV$. From formula (20.8) there also follows, in principle, the possibility of the existence of domains. Assume that the external field is oriented perpendicularly to the axis of easy magnetization, i.e. $H_z = 0$. Then (20.8) goes over into the equation

$$2\beta M \sin \theta - H = 0. \quad (20.9)$$

If $H < 2\beta M$, then (20.9) has two solutions

$$\theta_1 = \arcsin \frac{H}{2\beta M}, \quad \theta_2 = \arcsin \left(\frac{H}{2\beta M} - \pi \right).$$

To these solutions there corresponds one and the same minimum value of the thermodynamic potential, so that both of these are equilibrium solutions. However, the values of the magnetization \mathbf{M} will in these cases be respectively

$$M_x^{(1)} = M \sin \theta_1, \quad M_x^{(2)} = M \sin \theta_2 = -M \sin \theta_1 = -M_x^{(1)}. \quad (20.10)$$

Thus, in the equilibrium state two opposite orientations of the magnetization vector are possible.

If the entire crystal is divided into alternating regions with magnetization $M_x^{(1)}$ and $M_x^{(2)}$, then its thermodynamic potential will be a minimum and its state will be an equilibrium state.

We see that from the formal thermodynamic theory there follows the possibility of the existence of residual magnetization (and hysteresis) and the domain structure of the crystal.

The actual realization, magnitude and form of the domains depend on many factors.

For details we refer the reader to the book of L.D. Landau and E.M. Lifshitz and to the specialized literature of this field.

It goes without saying that the thermodynamic theory does not give and cannot give any answer to the basic question of the nature of spontaneous magnetization. The existence of the anisotropy energy is also postulated in this theory.

Let us now consider the dependence of the magnetic properties of ferromagnetics on the temperature near the Curie point. At the Curie point the ferromagnetic and paramagnetic states of the substance are in statistical equilibrium. This equilibrium is a phase equilibrium, and each of the states represents a phase, respectively the ferromagnetic phase and the paramagnetic phase.

The thermodynamic potential of the ferromagnetic phase is given by formula (20.5). Near the Curie point one can neglect the small term G_2 and expand G_1 in a series in powers of a small quantity (the magnetization \mathbf{M}) which reduces to zero at the point $T = \theta$. Then we have

$$G_{\text{ferro}}(p, T, \mathbf{M}) = G_0(p, T) + aM^2 + bM^4 - \mathbf{M} \cdot \mathbf{H}, \quad (20.11)$$

to terms of the fourth order of a small quantity.

The odd powers of \mathbf{M} drop out of the expansion: under the substitution ($t \rightarrow -t$) \mathbf{M} changes sign whereas G does not.

At the Curie point $T = \theta$ the coefficient a reduces to zero. Near the Curie point one can write

$$a \sim (T - \theta), \quad (20.12)$$

so that $a > 0$ above the Curie point and $a < 0$ below the Curie point. Assume that $b > 0$. As will be seen from what follows, for such a choice of the signs of a and b the thermodynamic theory well describes the ferromagnetic-paramagnetic phase transition.

The equilibrium condition reads

$$\partial G / \partial M = 2aM^2 + 4bM^3 - H = 0. \quad (20.13)$$

If there is no magnetic field, then in the equilibrium state either

$$M = 0, \quad (20.14)$$

or

$$a + 2bM^2 = 0. \quad (20.15)$$

Above the Curie point $a > 0$ and the condition of the minimum of the thermodynamic potential is the equality (20.14). Below the Curie point the equality (20.15) can be satisfied (since here $a < 0$) and

$$M = \left(\frac{|a|}{2b} \right)^{\frac{1}{2}} \sim (\theta - T)^{\frac{1}{2}}.$$

At the Curie point M reduces to zero and the thermodynamic potentials of the ferromagnetic and paramagnetic states are equal to each other. As is easily seen, the entropy does not change in the phase transition. Indeed, above the Curie point

$$S_{\text{para}} = - \left(\frac{\partial G_0}{\partial T} \right)_p.$$

Below the Curie point, by virtue of the relations (20.12) and (20.15), we have

$$\begin{aligned} S_{\text{ferro}} &= - \left(\frac{\partial G_{\text{ferro}}}{\partial T} \right)_p = - \left(\frac{\partial G_0}{\partial T} \right)_p - M^2 \frac{\partial a}{\partial T} = - \left(\frac{\partial G_0}{\partial T} \right)_p - \text{const} \cdot M^2 = \\ &= - \left(\frac{\partial G_0}{\partial T} \right)_p - \text{const} \cdot (\theta - T) = S_{\text{para}} - \text{const} \cdot (\theta - T). \end{aligned}$$

Hence it is seen that at the Curie point, for $T = \theta$, the entropy remains continuous. However, the heat capacity of the system undergoes a jump. Indeed,

$$(C_p)_{\text{ferro}} = T \left(\frac{\partial S_{\text{ferro}}}{\partial T} \right)_p = \text{const} \cdot T + (C_p)_{\text{para}}.$$

The jump of the heat capacity for $T = \theta$ is

$$\Delta C_p = \text{const} \cdot \theta,$$

the heat capacity of the ferromagnetic phase being higher than that of the paramagnetic phase (for $b > 0$), which is in complete agreement with experiment. The phase transition considered is a typical example of a phase transition of the second kind (see §63 of Part III).

For $H \neq 0$ one can find the paramagnetic susceptibility from the condition of equilibrium. Namely, for $H \neq 0$ the condition (20.13) instead of (20.14) must be fulfilled. Differentiating it with respect to H , we find

$$\frac{\partial}{\partial H} \left(\frac{\partial G}{\partial M} \right) = \frac{\partial M}{\partial H} (2a + 612bM^2) - 1 = 0,$$

whence

$$\kappa = \frac{\partial M}{\partial H} = \frac{1}{2a + 612bM^2}.$$

For $T > \theta$, $M = 0$, the paramagnetic susceptibility, in accordance with the Curie-Weiss law, is equal to

$$\kappa = \frac{1}{2a} \sim \frac{1}{(T - \theta)}. \quad (20.16)$$

In conclusion we shall dwell briefly on the calculation of electromagnetic fields in the presence of ferromagnetics. The calculation of such fields is particularly important in technology, where ferromagnetic materials are widely used.

At first sight it may seem that the non-linear relation between \mathbf{B} and \mathbf{H} makes the calculation of the magnetic field very difficult. In practice, however, this is not so. As a matter of fact, the calculation of the field distribution outside the ferromagnetic requires the definition of the boundary condition at its surface. The use of accurate boundary conditions would associate the external problem with the field distribution inside the ferromagnetic, i.e. would make the problem very complex. However, if the ferromagnetic is formally considered as a medium with a magnetic susceptibility (20.2) and a magnetic permeability $\mu = 1 + 4\pi\kappa$ then one obtains for μ values which are higher by 5–6 orders than those for the external medium. Hence one can assume with a high degree of accuracy that $\mu \rightarrow \infty$, and the boundary condition (5.5) at the surface of the ferromagnetic assumes the simple form

$$\mathbf{H} \times \mathbf{n} = 0,$$

i.e. the lines of the magnetic field are normal to the surface. A ferromagnetic in a constant magnetic field turns out to be similar to a conductor in a constant electrostatic field. The calculation of the magnetic field inside ferromagnetic bodies turns out, as a rule, to be a very difficult problem.

§21. Superconductivity

As far back as 1911 Kamerlingh-Onnes established that the temperature dependence of the resistance of mercury differs fundamentally from that of normal metals.

As the temperature decreases the resistance ceases to depend on the temperature as in the case of normal metals, and its value is determined by the impurities which are present in the sample. However, when the temperature is reduced to $T = 4.1$ K the resistance of the metal falls abruptly (fig. IV.10) to zero. This phenomenon, the discontinuous vanishing of the resistance, is called the transition of the metal into the superconducting state, or briefly, the appearance of superconductivity. The temperature of this transition is called the superconducting transition temperature.

It is now established that superconductivity is a relatively widespread phenomenon. It is known that there are 23 metals which can go into the superconducting state. Superconductivity is observed also for a large number of alloys.

There is no doubt that the reduction of the resistance to zero corresponds to the transition of the metal into a new state. The resistance of all metals in the superconducting state is no more than 10^{-10} of the resistance immediately before the transition. Current in a ring made of a superconducting material circulates for an indefinitely long time without any sign of weakening. Hence it should be recognized that the resistance of superconductors is not simply very small but is exactly equal to zero. Electrons in superconductors can move without any hindrance.

Initially it was assumed that the metal in the superconducting state is an ideal conductor, i.e. a body with an infinitely large conductivity. According to Ohm's law, for the ideal conductor (i.e. a body with $\sigma \rightarrow \infty$) a finite value

Fig. IV.10

of the current density \mathbf{j} corresponds to a field strength inside the conductor equal to zero:

$$\mathbf{E} = 0. \quad (21.1)$$

The absence of an electric field inside the superconductor implies definite magnetic properties. That is, from the Maxwell equation

$$\nabla \times \mathbf{E} = \frac{1}{c} \frac{\partial \mathbf{B}}{\partial t}$$

and from the fact that the field \mathbf{E} is equal to zero it follows that the magnetic induction in the superconductor has a constant value

$$\mathbf{B} = \text{const}. \quad (21.2)$$

The value of this constant is equal to the value of the magnetic induction in the superconductor at the moment of the transition into the superconducting state.

It turns out, however, that this inference is contrary to experiment. If a metal cylinder is placed in a magnetic field which is perpendicular to the axis of the cylinder, and if it is cooled below the transition temperature, then one can infer the character of the field inside the superconductor by its distribution near the sample. It turns out that the lines of the magnetic induction are pushed out of the superconductor (fig. IV.11). The induction inside the superconductor is equal to zero:

$$\mathbf{B} = 0. \quad (21.3)$$

Fig. IV.11

From the boundary condition (5.5) the normal component of the external magnetic field $(H_e)_n$ (equal to the induction: $(H_e)_n = (B_e)_n$) is also equal to zero at the surface of the superconductor. In other words, the external magnetic field is tangential to a body which is in the superconducting state.

Eq. (1.16) shows that, if there is no magnetic induction in the body, then in the absence of an alternating electric field the total mean current in the volume of the body is zero:

$$\overline{\rho \mathbf{v}} = 0. \quad (21.4)$$

Thus inside the superconductor the total current density is zero. This means that in the surface layer of the superconductor a surface current circulates having a value such that the magnetic induction in the body is reduced to zero. In other words, the mean field of the surface currents compensates for the external magnetic field applied to the superconductor.

From the condition $\mathbf{B} = 0$ it follows that inside the superconductor the equations

$$\nabla \times \mathbf{E} = 0, \quad \nabla \cdot (\epsilon \mathbf{E}) = 0$$

hold, so that the electric field inside the superconductor is zero. The surface current in the superconductor is not associated with the action of the electric field. To determine the surface current density use can be made of the boundary condition (5.3). Namely, since there is no magnetic field in the superconductor, then (5.3) gives directly (for $\mathbf{H}^{(e)} = \mathbf{B}^{(e)}$)

$$\mathbf{j}_S = \frac{e}{4\pi} [\mathbf{n} \times \mathbf{B}^{(e)}],$$

where $\mathbf{B}^{(e)}$ is the magnetic induction vector outside the superconductor. If the body is simply connected, then the sum of the surface currents is equal to zero. On the other hand, in the case of a multiply connected body, for example a superconducting ring, the total current can be different from zero. The appearance of current in a superconductor may not be associated with the action of an impressed e.m.f. but can be produced by the action of a magnetic field. A surface current excited in a superconductor can circulate for an indefinitely long time without any weakening.

Experiment has shown that, if the magnetic field strength in the space which surrounds the superconductor exceeds a certain critical value H_{cr} , then the superconductivity in the sample vanishes. The destruction of the superconducting state and the appearance of a resistance take place in a discontinuous way.

The critical value of the magnetic field strength turns out to be a function of the temperature, which is given approximately by the empirical formula

$$H_{cr} = \text{const} \cdot (T_{cr} - T).$$

For $T = T_{cr}$, $H_{cr} = 0$, i.e. any field destroys the superconductivity at $T = T_{cr}$.

The consideration of the superconductor as a metal in a special superconducting state allows one to draw certain conclusions about the character of the transition into this state. Namely, the superconducting state should be considered as a particular phase of the substance, and the transition of the metal from the normal state into the superconducting state as a phase transition.

Let us consider the normal-state to superconducting-state phase transition occurring in an external field. In the superconducting state the mean total current $\overline{\rho \mathbf{v}}$ is equal to zero and it is impossible to separate from it the part which corresponds to the magnetic moment (as has been done in §3). Nevertheless, we introduce formally the magnetic field strength \mathbf{H}_i and the magnetic moment \mathbf{M} of the superconductor by the relation

$$\mathbf{B}_i = 0 = \mathbf{H}_i + 4\pi\mathbf{M}.$$

One can easily connect the field \mathbf{H}_i with the external magnetic field \mathbf{H}_e , if one considers a long cylindrical superconductor whose axis is directed along the field. Then, by virtue of the continuity of the tangential field component (which is in this case the same as the total field),

$$\mathbf{H}_i = \mathbf{H}_e$$

and

$$\mathbf{M} = -\mathbf{H}_e/4\pi. \quad (21.5)$$

We note that there corresponds to the equality (21.5) the value $\kappa = -1/4\pi$.

Thus, there corresponds to the superconducting state the magnetic permeability $\mu = 1 + 4\pi\kappa = 0$ and it is ideally diamagnetic.

According to (18.2) the thermodynamic potential of a body in the superconducting state can be written in the form

$$G_s(p, T, H) = G_s(p, T) - V \int_0^H \mathbf{M}(\mathbf{H}) \cdot d\mathbf{H}, \quad (21.6)$$

where $G_s(p, T)$ is the potential of the body in the superconducting state in the absence of an external magnetic field.

Substituting into (21.6) the value of $\mathbf{M}(\mathbf{H})$ according to formula (21.5), we obtain

$$G_s(p, T, H) = G_s(p, T) + V|\mathbf{H}_e|^2/4\pi. \quad (21.7)$$

When the external field reaches the critical value H_{cr} the superconducting state is destroyed. In this case the thermodynamic potential of the superconducting state increases so much, on account of the second term of (21.7), that the thermodynamic potential of the superconducting state turns out to be equal to the thermodynamic potential of the normal state $G_n(p, T)$. At the transition point the following relation is fulfilled:

$$G_s(p, T) + \frac{VH_{cr}^2}{8\pi} = G_n(p, T). \quad (21.8)$$

In the expression for the thermodynamic potential G_n we shall omit the additional term associated with the magnetic field, since it is very small for ordinary diamagnetic and paramagnetic metals.

Differentiating eq. (21.8) with respect to the temperature and making use of the definition of entropy (29.10) of Part III, we find

$$S_s - S_n = -\frac{\partial G_s}{\partial T} + \frac{\partial G_n}{\partial T} = \frac{VH_{cr}}{4\pi} \frac{dH_{cr}}{dT}, \quad (21.9)$$

where S_n and S_s are the entropies of the normal and superconducting states at the temperature T .

We see that, if $H_{cr} \neq 0$, i.e. if the transition occurs at $T < T_{cr}$, the entropy of the system changes in a discontinuous way. The phase transition is accompanied by the release of latent heat

$$Q = T\Delta S = \frac{TVH_{cr}}{4\pi} \frac{dH_{cr}}{dT}. \quad (21.10)$$

Experiment shows that in the transition from the normal state into the superconducting state heat is always released.

If the phase transition into the superconducting state occurs without field (i.e. if $H_{cr} = 0$), then

$$S_s = S_n ,$$

and the latent heat of transition is absent.

We can easily find the discontinuity of the heat capacity if we differentiate (21.9) with respect to the temperature. We then have

$$\left(\frac{\partial S_s}{\partial T}\right)_V - \left(\frac{\partial S_n}{\partial T}\right)_V = \frac{V}{4\pi} \left(\frac{\partial H_{cr}}{\partial T}\right)^2 + \frac{V}{4\pi} H_{cr} \left(\frac{\partial^2 H_{cr}}{\partial T^2}\right). \quad (21.11)$$

In the absence of an external field we find a simple expression for the jump of the heat capacity in the transition from the normal state into the superconducting state:

$$\Delta C_V = T \left[\left(\frac{\partial S_s}{\partial T}\right)_V - \left(\frac{\partial S_n}{\partial T}\right)_V \right] = \frac{VT}{4\pi} \left(\frac{\partial H_{cr}}{\partial T}\right)^2. \quad (21.12)$$

Thus, the phase transition considered represents a phase transition of the second kind. The derived macroscopic (thermodynamic) relations and a number of other relations which we shall not touch upon * are in good agreement with experimental data. However, although the thermodynamic theory of superconductivity successfully describes a number of properties of superconductors, it leaves open the basic problem: the problem of the physical nature of superconductivity.

Until recently all attempts to create a microscopic theory of superconductivity in which the superconductivity would be associated with the properties of the electron gas in the metal failed. They were only crowned with success in 1958. The contemporary theory of superconductivity will be expounded in Part V.

In the development of the theory of superconductivity an important role was played by experimental data which showed that there was a connection between the phenomenon of superconductivity and the character of interaction of the electrons of the superconductor with its crystal lattice. This was the so-called isotope effect, which was discovered in 1950 by Maxwell, Reynolds and others. It was discovered that the critical temperature T_{cr} depends on the isotope of a given element of which the lattice is made up, i.e. on the mass of the ions of the lattice. The relation between the mass M_{ion}

* See L.D. Landau and E.M. Lifshitz, *Electrodynamics of continuous media* (Pergamon Press, Oxford, 1960).

of the ions of the lattice and the critical temperature of the transition is given by the empirical formula

$$M_{\text{ion}}^{\frac{1}{2}} T_{\text{cr}} = \text{const} , \quad (21.13)$$

where the constant has a definite value for each element.

In conclusion we point to the analogy existing between the superconducting state of a metal and the superfluid state of liquid helium II. The superconductivity can be considered as the superfluidity of the electron gas which can move without hindrance in the crystal lattice of the metal (see Part V).

Quasistationary Electromagnetic Fields

§22. Conditions of quasistationarity

We now go on to the study of electromagnetic fields changing in time. It turns out that there is a wide frequency range for which Maxwell's equations allow an essential simplification.

In §19 of Part I we considered the case of a slow movement of charges where it was possible to completely disregard the retardation in the system and to assume the electromagnetic field to propagate with an infinitely large velocity.

In the results of §26 of Part I the condition for disregarding the retardation reduced to the requirement

$$T \gg \tau = L/c, \quad (22.1)$$

where T is the period of motion in the system, τ is the delay time, and L is the geometrical extent of the region in which the electromagnetic perturbations are considered.

In macroscopic electrodynamics there is a number of important problems in the treatment of which one can assume condition (22.1) to be fulfilled. In the approximation (22.1), the velocity of propagation of electromagnetic

disturbances can be assumed to be infinitely large within the limits of the system considered. In this case the values of the fields at a given point will be in phase with those at any other point inside the system. It is clear that the possibility of neglecting the retardation in the system essentially simplifies the study of the corresponding electromagnetic fields.

In Part I we have called electromagnetic fields in which the phenomenon of retardation can be disregarded quasistationary fields. In studying electromagnetic phenomena in matter, quasistationary fields, must, in addition to the requirement (22.1) which we shall call the first condition of quasistationarity, satisfy two more restrictions which we are going to derive.

The condition (22.1) obviously imposes a restriction upon the period T of the variation of the electromagnetic field (or upon the frequency $\omega = 2\pi/T$). That is, the periods T must be sufficiently large (and the frequencies sufficiently low) for a given size of system.

For relatively low frequencies of the electromagnetic fields in conductors the following condition is always fulfilled:

$$\frac{4\pi}{c} \mathbf{j} \gg \frac{1}{c} \frac{\partial \mathbf{D}}{\partial t}. \quad (22.2)$$

As a matter of fact, it can be rewritten in the form

$$\sigma \mathbf{E} \gg \epsilon \frac{\partial \mathbf{E}}{\partial t} \approx \epsilon \omega \mathbf{E},$$

or

$$T \gg \epsilon / \sigma. \quad (22.3)$$

When the inequality (22.2), which should be called the second condition of quasistationarity, is satisfied in the region of space occupied by the conductors one can disregard the displacement current in comparison with the conduction current.

The third condition of quasistationarity is the requirement that the quantities characterizing the properties of matter — σ , ϵ and μ — should have the same value as in constant fields. We shall see in Part VI that the requirement about σ reduces to the need for the period T to be substantially longer than the mean time between collisions of electrons in the metal:

$$T \gg \lambda / \bar{v}, \quad (22.4)$$

where λ is the mean free path, and \bar{v} is the mean velocity of electrons in the metal. For smaller values of T the field manages to change its value appreciably between collisions, which obviously has an effect on the free path and, in the end, on the value of σ .

We shall consider later the dependence of ϵ on the frequency of the external field.

Numerical estimates show that conditions of quasistationarity for ordinary macroscopic systems containing metals as conductors are satisfied up to frequencies lying in the infrared part of the spectrum. The whole set of conditions determining quasistationary fields turns out to be fulfilled for a wide range of phenomena which have the common name "alternating currents". Alternating currents or low-frequency currents have a very wide application in technology and laboratory practice. This determines the practical importance of the theory of quasistationary processes.

The equations of the quasistationary electromagnetic field have the form

$$\left. \begin{aligned} \nabla \times \mathbf{H} &= \frac{4\pi}{c} \mathbf{j}, \\ \nabla \cdot \mathbf{B} &= 0, \end{aligned} \right\} \quad (22.5)$$

$$\left. \begin{aligned} \nabla \times \mathbf{E} &= -\frac{1}{c} \frac{\partial \mathbf{B}}{\partial t}, \\ \nabla \cdot \mathbf{D} &= 4\pi\rho. \end{aligned} \right\} \quad (22.6)$$

In the equation for the curl of the magnetic field, on the basis of (22.2) we have dropped the term expressing the displacement current. The constitutive relations are:

$$\mathbf{B} = \mu \mathbf{H}; \quad \mathbf{D} = \epsilon \mathbf{E}; \quad \mathbf{j} = \sigma(\mathbf{E} + \mathbf{E}^{\text{imp}}). \quad (22.7)$$

The equation of continuity for quasistationary fields can be written in the form

$$\nabla \cdot \mathbf{j} + \frac{\partial \rho}{\partial t} = \nabla \cdot \mathbf{j} + \frac{\partial}{\partial t} \left(\frac{\nabla \cdot \mathbf{D}}{4\pi} \right) = \nabla \cdot \left(\mathbf{j} + \frac{1}{4\pi} \frac{\partial \mathbf{D}}{\partial t} \right) \approx \nabla \cdot \mathbf{j} = 0. \quad (22.8)$$

Thus, the difference between the equations of the quasistationary field and those of the field of stationary currents reduces only to taking account

of the phenomena of electromagnetic induction. It will be shown below that the possibility of disregarding the retardation in the system allows one to obtain the equations of the electromagnetic field for the case of a system of linear conductors in the form of equations in total derivatives, and not partial derivatives, with constant coefficients.

For this purpose it is necessary to go over to Maxwell's equations in integral form.

§23. The law of induction in moving conductors and media

First of all it is necessary to find the flux of induction appearing in Maxwell's equations written in integral form. For this we have to generalize the notion of the flux of induction to the case of moving current loops.

Let a current loop be moving in a magnetic field. We assume the velocity of motion to be constant in space and small in comparison with the velocity of light c . Let us find the change in the flux of induction through a conducting loop.

We have, obviously,

$$\frac{d\Phi}{dt} = \frac{d}{dt} \int \mathbf{B} \cdot d\mathbf{S}.$$

By definition

$$\frac{d}{dt} \int \mathbf{B} \cdot d\mathbf{S} = \lim_{\Delta t \rightarrow 0} \left[(\Delta t)^{-1} \left(\int_{S_2} \mathbf{B}(t+\Delta t) \cdot d\mathbf{S} - \int_{S_1} \mathbf{B}(t) \cdot d\mathbf{S} \right) \right], \quad (23.1)$$

where $\mathbf{B}(t+\Delta t)$ is the induction vector taken at instant $t + \Delta t$, and S_2 is the surface into which the surface S_1 goes over at the instant $t + \Delta t$. The vectors of the normal to the two surfaces are assumed to be oriented in one direction.

We apply the Gauss-Ostrogradsky theorem to a closed volume (fig. IV.12) consisting of surfaces S_2 and S_1 and a lateral surface Σ which is formed when the loop is displaced from the position S_1 to the position S_2 . Since $\nabla \cdot \mathbf{B} = 0$, i.e. \mathbf{B} is a vector having no sources, one can write

$$\begin{aligned} \oint \mathbf{B}(t+\Delta t) \cdot d\mathbf{S} = \\ = \int_{S_2} \mathbf{B}(t+\Delta t) \cdot d\mathbf{S} + \int_{\Sigma} \mathbf{B}(t+\Delta t) \cdot d\mathbf{S} - \int_{S_1} \mathbf{B}(t+\Delta t) \cdot d\mathbf{S} = 0. \end{aligned} \quad (23.2)$$

Fig. IV.12

Here the minus sign is associated with our choice of the orientation of the normal vector. For the lateral surface Σ one can, obviously, write (see fig. IV.12)

$$d\Sigma = (dl \times v) \Delta t,$$

where v is the velocity of motion of the current loop, and dl is an element of its length. Hence

$$\int_{\Sigma} \mathbf{B} \cdot d\Sigma = \int \mathbf{B} \cdot (dl \times v) \Delta t = \Delta t \oint (\mathbf{v} \times \mathbf{B}) \cdot d\mathbf{l}, \quad (23.3)$$

where the integral is taken with respect to the curve bounding the surface S_1 (i.e. with respect to the current loop). Further, to an accuracy of second order infinitesimal quantities, one can write

$$\int_{S_1} \mathbf{B}(t+\Delta t) \cdot d\mathbf{S} \approx \int_{S_1} \mathbf{B}(t) \cdot d\mathbf{S} + \Delta t \int_{S_1} \frac{\partial \mathbf{B}}{\partial t} \cdot d\mathbf{S}. \quad (23.4)$$

From (23.3), (23.4) and (23.2) we find

$$\int_{S_2} \mathbf{B}(t+\Delta t) \cdot d\mathbf{S} \approx \int_{S_1} \mathbf{B}(t) \cdot d\mathbf{S} + \Delta t \int_{S_1} \frac{\partial \mathbf{B}}{\partial t} \cdot d\mathbf{S} - \Delta t \oint (\mathbf{v} \times \mathbf{B}) \cdot d\mathbf{l}.$$

Substituting this expression into (23.1) and passing over to the limit, we find

$$\frac{d\Phi}{dt} = \frac{d}{dt} \int \mathbf{B} \cdot d\mathbf{S} = \int_{S_1} \frac{\partial \mathbf{B}}{\partial t} \cdot d\mathbf{S} - \oint (\mathbf{v} \times \mathbf{B}) \cdot d\mathbf{l}. \quad (23.5)$$

Formula (23.5) shows that a change with time in the flux of induction through the current loop can occur either owing to a change in the induction vector, or owing to the motion of the current loop at a non-zero angle with respect to the lines of the field (so that the velocity vector is not parallel to \mathbf{B}). In other words, if the moving current loop intersects the lines of the induction vector \mathbf{B} , then a change in the induction flux Φ in time arises.

Passing, in the second integral, over to the integration with respect to the surface, we can write

$$\frac{d\Phi}{dt} = \int \left[\frac{\partial \mathbf{B}}{\partial t} - \nabla \times (\mathbf{v} \times \mathbf{B}) \right] \cdot d\mathbf{S}. \quad (23.6)$$

We now write Faraday's law of induction for the moving current loop in the form

$$\oint \mathbf{E} \cdot d\mathbf{l} = -\frac{1}{c} \frac{d\Phi}{dt}, \quad (23.7)$$

where \mathbf{E} is the field strength in the conductor. It is clear that the total change in the flux of induction must remain on the right-hand side of (23.7) irrespective of the cause of this change.

The continuity of the tangential component of \mathbf{E} allows one to pass over from the conductor to a neighbouring contour lying in the medium outside the conductor. In this case one should not speak of the motion of the current loop but of the motion of the medium. The velocity \mathbf{v} denotes then the velocity of motion of a given point of the medium. One can pass over from (23.7) to the Maxwell differential equation in a moving medium.

Namely, writing by means of (23.5)

$$\oint \mathbf{E} \cdot d\mathbf{l} = \int (\nabla \times \mathbf{E}) \cdot d\mathbf{S} = -\frac{1}{c} \int \frac{\partial \mathbf{B}}{\partial t} \cdot d\mathbf{S} + \frac{1}{c} \int \nabla \times (\mathbf{v} \times \mathbf{B}) \cdot d\mathbf{S},$$

we have

$$\nabla \times \mathbf{E} = -\frac{1}{c} \left[\frac{\partial \mathbf{B}}{\partial t} - \nabla \times (\mathbf{v} \times \mathbf{B}) \right]. \quad (23.8)$$

We transform the expression in parentheses, writing on the basis of (I.45) and (I.18) that

$$\begin{aligned}\frac{\partial \mathbf{B}}{\partial t} - \nabla \times (\mathbf{v} \times \mathbf{B}) &= \frac{\partial \mathbf{B}}{\partial t} - (\mathbf{B} \cdot \nabla) \mathbf{v} + (\mathbf{v} \cdot \nabla) \mathbf{B} - \mathbf{v}(\nabla \cdot \mathbf{B}) + \mathbf{B}(\nabla \cdot \mathbf{v}) = \\ &= \frac{\partial \mathbf{B}}{\partial t} + (\mathbf{v} \cdot \nabla) \mathbf{B} = \frac{d\mathbf{B}}{dt}\end{aligned}$$

by virtue of (22.5) and the constancy of \mathbf{v} .

Then we find finally the value of $\nabla \times \mathbf{E}$ in the moving medium:

$$\nabla \times \mathbf{E} = -\frac{1}{c} \frac{d\mathbf{B}}{dt}. \quad (23.9)$$

The importance of the results obtained and, in particular, Faraday's law of induction in the form (23.7), is associated with the fact that the motion of conductors in a magnetic field is in practice one of the basic methods of producing an e.m.f. (for example, in the dynamo).

§ 24. Maxwell's equations for quasistationary fields in integral form and their integration for the case of linear conductors

We can now consider the Maxwell system of equations for quasistationary fields in integral form by considering the general case of moving media:

$$\oint \mathbf{E} \cdot d\mathbf{l} = -\frac{1}{c} \frac{d\Phi}{dt}, \quad (24.1)$$

$$\oint \mathbf{B} \cdot d\mathbf{S} = 0, \quad (24.2)$$

$$\oint \mathbf{H} \cdot d\mathbf{l} = \frac{4\pi I}{c}, \quad (24.3)$$

$$\oint \mathbf{D} \cdot d\mathbf{S} = 4\pi \int \rho \, dV. \quad (24.4)$$

According to (22.8), the continuity equation is written in the form

$$\oint \mathbf{j} \cdot d\mathbf{S} = 0. \quad (24.5)$$

Consider the case of linear conductors carrying current. For simplicity we confine ourselves first to one conducting loop. We assume that the impressed e.m.f. in the loop is defined; the value of the e.m.f. can depend on the time. We write the generalized Ohm's law in integral form as follows:

$$\oint \mathbf{j} \cdot \frac{d\mathbf{l}}{\sigma} = \oint \mathbf{E} \cdot d\mathbf{l} + \oint \mathbf{E}^{\text{imp}} \cdot d\mathbf{l}. \quad (24.6)$$

Since we are considering a linear contour and the continuity equation is valid, we can write it by means of (24.1), (15.4) and (15.6) in the form

$$IR = -\frac{1}{c} \frac{d\Phi}{dt} + \mathcal{E}(t). \quad (24.7)$$

Eq. (24.7), which connects the current in a loop with a given impressed e.m.f. $\mathcal{E}(t)$, is usually called Ohm's law for an alternating-current circuit.

If we now consider a system consisting of an arbitrary number N of loops carrying alternating current, then for each of these we can write

$$I_i R_i = -\frac{1}{c} \frac{d\Phi_i}{dt} + \mathcal{E}_i(t), \quad (24.8)$$

where Φ_i is the flux of induction through the i th conducting loop.

The magnetic field is determined from eqs. (24.2) and (24.3) which do not differ from the equations for direct current. Hence the relations obtained for direct current remain valid for all magnetic quantities. However, the equations for the magnetic field distribution and the current distribution in the circuit turn out to be interrelated: the flux of magnetic induction through the i th current loop is determined by the magnetic field distribution; the magnetic field distribution is determined by the currents in all the loops.

It is easily shown, however, that in quasistationary fields the fluxes of induction turn out to be connected with the current densities by linear relations with constant coefficients of the type

$$\Phi_i = c \sum_{k=1}^N L_{ik} I_k \quad (L_{ik} = L_{ki}). \quad (24.9)$$

For the proof we shall consider the simplest case of two current loops in a medium with magnetic permeability μ .

The current in the second loop (fig. IV.13) produces in the first loop a flux

Fig. IV.13

$$\Phi_1(2) = \mu \int \mathbf{H} \cdot d\mathbf{S}_1 = \int (\nabla \times \mathbf{A}_2) \cdot d\mathbf{S}_1 = \oint \mathbf{A}_2 \cdot d\mathbf{l}_1, \quad (24.10)$$

where the index 1 refers to the first loop.

The vector potential of the magnetic field of the linear conductor carrying current I_2 is given by formula (17.4). Hence

$$\Phi_1(2) = \frac{\mu I_2}{c} \oint \oint \frac{d\mathbf{l}_1 \cdot d\mathbf{l}_2}{r_{12}} = c L_{12} I_2, \quad (24.11)$$

i.e. the flux of induction in the first loop, which is produced by the current in the second loop, is proportional to the current I_2 in the latter. The factor of proportionality L_{12} turns out to be a constant which depends only on the properties of the medium and the relative position of the loops:

$$L_{12} = \frac{\mu}{c^2} \oint \oint \frac{d\mathbf{l}_1 \cdot d\mathbf{l}_2}{r_{12}}, \quad (24.12)$$

where r_{12} is the distance between the elements of length $d\mathbf{l}_1$ and $d\mathbf{l}_2$. The quantity L_{12} is called the coefficient of mutual inductance.

Besides the flux of magnetic induction $\Phi_1(2)$, the flux produced by the current in the first loop itself

$$\Phi_1(1) = c L_{11} I_1, \quad (24.13)$$

passes through the first loop. The factor of proportionality L_{11} is called the coefficient of self-inductance. The meaning of the coefficient of self-inductance is the following. The flux of magnetic induction through a certain segment of the wire is obtained by summing the fluxes from its other segments. In all segments of the wire there flows the same current I_1 .

It is clear, however, that formula (24.12) cannot be used for the calculation of the coefficient of self-inductance. When the segment $d\mathbf{l}_2$ approaches the segment $d\mathbf{l}_1$ in the same conductor $r_{12} \rightarrow 0$, and the integral (24.12) diverges. The cause of this divergence lies in the fact that, if the segment $d\mathbf{l}_2$ is close to $d\mathbf{l}_1$, the transverse dimensions of the conductor become comparable with the distance r_{12} between these segments. This, in its turn, does not allow one to make use of the formula (17.4) which was found for the approximation of linear conductors. In other words, in considering the interrelation between nearby segments of one conductor the linear conductor approximation is undoubtedly incorrect. In later sections we shall see how one can find the coefficient of self-inductance without having recourse to the idea of the linear character of the conductor. In the meantime we can write the total flux of magnetic induction through the first conductor in the form

$$\Phi_1 = cL_{11}I_1 + cL_{12}I_2. \quad (24.14)$$

Analogously, the flux of magnetic induction through the second conductor is

$$\Phi_2 = cL_{22}I_2 + cL_{21}I_1.$$

It is easily shown that the equality $L_{21} = L_{12}$ holds. Indeed,

$$L_{21} = \frac{\mu}{c^2} \oint \oint \frac{d\mathbf{l}_2 \cdot d\mathbf{l}_1}{r_{21}} = \frac{\mu}{c^2} \oint \oint \frac{d\mathbf{l}_1 \cdot d\mathbf{l}_2}{r_{12}} = L_{12}. \quad (24.15)$$

The equation (24.7) of the generalized Ohm's law for the first loop assumes the form

$$I_1 R_1 = -L_{11} \frac{dI_1}{dt} - L_{12} \frac{dI_2}{dt} + \mathcal{E}_1(t). \quad (24.16)$$

An analogous expression can be written for the second loop.

In the general case of an arbitrary number of loops the flux of magnetic induction through the loop i is expressed according to formula (24.9) in terms of currents in all the loops, the coefficient of self-inductance L_{ii} and the coefficients of mutual inductance L_{ik} . Substituting (24.9) into Ohm's law for alternating-current circuits, we find the whole set of equations which determine the current I_i in each of the N loops:

$$I_i R_i = - \sum_k L_{ik} \frac{dI_k}{dt} + \mathcal{E}_i(t) \quad (i=1,2,\dots,N). \quad (24.17)$$

If the impressed e.m.f. \mathcal{E}_i and the geometrical properties of the system of loops determining the whole set of coefficients L_{ik} are defined, then the integration of the system of linear differential equations (24.17) with constant coefficients allows one to determine the currents I_i in the loops. In this case the magnetic fields will be determined according to formulae (24.2) and (24.3).

Thus, corresponding to what was said at the end of §22, the equations of the quasistationary electromagnetic field for the case of a system of linear conductors reduce to equations in total derivatives with constant coefficients. The latter, however, as is known from the general theory of differential equations, reduce to a system of algebraic equations. We shall carry this out in following sections.

The densities of volume charges arising in certain cases in conductors are usually calculated by means of formula (24.4) from a given distribution of the electric field.

As an example of the applications of formulae (24.11) and (24.12) we shall calculate the coefficient of mutual inductance of two straight parallel linear conductors of length l . For definiteness we assume the currents in the conductors to be directed in one direction. We denote by h the distance between the conductors. Then, according to formula (24.12), we have

$$\begin{aligned} L_{12} &= \frac{\mu}{c^2} \int \frac{d\mathbf{l}_1 \cdot d\mathbf{l}_2}{r_{12}} = \frac{\mu}{c^2} \int_0^l \int_0^l \frac{dx_1 dx_2}{[(x_1 - x_2)^2 + h^2]^{\frac{1}{2}}} = \\ &= \frac{\mu}{c^2} \int_0^l dx_1 \ln \left[\frac{(l - x_1) + [(l - x_1)^2 + h^2]^{\frac{1}{2}}}{-x_1 + [x_1^2 + h^2]^{\frac{1}{2}}} \right]. \end{aligned}$$

The calculation of the second integral is somewhat cumbersome. Integrating by parts, we obtain

$$L_{12} = \frac{\mu}{c^2} \left\{ l \ln \left[\frac{h}{-l + [l^2 + h^2]^{\frac{1}{2}}} \right] - 2([l^2 + h^2]^{\frac{1}{2}} - h) + l \ln \left[\frac{l}{-l + [l^2 + h^2]^{\frac{1}{2}}} \right] \right\}.$$

We can simplify this expression for two limiting cases: when $h \ll l$ or $h \gg l$.

In the first case we easily find, with an accuracy to the order of magnitude of h^2/l^2 ,

$$L_{12} \approx \frac{2\mu l}{c^2} \left[\ln \frac{2l}{h} - 1 + \frac{h}{l} \right].$$

In the other limiting case, with an accuracy to the order of magnitude of l^2/h^2 ,

$$L_{12} \approx \frac{\mu}{c^2} \frac{l^2}{h}.$$

In order to compare different methods of calculating L_{12} we shall find the coefficient of mutual inductance of two solenoids wound around a common toroidal core.

We assume the diameter D of the ring (proportional to the length of the solenoids) to be large in comparison with the diameter of the turns. The magnetic field inside the toroidal solenoid can be assumed to be uniform, and one can write

$$\oint \mathbf{H} \cdot d\mathbf{l} = 2\pi DH = \frac{4\pi}{c} n_1 I_1,$$

where n_1 is the number of turns in the first solenoid, and I_1 is the current in it. Whence

$$H = \frac{2n_1 I_1}{cD}. \quad (24.18)$$

The flux of induction through n_2 turns of the second solenoid (assuming that there is no leakage and that all lines of flux of the magnetic field produced by the first solenoid permeate the second solenoid) will be equal to

$$\Phi_{21} = \mu H n_2 S = \frac{2\mu n_1 n_2 S}{cD} I_1,$$

where S is the cross-section of the solenoid. From (24.11) we find

$$L_{21} = \frac{2\mu n_1 n_2 S}{c^2 D}.$$

§ 25. The energy of the magnetic field of a system of quasistationary currents

Let us find the energy of the magnetic field of a system of currents in the approximation of quasistationary fields.

As we have seen in § 7, the total energy (more precisely the free energy) of the magnetic field is

$$T_{\text{magn}} = \int \frac{\mathbf{B} \cdot \mathbf{H}}{8\pi} dV.$$

Here it has been assumed that there are no ferromagnetics in the volume V . The integration is carried out over all space.

Expressing \mathbf{B} in terms of the vector potential and making use of the first of eqs. (22.5), we have

$$\mathbf{B} \cdot \mathbf{H} = \mathbf{H} \cdot (\nabla \times \mathbf{A}) = \mathbf{A} \cdot (\nabla \times \mathbf{H}) + \nabla \cdot (\mathbf{A} \times \mathbf{H}) = \frac{4\pi}{c} (\mathbf{A} \cdot \mathbf{j}) + \nabla \cdot (\mathbf{A} \times \mathbf{H}).$$

Hence

$$T_{\text{magn}} = \frac{1}{2c} \int \mathbf{A} \cdot \mathbf{j} dV + \int \frac{\nabla \cdot (\mathbf{A} \times \mathbf{H})}{8\pi} dV. \quad (25.1)$$

In integrating over all space the last integral reduces to zero, and we find finally

$$T_{\text{magn}} = \frac{1}{2c} \int \mathbf{A} \cdot \mathbf{j} dV. \quad (25.2)$$

In formula (25.2) \mathbf{A} represents the vector potential produced at a given point by all the currents, and \mathbf{j} is the current density at the same point.

The integration over the entire volume can now be replaced by the integration over the volumes occupied by the current carrying conductors. Outside these volumes $\mathbf{j} = 0$ and the integral (25.2) vanishes. Hence

$$T_{\text{magn}} = \frac{1}{2c} \int \mathbf{A} \cdot \mathbf{j} dv, \quad (25.3)$$

where dv is a volume element of the conductor.

Let there be N conductors in the entire system. We divide the integral (25.3) into two parts, writing

$$T_{\text{magn}} = \frac{1}{2c} \sum_i \int \mathbf{A}_i \cdot \mathbf{j}_i dv_i + \frac{1}{c} \sum_{k>i} \int \mathbf{A}_k \cdot \mathbf{j}_i dv_i. \quad (25.4)$$

In the integral contained in the first sum, \mathbf{A}_i denotes the vector potential of the magnetic field produced in the volume element dv_i of a given conductor by the currents which are present in other elements of the same conductor.

In the integral in the second sum, \mathbf{A}_k represents the vector potential of the field produced in the volume element dv_i by the currents in all the other conductors. Consequently, the first sum represents the sum of the self energies of all the N conductors. The second sum gives the mutual energy of these conductors.

An actual calculation of the energy T_{magn} encounters great difficulties in the case of conductors which are placed in a medium which can be magnetized. Since the magnetic permeability of the conductors, generally speaking, differs from the permeability of the medium, it is necessary to know the distribution of the vector potential in a non-homogeneous medium in order to calculate the energy of the currents according to formula (25.4). Finding this distribution presents great difficulties. We shall therefore confine ourselves to the case where $\mu \approx \mu_0 \approx 1$ in the conductors as well as in the medium which surrounds them. In other words, we shall consider the conductors together with the medium which surrounds them as a quasi-homogeneous system. In this case the vector potential at any point of space is given by formula (17.4).

Substituting (17.4) into (25.4), we find

$$T_{\text{magn}} = \frac{\mu}{2c^2} \sum_i \iint \frac{\mathbf{j}'_i \cdot \mathbf{j}_i dv_i dv'_i}{r} + \frac{\mu}{c^2} \sum_{k>i} \iint \frac{\mathbf{j}_k \cdot \mathbf{j}_i dv_i dv_k}{r}, \quad (25.5)$$

where \mathbf{j}' is the density of the current in the volume element dv'_i producing the field in the volume dv_i , and r is the distance between dv_i and dv'_i .

Just as the energy of the electrostatic field in the case of a system of conductors reduces to the sum of the energies of the latter, the energy of the magnetic field given by formula (25.5) can be considered as the energy of the quasistationary currents.

We define the coefficients of self-inductance L_{ii} and the coefficients of mutual inductance L_{ik} in such a way that the following equality holds:

$$\begin{aligned}
 T_{\text{magn}} &= \frac{\mu}{2c^2} \sum_i \iint \frac{\mathbf{j}_i \cdot \mathbf{j}'_i dv_i dv'_i}{r} + \frac{\mu}{c^2} \sum_{k>i} \iint \frac{\mathbf{j}_k \cdot \mathbf{j}_i dv_i dv_k}{r} \equiv \\
 &\equiv \sum_i L_{ii} \frac{I_i^2}{2} + 2 \sum_{k>i} L_{ik} \frac{I_i I_k}{2}.
 \end{aligned} \tag{25.6}$$

The first sum represents the sum of the self energies of the currents in all the conductors, while the second sum represents the sum of the mutual energies.

Formula (25.6) is equally valid for linear and non-linear conductors.

In the case of linear conductors the definition of the coefficients of mutual inductance is the same as (24.12). Indeed, in this case

$$\frac{\mu}{c^2} \sum_{k>i} \iint \frac{\mathbf{j}_k \cdot \mathbf{j}_i dv_i dv_k}{r} = \frac{\mu}{c^2} \sum_{k>i} I_i I_k \iint \frac{d\mathbf{l}_1 \cdot d\mathbf{l}_2}{r} = \sum_{k>i} I_i I_k L_{ik},$$

where the definition of L_{ik} is the same as (24.12).

The new definition of the coefficients of self-inductance is of fundamental importance for non-linear conductors. It is free of the difficulties associated with an indefinite increase of the integral as $r \rightarrow 0$ (see § 24). As $r \rightarrow 0$ the volume elements $dv dv'$ decrease more rapidly than r^{-1} , and the integral tends to zero. For this reason, as we shall see below in a practical example, formula (25.6) serves as the definition of the coefficients of self-inductance.

The energy T_{magn} of a set of linear conductors can be written in another form. Namely, in the case of linear currents the first term of (25.4) can be written in the form

$$\begin{aligned}
 T_{\text{magn}} &= \frac{1}{2c} \sum_i \int \mathbf{A}_i \cdot \mathbf{j}_i d\mathbf{S}_i \cdot d\mathbf{l}_i = \frac{1}{2c} \sum_i I_i \oint \mathbf{A}_i \cdot d\mathbf{l}_i = \\
 &= \frac{1}{2c} \sum_i I_i \int (\nabla \times \mathbf{A}_i) \cdot d\mathbf{S}_i = \frac{1}{2c} \sum_i I_i \int \mathbf{B}_i \cdot d\mathbf{S}_i = \frac{1}{2c} \sum_i I_i \Phi_i,
 \end{aligned}$$

where $\Phi_i = \int \mathbf{B}_i \cdot d\mathbf{S}_i$ is the flux of magnetic induction through the i th conductor.

Let us find the coefficient of self-inductance for certain simple systems.

As the first example we shall consider the coefficient of self-inductance of a toroidal solenoid. The field inside the solenoid is given by formula (24.18). The energy of the field is equal to

$$\frac{\mu H^2 V}{8\pi} = \frac{\mu n^2 I^2 S \cdot 2\pi D}{2\pi c^2 D^2} = \frac{LI^2}{2},$$

hence

$$L = \frac{2\mu n^2 S}{c^2 D}.$$

Let us now consider the coefficient of self-inductance of two coaxial cylinders along which identical and oppositely directed currents of intensity I are flowing. Let the radii of the cylinders be R_1 and R_2 , their length l , and the thickness of the walls negligibly small. It is obvious that the magnetic field inside the small cylinder and outside the large cylinder is equal to zero. The field in the gap between the cylinders has the strength

$$H = \frac{2I}{cr}.$$

The energy of the field is equal to

$$\int \frac{\mu H^2}{8\pi} dV = \frac{\mu I^2 l}{c^2} \int_{R_1}^{R_2} \frac{r dr}{r^2} = \frac{\mu I^2 l}{c^2} \ln \frac{R_2}{R_1}.$$

Hence

$$L = \frac{2\mu l}{c^2} \ln \frac{R_2}{R_1}.$$

§26. Coefficients of self-inductance and mutual inductance for non-linear conductors

In calculating coefficients of self-inductance and mutual inductance for non-linear conductors we shall confine ourselves to the case where the magnetic permeability of the conductors and the medium is close to unity (i.e.

where there are no ferromagnetic materials in the system). In this case it can be assumed approximately that μ has the same value μ_0 over all space. In other words, we shall assume the entire system to be homogeneous in its magnetic properties.

For brevity of notation we shall assume that the system is made up of two non-linear conductors. We shall assume the geometrical form and the current density distribution inside the conductors to be invariable in time, and the conductors to be at rest and non-deformable.

We divide the two non-linear conductors into a set of current tubes. The possibility of such a division follows from the solenoidal character of currents in quasistationary fields. For each tube dS_α one can write the relation (24.6), i.e.

$$\oint \mathbf{j}_\alpha \cdot \frac{d\mathbf{l}_\alpha}{\sigma_\alpha} = \oint \mathbf{E}_\alpha \cdot d\mathbf{l}_\alpha + \oint \mathbf{E}_\alpha^{\text{imp}} \cdot d\mathbf{l}_\alpha. \quad (26.1)$$

The relations (16.5) – (16.7), which have been obtained for any solenoidal current, are valid for quasistationary currents. Multiplying both sides of the eq. (26.1) by $I^{-1}dI_\alpha$, a quantity which is constant along the conductor, and integrating over the entire section of the conductor, we have

$$\int_S \frac{dI_\alpha}{I} \oint \mathbf{j}_\alpha \cdot \frac{d\mathbf{l}_\alpha}{\sigma_\alpha} = \int_S \frac{dI_\alpha}{I} \oint \mathbf{E}_\alpha \cdot d\mathbf{l}_\alpha + \int_S \frac{dI_\alpha}{I} \oint \mathbf{E}_\alpha^{\text{imp}} \cdot d\mathbf{l}_\alpha. \quad (26.2)$$

We transform the integrals in (26.2) for example for the first conductor in the following way:

$$\begin{aligned} \int_{S_1} \frac{dI_\alpha^{(1)}}{I_1} \oint \mathbf{j}_1 \cdot \frac{d\mathbf{l}_1}{\sigma_1} &= \iint \frac{dI_\alpha^{(1)}}{I_1} \mathbf{j}_1 \cdot \frac{d\mathbf{l}_1}{\sigma_1} = \int_{S_1} \oint \psi_1 \frac{dS_\alpha^{(1)}}{S_1} \mathbf{j}_1 \cdot \frac{d\mathbf{l}_1}{\sigma_1} = \\ &= \iint \frac{I_1 \psi_1^2 dS_\alpha^{(1)} d\mathbf{l}_1}{\sigma_1 S_1^2} = I_1 \int_{S_1} \oint \frac{\psi_1^2 dS_\alpha^{(1)} d\mathbf{l}_1}{\sigma_1 S_1^2} = I_1 R_1, \end{aligned} \quad (26.3)$$

where R_1 is the total ohmic resistance of the first conductor. Here we have made use of (16.7) and (16.8). For a linear conductor $\psi = 1$ and the expression for R is the same as (15.4). Further, on the basis of (23.7) and (24.10) we have

$$\begin{aligned}
 \int_{S_1} \frac{dI_{\alpha}^{(1)}}{I} \oint \mathbf{E}_1 \cdot d\mathbf{l}_1 &= -\frac{1}{c} \int_{S_1} \frac{dI_{\alpha}^{(1)}}{I} \frac{d\Phi_1}{dt} = -\frac{1}{c} \frac{d}{dt} \oint_S \frac{dI_{\alpha}}{I} \mathbf{A}_1 \cdot d\mathbf{l}_1 = \\
 &= -\frac{1}{c} \frac{d}{dt} \oint_S \mathbf{j}_1 \cdot \frac{\mathbf{A}_1 dI_1 dS_{\alpha}}{I} = -\frac{1}{c} \frac{d}{dt} \frac{1}{I} \int \mathbf{j}_1 \cdot \mathbf{A}_1 dv, \quad (26.4)
 \end{aligned}$$

Here \mathbf{A}_1 is the vector potential of the magnetic field at a point in the volume element dv .

We shall now, for definiteness, consider the first conductor. Since by assumption the conductors and the medium are homogeneous in respect to their magnetic properties, we can make use of the expression (17.3) for \mathbf{A}_1 , which for our purposes is conveniently written in the form

$$\mathbf{A}_1 = \frac{\mu_0}{c} \int \mathbf{j}' \frac{dV'}{r} = \frac{\mu_0}{c} \int \mathbf{j}'_1 \frac{dv'_1}{r'_{11}} + \frac{\mu_0}{c} \int \mathbf{j}_2 \frac{dv_2}{r_{12}}. \quad (26.5)$$

The first term gives the vector potential produced by the currents in the volume of the first conductor, the second term gives the vector potential produced by the currents in the volume of the second conductor, r'_{11} denotes the distance between the points to which the element dv'_1 and the element $d\mathbf{l}_1$ are referred respectively, and r_{12} has an analogous meaning.

Substituting the value of \mathbf{A}_1 into (26.4), we have

$$\begin{aligned}
 \int_{S_1} \frac{dI_{\alpha}^{(1)}}{I_1} \oint \mathbf{E}_1 \cdot d\mathbf{l}_1 &= \\
 &= -\frac{\mu_0}{c^2} \frac{d}{dt} \frac{1}{I_1} \iint \frac{\mathbf{j}_1 \cdot \mathbf{j}'_1 dv_1 dv'_1}{r'_{11}} - \frac{\mu_0}{c^2} \frac{d}{dt} \frac{1}{I_1} \iint \frac{\mathbf{j}_1 \cdot \mathbf{j}_2 dv_1 dv_2}{r_{12}}. \quad (26.6)
 \end{aligned}$$

We now introduce the coefficients of self-inductance and mutual inductance, defining them by the formulae:

$$L_{11} = \frac{1}{I_1^2} \frac{\mu_0}{c^2} \iint \frac{\mathbf{j}'_1 \cdot \mathbf{j}_1 dv'_1 dv_1}{r'_{11}}, \quad (26.7)$$

$$L_{12} = \frac{1}{I_1 I_2} \frac{\mu_0}{c^2} \iint \frac{\mathbf{j}_1 \cdot \mathbf{j}_2 dv_1 dv_2}{r_{12}}, \quad (26.8)$$

$$L_{21} = L_{12} . \quad (26.9)$$

It is easily seen that L_{11} and L_{12} do not depend on the current intensities I_1 and I_2 . Indeed, from (16.8) we have

$$L_{11} = \frac{\mu_0}{c^2} \iint \frac{\psi_1 \psi'_1}{S_1 S'_1} \frac{\mathbf{l}_1 \cdot \mathbf{l}'_1}{r'_{11}} dv'_1 dv_1 , \quad (26.10)$$

$$L_{12} = \frac{\mu_0}{c^2} \iint \frac{\psi_1 \psi_2}{S_1 S_2} \frac{\mathbf{l}_1 \cdot \mathbf{l}_2}{r_{12}} dv_1 dv_2 . \quad (26.11)$$

Then, finally,

$$\int_{S_1} \frac{dI_\alpha}{I_1} \oint \mathbf{E}_1 \cdot d\mathbf{l}_1 = -L_{11} \frac{dI_1}{dt} - L_{12} \frac{dI_2}{dt} \quad (26.12)$$

and analogously for the second conductor.

In the integral $\int I^{-1} dI_\alpha \oint \mathbf{E}^{\text{imp}} \cdot d\mathbf{l}$ one can assume that the impressed e.m.f. is the same over the whole section of the conductor and write

$$\int \frac{dI'_\alpha}{I_1} \oint \mathbf{E}_1^{\text{imp}} \cdot d\mathbf{l}_1 = \mathcal{E}_1 . \quad (26.13)$$

Substituting (26.3), (26.12) and (26.13) into (26.2), we find finally

$$I_1 R_1 = -L_{11} \frac{dI_1}{dt} - L_{12} \frac{dI_2}{dt} + \mathcal{E}_1 \quad (26.14)$$

and analogously

$$I_2 R_2 = -L_{22} \frac{dI_2}{dt} - L_{21} \frac{dI_1}{dt} + \mathcal{E}_2 . \quad (26.15)$$

Eqs. (26.14) and (26.15) are the same as eqs. (24.17) for linear currents. A difference between them lies in the fact that for non-linear conductors finding the resistances and coefficients of inductance is a very complex problem. All these quantities involve current distributions over the cross-sections of the conductors. Therefore the practical importance of the equations obtained is not great. To make up for it we have obtained a definition of coefficients of inductance (26.7) – (26.9) which is not based (in contrast to (24.12) and (24.13)) on the assumption of linearity of the conductors.

In conclusion we stress that, as is easily seen, the coefficient of mutual inductance defined by formula (26.8) for a linear conductor ($\psi_1 = \psi_2 = 1$) is the same as (24.12).

§27. Lagrange's equations for a system of quasistationary currents

Up to now we have assumed that the relative position of the current carrying conductors is given. In practice one often has to consider the more general case of moving conductors or conductors changing their shape, relative position etc., which are placed in an electromagnetic field. The capacitances, self-inductances, mutual inductances and other quantities, which we have before assumed to be constant, turn out in this case to be functions of certain parameters q_i which characterize the configuration of the system. In considering such systems it is very convenient to make use of Lagrange's method in which, as will be seen from what follows, the electromagnetic and mechanical quantities characterizing the system come in as formally equivalent quantities. It turns out that the quoted parameters q_i , as well as the values of charges Q_i in the conductors, can be chosen as generalized coordinates.

Let us work out the Lagrange equations characterizing the system in generalized coordinates q_i and Q_i . The generalized velocities corresponding to the charges Q_i are the quantities $\dot{Q}_i = I_i$, i.e. currents flowing in the conductors. If the energy of the magnetic field is included in the kinetic energy of the system, then the total kinetic energy is equal to

$$\begin{aligned} T = T_{\text{mech}} + T_{\text{magn}} &= \frac{1}{2} \sum_{i,k} L_{ik}(q_i, t) I_i(t) I_k(t) + T_{\text{mech}} = \\ &= \frac{1}{2} \sum_{i,k} L_{ik} \dot{Q}_i \dot{Q}_k + T_{\text{mech}}, \end{aligned} \quad (27.1)$$

where T_{mech} is the kinetic energy of the mechanical motion of the conductors.

Analogously, we assume the potential energy of the system to be made up of the energy of the electric field (i.e. the energy of the capacitances present in the system) and the mechanical potential energy:

$$U = \sum \frac{Q_i^2(t)}{2C_i(q_i, t)} + U_{\text{mech}}. \quad (27.2)$$

Then the Lagrange function will have the form

$$L = \frac{1}{2} \sum L_{ik} \dot{Q}_i \dot{Q}_k - \frac{1}{2} \sum \frac{Q_i^2}{C_i} + (T_{\text{mech}} - U_{\text{mech}}). \quad (27.3)$$

We also introduce the dissipative function

$$F = \frac{1}{2} \sum R_i(q_i, t) \dot{Q}_i^2 \quad (27.4)$$

and arbitrary "external" forces acting on the system — impressed e.m.f. \mathcal{E}_i . We recall that external forces F_{ext} in the Lagrange equations represent forces which depend not only on the generalized coordinates but also on other parameters bearing no relation to the given system. These forces are defined by the usual relation $\delta A = F_{\text{ext}} \delta q$, where δA is the virtual work done in the virtual displacement δq .

Then the Lagrange equations for the generalized coordinates Q_i assume the form

$$\frac{d}{dt} \frac{\partial L}{\partial \dot{Q}_i} - \frac{\partial L}{\partial Q_i} = - \frac{\partial F}{\partial \dot{Q}_i} + F_{\text{ext}}. \quad (27.5)$$

Upon substituting L into (27.5) and assuming that the current loops are motionless and non-deformable (constant inductances and capacitances) we obtain

$$\sum L_{ik} \ddot{Q}_k + \frac{Q_i}{C_i} = - R_i \dot{Q}_i + \mathcal{E}_i, \quad (27.6)$$

which shows that the expressions for the kinetic and potential energies are appropriately chosen.

From the Lagrange equation (27.6) there follows the momentum conservation law and the energy conservation law. For a system which is not acted upon by any external forces (i.e. $F_{\text{ext}} = 0$) and in which no energy dissipation occurs (i.e. $F = 0$) eq. (27.5) assumes the form

$$\frac{d}{dt} \frac{\partial L}{\partial \dot{Q}_i} - \frac{\partial L}{\partial Q_i} = 0.$$

If there is no capacitance in the i th current loop, then the corresponding coordinate is cyclic and the following equality holds for it:

$$\frac{\partial L}{\partial Q_i} = 0.$$

In this case the corresponding generalized momentum is conserved:

$$\frac{\partial L}{\partial \dot{Q}_i} = \frac{\partial L}{\partial I_i} = \sum L_{ik} I_k = \text{const}.$$

Let us now write the energy conservation law for a system of conductors at rest. According to general rules, the energy of the system is

$$E = \sum \frac{\partial L}{\partial \dot{Q}_i} \dot{Q}_i - L = \frac{1}{2} \sum L_{ik} \dot{Q}_i \dot{Q}_k + \frac{1}{2} \sum \frac{Q_i^2}{C_i}. \quad (27.7)$$

In the presence of dissipative processes

$$\frac{dE}{dt} = -2F + \sum F_{\text{ext}} \dot{Q}_i.$$

Here $2F$ is the energy dissipated, and $\sum F_{\text{ext}} \dot{Q}_i$ is the work done by external forces per unit time.

Substituting the values of E and F , we write the energy conservation law in the form

$$\frac{d}{dt} \left(\frac{1}{2} \sum L_{ik} \dot{Q}_i \dot{Q}_k + \frac{1}{2} \sum \frac{Q_i^2}{C_i} \right) = - \sum R_i \dot{Q}_i^2 + \sum \mathcal{E}_i \dot{Q}_i. \quad (27.8)$$

Rewriting it in the form

$$\frac{d}{dt} (T_{\text{magn}} + U_{\text{el}}) = \sum (\mathcal{E}_i I_i - R_i I_i^2), \quad (27.9)$$

we see that in a closed system which is not acted upon by any external forces ($\mathcal{E}_i = 0$) and in which there are no dissipative forces ($R_i \neq 0$) the energy of the system is conserved:

$$T_{\text{magn}} + U_{\text{el}} = 0. \quad (27.10)$$

In the case where $\mathcal{E}_i \neq 0$, $R_i \neq 0$, formula (27.9) shows that the difference between the work done by the impressed e.m.f. and the Joule heat released goes into an increase in the energy of the magnetic and electric fields as well as into the increase in the mechanical energy of the system in the case of a system of moving current contours.

In the particular case of one motionless current loop, (27.9) can be rewritten in the form

$$\frac{d}{dt} \left(\frac{LI^2}{2} + \frac{Q^2}{2C} \right) = \mathcal{E}I - RI^2.$$

The relations obtained are valid for a system of loops which are coupled with each other inductively (i.e. in the presence of coefficients L_{ik} differing from zero) as well as for a system of branched loops. In the latter case Kirchhoff's law allows one to reduce the number of independent currents I_i or coordinates Q_i .

In conclusion we note that the results of this section justify to a certain degree the term "impressed e.m.f.", since this quantity indeed plays the role of a generalized force acting on the system.

We apply the results obtained to a single alternating current circuit of resistance, inductance and capacitance in series (the so-called RLC -series circuit). Eq. (27.6) assumes the form

$$L \frac{d^2 Q}{dt^2} + \frac{Q}{C} = -R\dot{Q} + \mathcal{E}(t). \quad (27.11)$$

If the source of the alternating current (an impressed e.m.f.) represents a harmonic function of time

$$\mathcal{E}(t) = \mathcal{E}_0 e^{i\omega t},$$

then the particular solution of (27.11) has the form

$$Q = Q_0 e^{i\omega t}.$$

We are interested in the dependence of the current on time, which also can be written in the form

$$I = I_0 e^{i\omega t}.$$

Substituting this into (27.11), we obtain

$$I_0 = \mathcal{E}_0 / Z^*,$$

where the quantity Z^* , called the impedance, is equal to

$$Z^* = R + i \left(\omega L - \frac{1}{\omega C} \right). \quad (27.12)$$

Passing over from the complex expression to the real expression for the current, we find

$$I = \frac{\mathcal{E}_0 \cos(\omega t - \varphi)}{[R^2 + (\omega L - 1/\omega C)^2]^{\frac{1}{2}}}, \quad (27.13)$$

$$\varphi = \arctan \frac{(\omega L - 1/\omega C)}{R}.$$

We see that forced current oscillations with frequency ω , which are shifted in phase by an angle φ with respect to the impressed e.m.f., arise in the circuit.

Besides the forced oscillations there can exist free or natural oscillations. If the impressed e.m.f. is $\mathcal{E} = 0$, then from (27.11) we easily find

$$I = I_0 e^{i\omega_0 t},$$

where the frequency of the natural oscillations is

$$\omega_0 = i \frac{R}{2C} \pm \left(\frac{1}{LC} - \left(\frac{R}{2L} \right)^2 \right)^{\frac{1}{2}}. \quad (27.14)$$

For $R/2C < (CL)^{-\frac{1}{2}}$ damped oscillations occur, the damping being characterized by the time $\tau = 2C/R$. For $R/2C > (CL)^{-\frac{1}{2}}$ the discharge has an aperiodic character.

If the system contains several loops which are connected with each other by corresponding coefficients of mutual inductance, then the system of eqs. (27.6) can be solved according to the general rules of solution of a system of linear equations with constant coefficients. For a detailed analysis of such problems, which is of special interest in electrical engineering, we refer the reader to specific literature *.

* See, for example, W.R.Smythe, *Static and dynamic electricity* (McGraw-Hill, New York, 1950).

§28. The generalized ponderomotive forces in a system with moving current loops

In the preceding section we have confined ourselves to the case of motionless loops. We shall now consider moving current loops.

We shall find, first of all, an expression for the generalized force corresponding to the mechanical generalized coordinate q_i characterizing the spatial configuration of the i th current loop. By definition

$$F_{q_i} = \frac{\partial L}{\partial q_i}.$$

It can usually be assumed that the capacitances which are present in the system do not change when the conductors are moving. Then substituting L from (27.3), we find

$$F_{q_i} = \frac{\partial L}{\partial q_i} = \frac{\partial}{\partial q_i} T_{\text{magn}} = \frac{\partial}{\partial q_i} \frac{1}{2} \sum L_{ik}(q_i, q_k) I_i I_k. \quad (28.1)$$

We see that the energy of the magnetic field plays a double role: with respect to the coordinates of electromagnetic character, Q_i , it represents a kinetic energy, while with respect to the space coordinates q_i it represents a potential energy taken with the opposite sign. Ponderomotive forces act in a direction which corresponds to an increase of the magnetic energy of the field.

We shall apply formula (28.1) to certain practical cases.

Let us first consider mechanical forces acting on a single current loop. Let q be the generalized coordinate characterizing the size of the loop. The force acting on the loop on the part of its own magnetic field is

$$F_q = \frac{I^2}{2} \frac{\partial L_{ii}}{\partial q}, \quad (28.1')$$

The force acting on the current loop increases with increasing $\partial L_{ii}/\partial q$. Since the self-inductance increases with increasing size of the loop, this means that the magnetic field of the current loop tends to deform the conductor in such a way that its size would increase.

For a system of conductors we shall first consider one moving loop whose position is characterized by the coordinate q_α . We assume that the configuration and currents in all other loops in the system are given. Then the force acting on the moving loop is

$$\begin{aligned}
 F_{q_\alpha} &= \frac{\partial}{\partial q_\alpha} \frac{1}{2} \sum_{i,k} L_{ik}(q_i, q_k) I_i I_k = \\
 &= \frac{1}{2} \sum_k \frac{\partial L_{\alpha k}}{\partial q_\alpha} I_\alpha I_k + \frac{1}{2} \sum_i \frac{\partial L_{i\alpha}}{\partial q_\alpha} I_i I_\alpha = \\
 &= I_\alpha \sum_k \frac{\partial L_{\alpha k}}{\partial q_\alpha} I_k = \frac{I_\alpha}{c} \frac{\partial \Phi_\alpha}{\partial q_\alpha}, \quad (28.2)
 \end{aligned}$$

The fixed positions in space of all the loops except the α th correspond to a given value of the external field. In this derivation we have made use of the equality (24.9): the definition of the flux of induction.

If, in particular, the generalized coordinate q_α represents the angle θ which characterizes the position of a flat current loop in an external field, then the generalized force F_θ represents the torque acting on the loop:

$$M = \frac{I}{c} \frac{\partial \Phi}{\partial \theta}.$$

The flux of induction through a non-deformable flat current loop in an external field \mathbf{B}_0 is equal to

$$\Phi = B_0 S \cos \theta,$$

where S is the area of the contour, and θ is the angle between \mathbf{B}_0 and the normal to the plane. Hence

$$M = -\frac{IS}{c} B_0 \sin \theta. \quad (28.3)$$

We note that the generalized force (28.2) reduces, in the case of one current loop in an external magnetic field, to the Lorentz force. Indeed, writing for $\delta\Phi$

$$\delta\Phi = \mathbf{B} \cdot (\delta\mathbf{q} \times \delta\mathbf{l}) = (\delta\mathbf{l} \times \mathbf{B}) \cdot \delta\mathbf{q},$$

we have

$$d\mathbf{F} = c^{-1} I(d\mathbf{l} \times \mathbf{B}) = c^{-1} (d\mathbf{l} \times \mathbf{B})(\mathbf{j} \cdot d\mathbf{S}) = c^{-1} (\mathbf{j} \times \mathbf{B}) dV, \quad (28.4)$$

where $dV = d\mathbf{S} \cdot d\mathbf{l}$ is a volume element of the current carrying conductor. The force (28.4) is the averaged Lorentz force in which the mean magnetic field in the medium \mathbf{B} appears instead of the field in vacuum \mathbf{H} .

Let us now consider a system of two current carrying conductors and find the force of interaction between them. In this case one has to choose the distance r_{12} between the elements $d\mathbf{l}_1$ and $d\mathbf{l}_2$ of the two conductors as the generalized coordinate q .

From the definition of the coefficient of self-inductance (24.12), (24.11) and (28.2) we have

$$\mathbf{F} = I_1 I_2 \frac{\mu}{c^2} \frac{\partial}{\partial r_{12}} \oint \oint \frac{d\mathbf{l}_1 \cdot d\mathbf{l}_2}{r_{12}} = - \frac{\mu I_1 I_2}{c^2} \oint \oint \frac{r_{12} d\mathbf{l}_1 \cdot d\mathbf{l}_2}{r_{12}^3}. \quad (28.5)$$

In particular, let the two currents flow in the same direction in parallel linear conductors. Then $d\mathbf{l}_1 \parallel d\mathbf{l}_2$ and the force \mathbf{F} corresponds to the attraction between the two current carrying conductors.

On the other hand, in the case of currents flowing in opposite directions, a repulsion arises between the conductors.

We see that two currents in the same direction tend to approach each other and thus intensify their common magnetic field. It is in this respect that they differ from static charges of the same sign, which tend to separate and thus weaken their electrostatic field.

We shall consider in addition the problem of the work which is done by the force displacing a current loop. According to (28.2), this work is equal to

$$\delta W = F_{q_\alpha} \delta q_\alpha = c^{-1} I_\alpha \delta \Phi_\alpha.$$

At first sight we arrive at a paradoxical result: the work δW is done by the force due to the magnetic field acting on the charges. This force, however, is perpendicular to the velocity of the charges and cannot do any work on them. In fact, however, in writing the formula for the work we have not taken into account induction phenomena which occur in a conductor moving in a magnetic field. As the conductor moves, an e.m.f. \mathbf{E}^{ind} is induced in it, and work $\delta W'$ equal to

$$\delta W' = \delta t \int \mathbf{j} \cdot \mathbf{E}^{\text{ind}} dV = I \delta t \oint \mathbf{E}^{\text{ind}} \cdot d\mathbf{l} = - c^{-1} I_\alpha \delta \Phi_\alpha$$

is done on the charges. The total work done by the magnetic field on the current loop is

$$\delta W + \delta W' = 0,$$

as was to be expected.

This result is of a general character and can also be applied to non-linear conductors.

When we have spoken about the work of magnetization and the change in the thermodynamic potentials of the system which is associated with it, we have meant by this the work done on the currents by the electric field induced when the magnetic field is switched on. We write it in another, more general form:

$$\begin{aligned}\delta W' &= \delta t \int \mathbf{j} \cdot \mathbf{E} dV = \delta t \frac{c}{4\pi} \int \mathbf{E} \cdot (\nabla \times \mathbf{H}) dV = \\ &= -\frac{c}{4\pi} \delta t \int \nabla \cdot (\mathbf{E} \times \mathbf{H}) dV + \frac{c}{4\pi} \delta t \int \mathbf{H} \cdot (\nabla \times \mathbf{E}) dV = \\ &= -\frac{c}{4\pi} \delta t \oint (\mathbf{E} \times \mathbf{H}) \cdot d\mathbf{S} - \frac{1}{4\pi} \delta t \int \mathbf{H} \cdot \frac{\partial \mathbf{B}}{\partial t} dV = \\ &= -\frac{1}{4\pi} \int \mathbf{H} \cdot \left(\delta t \frac{\partial \mathbf{B}}{\partial t} \right) dV = -\frac{1}{4\pi} \int \mathbf{H} \cdot \delta \mathbf{B} dV.\end{aligned}$$

Hence it follows that the body which is magnetized gets an additional energy $-\delta W'$.

Therefore the free energy per unit volume can be written in the form

$$dF = dF_0 + \frac{1}{4\pi} \mathbf{H} \cdot d\mathbf{B}.$$

We define the thermodynamic potential G_1 as

$$G_1 = F + TS - \mathbf{B} \cdot \mathbf{H}/4\pi.$$

For $\mathbf{B} = \mu \mathbf{H}$ we have

$$G_1 = F + TS - \mu H^2/8\pi.$$

For dG we have

$$dG = dG_1 - \mathbf{B} \cdot d\mathbf{H}/4\pi.$$

Hence

$$\mathbf{B} = -4\pi(\partial G/\partial \mathbf{H})_{T,p}.$$

To obtain (20.3) use can be made of the last formula, expressing \mathbf{B} in terms of \mathbf{M} :

$$\mathbf{B} = \mathbf{H} + 4\pi\mathbf{M} = -4\pi(\partial G/\partial \mathbf{H})_{T,p}.$$

Integrating with respect to \mathbf{H} and assuming \mathbf{M} to be the independent variable, we obtain

$$G = G_1 - \mathbf{M} \cdot \mathbf{H} - H^2/8\pi.$$

The quantity $\int (H^2/8\pi)dV$ represents the energy of the external field in the volume of the body.

In conclusion we shall consider an example which illustrates in an obvious way the merits of the Lagrange method.

Let there be two loops: the first carrying a current I_1 and rotating inside the second under the action of a force F , the second loop being at rest. A current, I_2 , is induced in the second loop. In both loops there is no capacitance. It is clear that such an arrangement represents an alternating-current machine. The first loop is called the rotor, and the second loop is called the stator. The Lagrange function of the system has the form

$$L = \frac{1}{2}L_{11}I_1^2 + L_{12}I_1I_2 + \frac{1}{2}L_{22}I_2^2 + \frac{1}{2}I_0(d\alpha/dt)^2 - U_{\text{mech}},$$

where α is the angle of rotation, and I_0 is the moment of inertia of the rotor. The coefficient of mutual inductance depends on the orientation of the rotor and stator, i.e. on the angle α .

The equation of motion for the generalized coordinate, the angle α , has the form

$$I_0\ddot{\alpha} - I_1I_2 \frac{dL_{12}}{d\alpha} = M_0, \quad (28.6)$$

where $M_0 = -\partial U_{\text{mech}}/\partial \alpha$ is the moment of the rotational force.

The equation of motion for the generalized coordinate, the charge Q_2 , i.e. the equation of the current in the stator, according to (27.5), has the form

$$\frac{d}{dt} \frac{\partial L}{\partial I_2} = -R_2 I_2,$$

or

$$\frac{d}{dt} (L_{22} I_2 + L_{12} I_1) = -R_2 I_2.$$

Hence

$$L_{22} \frac{dI_2}{dt} + R_2 I_2 + L_{12} \frac{dI_1}{dt} + I_1 \frac{dL_{12}}{dt} = 0. \quad (28.7)$$

The state of the system is to be found from the simultaneous solution of eqs. (28.6) and (28.7).

Assuming the resistance R_2 to be very large (a large load resistance in the circuit of the stator), one can write approximately

$$I_2 \approx -\frac{I_1}{R_2} \frac{dL_{12}}{dt} = -\frac{I_1}{R_2} \frac{dL_{12}}{d\alpha} \frac{d\alpha}{dt}. \quad (28.8)$$

We have neglected small terms in (28.7) which do not contain R_2 . Substituting (28.8) into (28.6), we obtain

$$I_0 \frac{d^2 \alpha}{dt^2} + \frac{I_1^2}{R_2} \left(\frac{dL_{12}}{d\alpha} \right)^2 \frac{d\alpha}{dt} = M_0.$$

For the quasistationary state one can disregard the term with the angular acceleration $d^2 \alpha / dt^2$, since it is small. Then for the angular velocity of rotation we find

$$\frac{d\alpha}{dt} = \frac{M_0 R_2}{I_1^2} \left(\frac{dL_{12}}{d\alpha} \right)^{-2} = \text{const}. \quad (28.9)$$

The expressions (28.8) and (28.9) give the solution of the problem. In practice one usually makes use of more complex schemes, for example machines with self-excitation in which the induced current I_2 is introduced into the first

We have not considered the important properties of real machines associated with the presence of magnetizable cores. The example discussed illustrates only the merits of the Lagrange method in the case of systems in which the mechanical motion and currents are directly connected with each other.

§ 29. Fluctuations in conductors and the Nyquist formula

As a result of fluctuation processes in an electric circuit current fluctuations arise which in practice are called noise. Physically the appearance of fluctuation currents in a conductor (in the absence of impressed e.m.f.) is associated with the fluctuations of the number of electrons moving in a particular direction. In the presence of an impressed e.m.f., fluctuation currents are superimposed upon the stationary or quasistationary current.

Current fluctuations in a radio set are of very great importance in radio engineering. The noise background determines the limit of sensitivity of reception of a single signal. A further increase in sensitivity can be achieved only by repeated measurements.

We shall consider the theory of fluctuations in an electric circuit with inductance L and ohmic resistance R . Fluctuation processes in the circuit can be characterized by a random fluctuating e.m.f. $\mathcal{E}(t)$. The variations of the e.m.f. $\mathcal{E}(t)$ occur in a time which is very small in comparison with the relaxation time $T = L/R$ of the circuit.

It is natural to try to describe the processes occurring in the circuit by means of the generalized Ohm's law

$$L \frac{di}{dt} + Ri = \mathcal{E}(t). \quad (29.1)$$

Eq. (29.1) is based on the rather natural assumption that between the random current in a circuit and the random e.m.f. producing it there is the same relation as between an ordinary current and the ordinary e.m.f. The current relaxation is characterized by a constant resistance R . It should be stressed that at high frequencies the resistance R (or $\sigma = R^{-1}$; see § 14) turns out to be a function of the frequency. This fact does not however affect the general results of the theory.

The random e.m.f. $\mathcal{E}(t)$ has, obviously, the following properties:

$$\overline{\mathcal{E}(t)} = 0 \quad \overline{[\mathcal{E}(t)]^2} \neq 0, \quad (29.2)$$

We integrate the linear equation (29.1) with respect to time. We then have for the random current:

$$i(t) = i_0 e^{-t/T} + e^{-t/T} \int_0^t e^{t'/T} \mathcal{E}(t') dt'. \quad (29.3)$$

It should be noted that the integration of eq. (29.1) with the random function on the right-hand side requires some justification from the purely mathematical point of view. For the details of this problem we refer the reader to more specialized literature*.

By means of formula (5.3) of Part III one can work out the correlation function:

$$\begin{aligned} \langle i(t) i(t+\tau) \rangle &= \left\langle \left[i_0 e^{-t/T} + e^{-t/T} \int_0^t e^{t'/T} \mathcal{E}(t') dt' \right] \right. \\ &\quad \times \left. \left[i_0 e^{-(t+\tau)/T} + e^{-(t+\tau)/T} \int_0^{t+\tau} e^{t''/T} \mathcal{E}(t'') dt'' \right] \right\rangle = \\ &= i_0^2 e^{-(2t+\tau)/T} \\ &\quad + e^{-(2t+\tau)/T} \int_0^t \int_0^{t+\tau} e^{(t'+t'')/T} \langle \mathcal{E}(t') \mathcal{E}(t'') \rangle dt' dt''. \end{aligned} \quad (29.4)$$

Terms containing the random function $\mathcal{E}(t)$ in the first power reduce to zero in averaging.

The double integral in (29.4) can be calculated in the following way. Introducing new variables $x = t' + t''$, $y = t' - t''$, we have

$$I(t, \tau) = \frac{1}{2} e^{-(2t+\tau)/T} \int_0^{2t} e^{x/T} dx \int_{-t}^t \langle \mathcal{E}(\frac{1}{2}x - \frac{1}{2}y) \mathcal{E}(\frac{1}{2}x + \frac{1}{2}y) \rangle dy.$$

The correlation function $\langle \mathcal{E}(\frac{1}{2}x - \frac{1}{2}y) \mathcal{E}(\frac{1}{2}x + \frac{1}{2}y) \rangle$, cannot, according to (5.4) of Part III, depend on the choice of the variable x . Assuming that $x = y$, we have

* See, for example, S.Chandrasekhar, *Stochastic problems in physics and astronomy*,

$$\langle \mathcal{E}(\frac{1}{2}x - \frac{1}{2}y) \mathcal{E}(\frac{1}{2}x + \frac{1}{2}y) \rangle \equiv \langle \mathcal{E}(0) \mathcal{E}(y) \rangle .$$

Since the correlation function rapidly decreases with increasing y , the range of integration can be extended to infinity, so that

$$\begin{aligned} I(t, \tau) &= \frac{1}{2} e^{-(2t+\tau)/T} \int_0^{2t} e^{x/T} dx \int_{-\infty}^{\infty} \langle \mathcal{E}(0) \mathcal{E}(y) \rangle dy = \\ &= \frac{1}{2} T e^{-\tau/T} (1 - e^{-2t/T}) \int_{-\infty}^{\infty} \langle \mathcal{E}(0) \mathcal{E}(y) \rangle dy . \end{aligned}$$

Finally we find

$$\langle i(t) i(t+\tau) \rangle = i_0^2 e^{-(2t+\tau)/T} + \frac{1}{2} T e^{-\tau/T} (1 - e^{-2t/T}) \int_{-\infty}^{\infty} \langle \mathcal{E}(0) \mathcal{E}(y) \rangle dy . \quad (29.5)$$

Assuming $t = 0$, we obtain from (29.5) the correlation function for the current

$$\langle i(0) i(\tau) \rangle = i_0^2 e^{-\tau/T} . \quad (29.6)$$

Making use of the law of equipartition, one can write the mean value of the fluctuation current in the circuit $\frac{1}{2} L i_0^2 = \frac{1}{2} k T \equiv \frac{1}{2} \theta$ so that finally the autocorrelation function for the current assumes the form

$$\langle i(0) i(\tau) \rangle = \theta L^{-1} e^{-|\tau|/T} . \quad (29.7)$$

On the other hand, assuming $\tau = 0$, we find

$$\langle i(t)^2 \rangle = i_0^2 e^{-2t/T} + \frac{1}{2} T (1 - e^{-2t/T}) \int_{-\infty}^{\infty} \langle \mathcal{E}(0) \mathcal{E}(y) \rangle dy .$$

For large values of t , $t \gg T$, a statistical equilibrium must be established in the system. Dropping as small the quantities with $e^{-2t/T}$, we find

$$\langle i(t)^2 \rangle = \theta L^{-1} = \frac{1}{2} T \int_{-\infty}^{\infty} \langle \mathcal{E}(0) \mathcal{E}(y) \rangle dy .$$

Hence we find, substituting $T = LR^{-1}$:

$$R = \frac{1}{2} L^2 \theta^{-1} \int_{-\infty}^{\infty} \langle \mathcal{E}(0) \mathcal{E}(y) \rangle dy . \quad (29.8)$$

Formula (29.8) relates the autocorrelation function of the random e.m.f. and the resistance of the circuit. This relation has a deep meaning: it connects a characteristic of reversible random processes, the correlation function $\langle \mathcal{E}(0) \mathcal{E}(y) \rangle$, with a characteristic of the irreversible dissipative process, the relaxation time T or the resistance R

$$T^{-1} = \frac{1}{2} L \theta^{-1} \int_{-\infty}^{\infty} \langle \mathcal{E}(0) \mathcal{E}(y) \rangle dy . \quad (29.9)$$

If one makes use of the Wiener–Khinchin formula (5.16) of Part III, then one can express the correlation function in terms of the spectral density. Then we have

$$\frac{1}{2} \pi^{-1} \int_{-\infty}^{\infty} \langle \mathcal{E}(0) \mathcal{E}(y) \rangle dy = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} e^{-i\omega y} g(\omega) d\omega dy = g(0) , \quad (29.10)$$

and, consequently,

$$R = \frac{1}{2} L^2 \theta^{-1} g(0) . \quad (29.11)$$

This formula is a particular case of an important fluctuation–dissipation theorem establishing a connection between the characteristics of fluctuation processes and dissipative processes.

In formula (29.1) we have restricted ourselves to the case where the resistance can be assumed to be independent of the frequency. The problem of the connection between fluctuation processes and irreversible processes will be considered in detail in Part VI which is devoted to physical kinetics.

We return to the autocorrelation function for the current and, making use of the Wiener–Khinchin theorem, we find the spectral density of random currents in the circuit. Namely, according to (5.16) of Part III and (29.11), we can write

$$g_I(\omega) = \frac{1}{2} \pi^{-1} \int_{-\infty}^{\infty} \langle i(0) i(\tau) \rangle e^{-i\omega \tau} d\tau , \quad (29.12)$$

where the spectral density of the current $g_i(\omega)$ is defined by the formula

$$\overline{i^2} = \int_0^\infty g_i(\omega) d\omega. \quad (29.13)$$

Substituting the expression for $\langle i(0)i(\tau) \rangle$ from (29.7) into (29.12), we find

$$g_i(\omega) = \frac{\theta}{\pi L} \int_0^\infty e^{-\tau/T} \cos \omega \tau d\tau = \frac{\theta}{\pi R} \frac{1}{1 + (\omega L/R)^2}. \quad (29.14)$$

Usually in metals $T = LR^{-1} \sim 10^{-13}$ sec, and one can write to a good approximation that

$$g_i(\omega) \approx \theta \pi^{-1} R^{-1}. \quad (29.15)$$

Thus, the mean-square value of the current in a closed circuit generated by a random e.m.f. in a frequency interval ω , $\omega + d\omega$ can be written in the form

$$\overline{i^2} d\omega = \theta \pi^{-1} R^{-1} d\omega. \quad (29.16)$$

In the case of an open circuit, instead of (29.16) one can write for the spontaneous fluctuations of e.m.f. the relation

$$\overline{\mathcal{E}^2} d\omega = \theta R \pi^{-1} d\omega. \quad (29.17)$$

Formulae (29.17) and (29.16) are called the Nyquist formulae. They allow one to take into account fluctuation phenomena in calculations on quasi-stationary circuits, for example, the fluctuation e.m.f., besides other macroscopic characteristics.

According to (29.16) the fluctuation current is proportional to $\theta^{\frac{1}{2}}$ and inversely proportional to $R^{\frac{1}{2}}$. This has a simple meaning. The resistance $R = \sigma^{-1} \sim n^{-1}$, where n is the number of electrons per cm^3 . In correspondence with the general formula (3.7) of Part III, $(\overline{i^2})^{\frac{1}{2}} \sim n^{\frac{1}{2}}$.

The above derivation was made under an essential restriction: the resistance has been calculated without taking into account the frequency. In Part VI we shall return to the Nyquist formula for the region of high frequencies. A detailed calculation will be made of the quantum effects at frequencies $\omega > kt/h \equiv \theta/h$.

In semiconductors an additional noise-producing mechanism arises which will also be discussed in Part VI.

§ 30. Skin effect

We have, up to now, studied quasistationary currents in linear circuits, considering the conductors to be infinitesimally thin. We shall now consider the distribution of alternating current over the cross-section of the conductor. Assuming, as before, that the conditions of quasistationarity are fulfilled, we write Maxwell's equations in a homogeneous conducting medium:

$$\nabla \times \mathbf{E} = -\frac{\mu}{c} \frac{\partial \mathbf{H}}{\partial t},$$

$$\nabla \times \mathbf{H} = \frac{4\pi\sigma}{c} \mathbf{E},$$

$$\nabla \cdot \mathbf{H} = 0,$$

$$\nabla \cdot \mathbf{E} = 0.$$

It is easy to obtain separate equations for the electric and magnetic fields. Taking the curl of curl \mathbf{E} , we find

$$\nabla \times (\nabla \times \mathbf{E}) = \nabla(\nabla \cdot \mathbf{E}) - \nabla^2 \mathbf{E} = -\nabla^2 \mathbf{E} = \frac{\mu}{c} \frac{\partial}{\partial t} (\nabla \times \mathbf{H}),$$

or

$$\nabla^2 \mathbf{E} = \frac{4\pi\sigma\mu}{c^2} \frac{\partial \mathbf{E}}{\partial t}. \quad (30.1)$$

A similar equation is obtained for the magnetic field.

Eq. (30.1) and the analogous equation for the vector \mathbf{H} determine the dependence of the fields on time and coordinates in the space occupied by the conductor. At the boundary of this space, i.e. at the surface of the conductor, the field vectors satisfy the usual boundary conditions.

We restrict ourselves to the solution of the field equations in the simple case of alternating current flowing in a conductor which occupies a half-space $z > 0$. The direction of the current is along the x -axis and its dependence on time is assumed to be defined:

$$j_x = j(z) e^{i\omega t}; \quad j_y = j_z = 0.$$

We note that j_x cannot depend on the coordinate x by virtue of the continuity equation which gives

$$\frac{\partial j_x}{\partial x} = 0.$$

In correspondence with Ohm's law we seek the electric field satisfying eq. (30.1) in the form

$$E_x = E(z) e^{i\omega t}; \quad E_y = E_z = 0. \quad (30.2)$$

The substitution of (30.2) into (30.1) gives

$$\frac{d^2 E(z)}{dz^2} = i \frac{4\pi\mu\sigma\omega}{c^2} E(z). \quad (30.3)$$

The general solution of the last equation is

$$E(z) = A e^{-kz} + B e^{kz},$$

where

$$k = \left(i \frac{4\pi\mu\sigma\omega}{c^2} \right)^{\frac{1}{2}} = \frac{1+i}{\sqrt{2}} \left(\frac{4\pi\mu\sigma\omega}{c^2} \right)^{\frac{1}{2}}.$$

We introduce the notation

$$\delta = \frac{c}{(2\pi\mu\sigma\omega)^{\frac{1}{2}}}. \quad (30.4)$$

Then

$$E(z) = A e^{-iz/\delta} e^{-z/\delta} + B e^{iz/\delta} e^{z/\delta}.$$

The value of B must, obviously, be equal to zero, in order that the field may have a finite value everywhere.

Thus, finally,

$$E_x = A e^{-z/\delta} e^{-i(z/\delta - \omega t)}. \quad (30.5)$$

Formula (30.5) shows that the electric field strength decreases exponentially inside a conductor.

An effective decrease in the field strength (decrease by a factor of e) takes place at a distance δ from the surface.

Knowing the electric field distribution in the conductor, one can find the magnetic field distribution.

We have, obviously,

$$-i \frac{\mu\omega}{c} H_y = (\nabla \times \mathbf{E})_y = \frac{\partial E_x}{\partial z} = -\frac{(i+1)}{\delta} E_x,$$

$$H_x = H_z = 0.$$

Hence

$$H_y = (1-i) \frac{c}{\mu\omega\delta} A e^{-i(z/\delta - \omega t)} e^{-z/\delta}. \quad (30.6)$$

The magnetic field turns out to be perpendicular to the electric field. It decreases inside the conductor according to the same law as the electric field. In absolute value $|H_y| \approx (c/\omega\delta) |E_x|$, i.e. is larger than the electric field by a factor λ/δ .

Thus, the electromagnetic field and correspondingly the entire current in a conductor turn out to be localized in a thin surface layer of thickness δ . The localization of the field in the thin surface layer is called the skin effect, and the quantity δ is called the skin depth.

It is easily seen that the entire Joule heat j^2/σ is released in the region of the skin depth.

From the definition of δ it is clear that its numerical value can vary within a wide range for different frequencies ω and conductivities σ . In order to get an idea of the order of magnitude of this quantity, we point out that for copper $\delta \approx 1$ cm for a frequency of 50 hertz and $\delta \approx 3 \times 10^{-3}$ cm for frequencies $\sim 10^5$ hertz.

As $\omega \rightarrow 0$, i.e. in the transition to direct current, $\delta \rightarrow \infty$ and the skin effect vanishes. The current is uniformly distributed over the entire cross-section of the conductor. On the other hand, in the transition to the limit $\sigma \rightarrow \infty$ the thickness of the skin layer tends to zero. This represents the case of the ideal conductor.

The result which we have obtained for the case of a simplified model of a conductor is of general character. For any geometric configuration of con-

auctors the field in them turns out to be localized in the skin depth.

If the distribution depends on the geometric properties of a conductor, then the problem of finding the field in it becomes only slightly more complicated than in the example discussed. Thus, in the case of a current flowing along a long cable of circular cross-section, solid or hollow, the current density vector is directed parallel to the generatrix of the cable. Hence the general trend of the solution of the problem of finding the field distribution in the cable is the same as in the example which we have discussed. For the skin depth one obtains the same numerical value. The geometric distribution of the field differs relatively little from an exponential decrease, particularly at high frequencies, when the radius of the cable is large in comparison with the skin depth. In the general case of a solid conductor of arbitrary form finding the alternating-field distribution represents a problem which is complex from the mathematical standpoint *. However, irrespective of the form of the conductor and even of the mechanism of excitation of the field in it (by means of an impressed e.m.f., an external alternating magnetic field etc.) the general inference remains valid: the alternating electromagnetic field penetrates into the conductor to the depth of the skin layer δ . In this case the magnetic field is larger than the electric field in the ratio λ/δ .

Analogous results can be obtained in the consideration of another problem. Let the metal be acted upon by an alternating electromagnetic field depending on time according to the law $e^{i\omega t}$.

If the magnetic field at the surface of the conductor $z = 0$ has a value H_0 , the boundary condition (5.4) allows one to formulate the boundary value problem

$$\frac{\partial^2 H(z, t)}{\partial z^2} = \frac{4\pi\sigma\mu}{c^2} \frac{\partial H(z, t)}{\partial t},$$

$$H = H_0 \quad \text{for} \quad z = 0,$$

$$H \rightarrow 0 \quad \text{for} \quad z \rightarrow \infty.$$

The solution of the boundary value problem can be written, analogously to (30.5), in the form

$$H(z, t) = H_0 e^{-z/\delta} e^{i\omega t},$$

where the thickness of the skin layer δ is given by formula (30.4).

* See W.R.Smythe, *Static and dynamic electricity* (McGraw-Hill, New York, 1950).

It should be emphasized that the skin effect becomes more pronounced in going to high frequencies. We shall see in the next chapter that in high-frequency fields, when the fields can no longer be considered as quasistationary, there is as before a skin effect, although the penetration depth turns out, as a rule, to be different (see §33). The skin effect plays an important role in alternating-current engineering. It allows one to use hollow cables or cables covered with a layer of metal of a particularly high conductivity, which reduces the expenditure of material and power.

High-frequency Fields

§31. Electromagnetic waves in a homogeneous isotropic medium

We consider the propagation of the electromagnetic field in a spatially homogeneous and isotropic medium characterized by material constants ϵ_0 , μ_0 and σ_0 , i.e. in a medium without spatial dispersion. The subscript zero denotes that the material constants have a static value and are referred to the frequency $\omega = 0$. We shall discuss below the conditions of applicability of this assumption.

We assume the medium to be non-ferromagnetic ($\mu_0 \approx 1$). We have seen above that for metals the penetration of the field is very small, even at relatively low frequencies. Therefore it makes no sense to consider the propagation of the electromagnetic field inside the metal. However, such a consideration is not out of place for media having conductivities which are lower than those for metals (e.g. semi-conductors or solutions of electrolytes). In the limiting case $\sigma \rightarrow 0$ we pass over to the case of ideal dielectrics. We can also assume that the magnetic permeability of the medium is equal to unity. Maxwell's equations then have the form

$$\nabla \times \mathbf{H} = \frac{4\pi\sigma}{c} \mathbf{E} + \frac{\epsilon_0}{c} \frac{\partial \mathbf{E}}{\partial t}, \quad (31.1)$$

$$\nabla \times \mathbf{E} = -\frac{1}{c} \frac{\partial \mathbf{H}}{\partial t}, \quad (31.2)$$

$$\nabla \cdot \mathbf{E} = 0, \quad (31.3)$$

$$\nabla \cdot \mathbf{H} = 0. \quad (31.4)$$

Taking the curl of the first equation and making use of the last, we have

$$\nabla \times (\nabla \times \mathbf{H}) = -\nabla^2 \mathbf{H} = \frac{4\pi\sigma}{c} (\nabla \times \mathbf{E}) + \frac{\epsilon_0}{c} \frac{\partial}{\partial t} (\nabla \times \mathbf{E}),$$

or, using (31.2),

$$\nabla^2 \mathbf{H} - \frac{\epsilon_0}{c^2} \frac{\partial^2 \mathbf{H}}{\partial t^2} = \frac{4\pi\sigma}{c^2} \frac{\partial \mathbf{H}}{\partial t}. \quad (31.5)$$

Proceeding analogously with (31.2), we easily arrive at the equation

$$\nabla^2 \mathbf{E} - \frac{\epsilon_0}{c^2} \frac{\partial^2 \mathbf{E}}{\partial t^2} = \frac{4\pi\sigma}{c^2} \frac{\partial \mathbf{E}}{\partial t}. \quad (31.6)$$

We seek solutions of eqs. (31.5) and (31.6) in the form of monochromatic plane waves propagating along the x -axis.

Consequently, we assume that the solutions of (31.5) and (31.6) have the form

$$\mathbf{H}(x, t) = \mathbf{H}_0(x) e^{i\omega t}, \quad (31.7)$$

$$\mathbf{E}(x, t) = \mathbf{E}_0(x) e^{i\omega t}. \quad (31.8)$$

Substituting (31.7) into (31.5), we find

$$\frac{d^2 \mathbf{H}_0(x)}{dx^2} + k^2 \mathbf{H}_0(x) = 0, \quad (31.9)$$

where k denotes the complex quantity

$$k = \frac{\omega}{c} \left(\epsilon_0 - i \frac{4\pi\sigma}{\omega} \right)^{\frac{1}{2}}. \quad (31.10)$$

We introduce the important notion of the complex dielectric permittivity $\epsilon(\omega)$ in a conducting medium, defining it by the relation

$$k = \frac{\omega}{c} [\epsilon(\omega)]^{\frac{1}{2}} = k_v [\epsilon(\omega)]^{\frac{1}{2}}, \quad (31.11)$$

where $k_v = \omega/c$ is the wave number in vacuum.

From (31.10) it follows that

$$\epsilon(\omega) = \epsilon_0 - i \frac{4\pi\sigma}{\omega}. \quad (31.12)$$

This important formula establishes the relation between the dielectric permittivity and the conductivity. Further, we write the complex quantity $[\epsilon(\omega)]^{\frac{1}{2}}$ in the form

$$[\epsilon(\omega)]^{\frac{1}{2}} = n - i\kappa. \quad (31.13)$$

The quantities n and κ are called, respectively, the refractive index and the absorption coefficient. The sign of κ is chosen in such a way that the imaginary part of k is essentially negative (for $\kappa > 0$). The reason for such a choice is obvious from what follows.

The solutions (31.7) have the form

$$\mathbf{H} = \mathbf{A}_1 e^{-k_v \kappa x} e^{i(\omega t - k_v n x)}, \quad (31.14)$$

where the vector \mathbf{A}_1 is the complex amplitude. Analogously, for the electric field one can write

$$\mathbf{E} = \mathbf{A}_2 e^{-k_v \kappa x} e^{i(\omega t - k_v n x)}. \quad (31.15)$$

In the case of arbitrary direction of propagation the field vectors can be written in the form

$$\mathbf{H} = \mathbf{A}_1 e^{i(\omega t - \mathbf{k} \cdot \mathbf{r})}, \quad (31.16)$$

$$\mathbf{E} = \mathbf{A}_2 e^{i(\omega t - \mathbf{k} \cdot \mathbf{r})}, \quad (31.17)$$

where \mathbf{k} is the wave vector, $\mathbf{k} = k\mathbf{k}_0$, and \mathbf{k}_0 is a unit vector in the direction of propagation of the wave. The relation between the vectors \mathbf{H} and \mathbf{E} can be

$$\nabla \times \mathbf{E} = -i(\mathbf{k} \times \mathbf{E}) = -ik(\mathbf{k}_0 \times \mathbf{E}) = -i \frac{\omega}{c} [\epsilon(\omega)]^{\frac{1}{2}} (\mathbf{k}_0 \times \mathbf{E}) = -i \frac{\omega}{c} \mathbf{H}.$$

Hence we find

$$\mathbf{H} = [\epsilon(\omega)]^{\frac{1}{2}} (\mathbf{k}_0 \times \mathbf{E}). \quad (31.18)$$

In contrast to the case of the propagation of electromagnetic waves in vacuum, the amplitudes of the electric and magnetic field here turn out to be different. However, as in a vacuum, electromagnetic waves in a homogeneous and isotropic medium are transverse. Indeed, substituting (31.16) and (31.17) into (31.3) and (31.4), we find

$$\mathbf{k} \cdot \mathbf{E} = \mathbf{k} \cdot \mathbf{H} = 0. \quad (31.19)$$

Formulae (31.16) – (31.19) show that Maxwell's equations allow solutions in the form of transverse plane waves with wave number k and an arbitrary frequency ω in a homogeneous and isotropic medium, as in vacuum. However damping of the wave according to an exponential law occurs in the medium. The effectiveness of the damping is determined by the quantity κ . We find the values of n and κ from (31.12) and (31.13). Squaring (31.13), substituting in (31.12) and separating the real and imaginary parts, we obtain

$$n^2 - \kappa^2 = \epsilon_0, \quad \kappa n = 2\pi\sigma/\omega. \quad (31.20)$$

The solution of (31.20) gives

$$n = [\frac{1}{2}(\epsilon_0^2 + 16\pi^2\sigma^2/\omega^2)^{\frac{1}{2}} + \epsilon_0]^{\frac{1}{2}}, \quad (31.21)$$

$$\kappa = [\frac{1}{2}(\epsilon_0^2 + 16\pi^2\sigma^2/\omega^2)^{\frac{1}{2}} - \epsilon_0]^{\frac{1}{2}}. \quad (31.22)$$

The signs of the roots are chosen in such a way that n and κ have real values and, in addition, that κ is positive.

Formulae (31.21) and (31.22) determine the law of dispersion in a conducting medium. It should be noted that at sufficiently high frequencies the conductivity σ is also dependent on the frequency.

Let us consider the limiting cases of formulae (31.21) and (31.22). If the inequality

$$\sigma \ll \epsilon_0 \omega / 4\pi \quad (31.23)$$

is valid, then this means that the conduction current $\sigma \mathbf{E}$ is small in comparison with the displacement current $(\epsilon_0/4\pi)(\partial \mathbf{E}/\partial t) \sim (\epsilon_0 \omega/4\pi) \mathbf{E}$. This holds for ideal dielectrics (for which $\sigma \rightarrow 0$) as well as for real dielectrics possessing a very low conductivity, and also for conductors of non-metallic type (semiconductors, electrolytes) at sufficiently high frequencies.

In this case one can simplify formulae (31.21) and (31.22), writing them in the form

$$n \approx \epsilon_0^{\frac{1}{2}}, \quad (31.24)$$

$$\kappa \approx 2\pi\sigma/\omega\epsilon_0^{\frac{1}{2}}. \quad (31.25)$$

By virtue of the inequality (31.23), the following inequality also holds:

$$n \gg \kappa.$$

If one can completely disregard the quantity κ which, strictly speaking, is equal to zero only in an ideal dielectric, then the medium is called transparent. For a transparent medium the formulae for the field vectors are simplified and assume the form

$$\mathbf{E} = \mathbf{A} \exp \left[i \left(\omega t - \frac{\omega}{c} \epsilon_0^{\frac{1}{2}} \mathbf{k}_0 \cdot \mathbf{r} \right) \right] = \mathbf{A} \exp [i(\omega t - \mathbf{k} \cdot \mathbf{r})], \quad (31.26)$$

$$\mathbf{H} = \epsilon_0^{\frac{1}{2}} \mathbf{A} \exp \left[i \left(\omega t - \frac{\omega}{c} \epsilon_0^{\frac{1}{2}} \mathbf{k}_0 \cdot \mathbf{r} \right) \right] = \epsilon_0^{\frac{1}{2}} \mathbf{A} \exp [i(\omega t - \mathbf{k} \cdot \mathbf{r})], \quad (31.27)$$

$$\mathbf{k} = \frac{\omega}{c} \epsilon_0^{\frac{1}{2}} \mathbf{k}_0 = \frac{\omega}{v} \mathbf{k}_0, \quad (31.28)$$

where v is the phase velocity of propagation of the waves

$$v = c\epsilon_0^{-\frac{1}{2}}. \quad (31.29)$$

The last formula justifies the name of the quantity n . Indeed, as is well known (see §37), the refractive index means the ratio of the velocity of propagation of electromagnetic waves in vacuum to that in the medium:

$$n = \frac{c}{v} = \epsilon_0^{\frac{1}{2}}. \quad (31.30)$$

Electromagnetic waves in a non-conducting medium differ from those in vacuum only in the velocity of propagation, which is smaller by a factor of $\epsilon_0^{\frac{1}{2}}$ than the velocity of light in vacuum c . Moreover, the amplitudes of the electric and magnetic fields are in the ratio

$$\frac{|H|}{|E|} = \epsilon_0^{\frac{1}{2}} = n. \quad (31.31)$$

The above ratios, established by Maxwell, played an important role in the history of the development of the theory of the electromagnetic field. In particular, formula (31.30) established a relation between electromagnetic and optical phenomena, which before the work of Faraday and Maxwell were considered to be completely independent.

Formula (31.30) was subjected to extensive experimental test for a large number of liquids and gases. Good agreement with experiment was found for a number of liquids and gases in the visible and infrared parts of the spectrum. However, the relation (31.30) is not satisfied at all for liquids (e.g. water) and gases whose molecules have a considerable intrinsic dipole moment. Other restrictions on the applicability of (31.30) are associated with the existence of absorption and dispersion.

In the case of weak absorption it is convenient to write $\epsilon^{\frac{1}{2}}$ in the form

$$[\epsilon(\omega)]^{\frac{1}{2}} = (n^2 + \kappa^2)^{\frac{1}{2}} \exp [-i \arctan (\kappa/n)] \quad (31.32)$$

and to write the formulae for the field vectors in the form

$$\mathbf{E} = \mathbf{A} \exp [-\kappa \mathbf{k}_0 \cdot \mathbf{r}] \exp [i(\omega t - n \mathbf{k}_0 \cdot \mathbf{r})], \quad (31.33)$$

$$\mathbf{H} \approx n(\mathbf{k}_0 \times \mathbf{E}) \exp [-i \arctan (\kappa/n)]. \quad (31.34)$$

The magnetic field strength differs in phase from the electric field strength by an amount $\arctan (\kappa/n)$.

In addition we shall find the time average of the electromagnetic field energy density in a weakly absorbing medium. We have, obviously,

$$\overline{\frac{\epsilon_0}{8\pi} E^2} = \frac{\epsilon_0 A^2}{16\pi} e^{-2\kappa x},$$

$$\overline{\frac{H^2}{8\pi}} = \frac{n^2 + \kappa^2}{16\pi} A^2 e^{-2\kappa x} \approx \frac{\epsilon_0 A^2}{16\pi} e^{-2\kappa x},$$

since $n^2 + \kappa^2 \approx n^2 = \epsilon_0$. As in vacuum, the energies of the electric and magnetic fields in the wave are nearly equal to each other.

Let us now consider the opposite limiting case where the conduction current is large in comparison with the displacement current. Formally, this case is obtained immediately from the dispersion formulae for low frequencies and large conductivity. We have, obviously,

$$\kappa \approx (2\pi\sigma/\omega)^{\frac{1}{2}}, \quad (31.35)$$

$$n \approx \kappa \approx (2\pi\sigma/\omega)^{\frac{1}{2}}. \quad (31.36)$$

As is shown by comparison of (31.35) with (30.4), the attenuation of the field in a medium takes place over the thickness of its skin depth. This represents the case of strong absorption.

It is clear, however, that these formulae have a somewhat relative character, since it is difficult to speak of the propagation of waves if they are damped over the thickness of the skin layer.

In conclusion, let us write the energy conservation law for a medium with frequency dispersion. Assuming the medium to be in a state of thermodynamic equilibrium at constant temperature, we can write for the change of internal energy per unit volume

$$\frac{dU_0}{dt} = \frac{dQ}{dt} + \frac{dW}{dt} = \frac{dQ}{dt} + \frac{\mathbf{E}}{8\pi} \frac{d\mathbf{D}}{dt}. \quad (31.37)$$

We average eq. (31.37) over time, assuming that the temperature is maintained constant. Then, on the average, the energy of the medium in an external periodic field remains constant, so that for the heat released we obtain

$$\overline{\frac{dQ}{dt}} = -\overline{\frac{\mathbf{E}}{8\pi} \frac{d\mathbf{D}}{dt}}.$$

Setting

$$\mathbf{D} = [\epsilon_1(\omega) + i\epsilon_2(\omega)] (\mathbf{E}_0 \cos \omega t + i\mathbf{E}_0 \sin \omega t),$$

we have

$$\frac{dQ}{dt} = \frac{\epsilon_2 \omega E_0^2}{8\pi}. \quad (31.38)$$

Thus release of heat determined by the quantity $\epsilon_2(\omega)$ occurs in the medium. Formula (31.38) makes sense if the heat released can be removed and the temperature of the medium maintained constant. Since heat is emitted only, Q is always non-negative and, correspondingly,

$$\epsilon_2 \geq 0. \quad (31.39)$$

The sign of ϵ_1 can be either positive or negative.

§32. Dispersion relations (the Kramers—Kronig formulae)

We have already pointed out in §6 that the phenomenon of dispersion occurs at high frequencies, when the frequency of the radiation is comparable with characteristic atomic frequencies and its wavelength is comparable with the dimensions of spatial non-uniformities in the medium.

In the case of a homogeneous and isotropic medium the general formula (6.5) can be written in the form

$$\mathbf{D}(\mathbf{r}, t) = \int_{-\infty}^t dt' \int \epsilon(|\mathbf{r}-\mathbf{r}'|, t-t') \mathbf{E}(\mathbf{r}', t') dV'. \quad (32.1)$$

The function $\epsilon(|\mathbf{r}-\mathbf{r}'|, t-t')$ depends only on the difference between the coordinates, since in a homogeneous medium there are no unique points. A contribution to \mathbf{D} is given by the change in polarization which is transferred in a time $t-t'$ over a distance $|\mathbf{r}-\mathbf{r}'|$. The integral is taken only with respect to the past, in order to satisfy the principle of causality. It is obvious that $|\mathbf{r}-\mathbf{r}'| < c(t-t')$, but for simplicity we shall not take into account this restriction*.

We expand the electric field and induction in Fourier integrals:

$$\mathbf{E}(\mathbf{r}, t) = \frac{1}{(2\pi)^4} \int \mathbf{E}(\mathbf{k}, \omega) e^{i(\mathbf{k} \cdot \mathbf{r} - \omega t)} d\mathbf{k} d\omega, \quad (32.2)$$

$$\mathbf{D}(\mathbf{r}, t) = \frac{1}{(2\pi)^4} \int \mathbf{D}(\mathbf{k}, \omega) e^{i(\mathbf{k} \cdot \mathbf{r} - \omega t)} d\mathbf{k} d\omega. \quad (32.3)$$

Then, substituting into (32.1), we find

$$\mathbf{D}(\mathbf{k}, \omega) = \epsilon(\mathbf{k}, \omega) \mathbf{E}(\mathbf{k}, \omega), \quad (32.4)$$

* See M.A. Leontovich, Soviet Physics JETP 13 (1961) 634.

where

$$\begin{aligned}\epsilon(\mathbf{k}, \omega) &= \int_{-\infty}^t dt' \int \epsilon(|\mathbf{r}-\mathbf{r}'|, t-t') e^{i\mathbf{k}\cdot(\mathbf{r}-\mathbf{r}')} e^{-i\omega(t-t')} dV' = \\ &= \int_{-\infty}^{\infty} d\tau \int \epsilon(\mathbf{R}, \tau) e^{-i(\mathbf{k}\cdot\mathbf{R}-\omega\tau)} d\mathbf{R}.\end{aligned}\quad (32.5)$$

Here new variables $\mathbf{R} = \mathbf{r} - \mathbf{r}'$ and $\tau = t - t'$ are introduced. The function $\epsilon(\mathbf{k}, \omega)$ is not the Fourier transform of $\epsilon(\mathbf{R}, \tau)$, since the integral with respect to τ is taken in the range from zero to infinity. It is the function $\epsilon(\mathbf{k}, \omega)$ (and not $\epsilon(\mathbf{R}, \tau)$) which is of basic importance, because, according to (32.4), it relates the vectors \mathbf{D} and \mathbf{E} . It is called the dielectric permittivity, and depends on the frequency and the wave vector.

We note that the dependence of $\epsilon(\mathbf{k}, \omega)$ on the wave vector \mathbf{k} is associated with the dependence of $\epsilon(\mathbf{R}, \tau)$ on the space coordinates \mathbf{R} , i.e. with the taking into account of spatial dispersion.

If the wavelength is small compared with the spatial non-uniformities, then one can assume the dielectric constant to be a function of $t - t'$ only and, instead of (32.5), one can write the simpler relation

$$\epsilon(\omega) = \int_0^{\infty} \epsilon(\tau) e^{-i\omega\tau} d\tau, \quad (32.6)$$

in which the dielectric constant depends only on the frequency. In this case the relation (32.4) is simplified and becomes

$$\mathbf{D}(\omega) = \epsilon(\omega) \mathbf{E}(\omega). \quad (32.7)$$

We note that if the dielectric constant depends on the frequency, then only eq. (32.7) represents the correct form of notation of the constitutive equation. The relation

$$\mathbf{D}(\mathbf{r}, t) = \epsilon(\omega) \mathbf{E}(\mathbf{r}, t)$$

(where \mathbf{D} and \mathbf{E} are the vectors themselves and not their Fourier amplitudes, as in (32.4)) which is often presented in old text-books, makes no sense. If ϵ is a function of the frequency, then eq. (32.4) must contain quantities referring to this frequency.

The function $\epsilon(\mathbf{k}, \omega)$ is, in general, complex and can be written in the form

$$\epsilon(\mathbf{k}, \omega) = \epsilon^{\text{re}}(\mathbf{k}, \omega) + i\epsilon^{\text{im}}(\mathbf{k}, \omega).$$

It is obvious that the real and imaginary parts are

$$\epsilon^{\text{re}}(\mathbf{k}, \omega) = \frac{\epsilon(\mathbf{k}, \omega) + \epsilon^*(\mathbf{k}, \omega)}{2}, \quad (32.8)$$

$$\epsilon^{\text{im}}(\mathbf{k}, \omega) = \frac{\epsilon(\mathbf{k}, \omega) - \epsilon^*(\mathbf{k}, \omega)}{2i}.$$

Moreover, from the definition (32.5) it follows that

$$\epsilon(\mathbf{k}, \omega) = \epsilon^*(-\mathbf{k}, -\omega). \quad (32.9)$$

Substituting the expression (32.5) into (32.8) and taking into account (32.9), we find

$$\epsilon^{\text{re}}(\mathbf{k}, \omega) = \frac{1}{2} \int_{-\infty}^{\infty} d\tau \int \epsilon(|\mathbf{R}|, |\tau|) e^{-i(\mathbf{k} \cdot \mathbf{R} - \omega\tau)} d\mathbf{R}. \quad (32.10)$$

Analogously,

$$\begin{aligned} \epsilon^{\text{im}}(\mathbf{k}, \omega) &= \frac{1}{2i} \int_0^{\infty} d\tau \int \epsilon(|\mathbf{R}|, |\tau|) e^{-i(\mathbf{k} \cdot \mathbf{R} - \omega\tau)} d\mathbf{R} \\ &\quad - \frac{1}{2i} \int_{-\infty}^0 d\tau \int \epsilon(|\mathbf{R}|, |\tau|) e^{-i(\mathbf{k} \cdot \mathbf{R} - \omega\tau)} d\mathbf{R} = \\ &= \frac{1}{2i} \int_{-\infty}^{\infty} d\tau \int \epsilon(|\mathbf{R}|, |\tau|) e^{-i(\mathbf{k} \cdot \mathbf{R} - \omega\tau)} \text{sgn } \tau d\mathbf{R}, \end{aligned} \quad (32.11)$$

where the sign function $\text{sgn } \tau$ is determined according to formula (III.16). Since the real and imaginary parts of $\epsilon(\mathbf{k}, \omega)$ are expressed in terms of $\epsilon(|\mathbf{R}|, |\tau|)$ according to formulae (32.10) and (32.11), they can be interrelated.

That is, since formula (32.11) represents the Fourier transform of $(\text{sgn } \tau \cdot \epsilon)$, then taking the inverse of this transform we have

$$\text{sgn } \tau \cdot \epsilon(|\mathbf{R}|, |\tau|) = \frac{i}{\pi} \int \epsilon^{\text{im}}(\mathbf{k}', \omega') e^{i(\mathbf{k}' \cdot \mathbf{R} - \omega'\tau)} d\mathbf{k}' d\omega'. \quad (32.12)$$

Substituting the value of $\epsilon(|\mathbf{R}|, |\tau|)$ from (32.12) into (32.10), we find

$$\begin{aligned}
 \epsilon^{\text{re}}(\mathbf{k}, \omega) &= \frac{i}{(2\pi)^4} \int_{-\infty}^{\infty} d\tau \int d\omega' \int d\mathbf{k}' \int d\mathbf{R} \epsilon^{\text{im}}(\mathbf{k}', \omega') \operatorname{sgn} \tau e^{i(\mathbf{k}' - \mathbf{k}) \cdot \mathbf{R}} e^{-i(\omega - \omega')\tau} \\
 &= \frac{i}{(2\pi)^4} \int d\omega' \int d\mathbf{k}' \epsilon^{\text{im}}(\mathbf{k}', \omega') \int_{-\infty}^{\infty} e^{-i(\omega - \omega')\tau} \operatorname{sgn} \tau d\tau \int e^{i(\mathbf{k} - \mathbf{k}') \cdot \mathbf{R}} d\mathbf{R} \\
 &= \frac{i}{2\pi} \int d\omega' \int d\tau \operatorname{sgn} \tau e^{-i(\omega - \omega')\tau} \int \epsilon^{\text{im}}(\mathbf{k}', \omega') \delta(\mathbf{k} - \mathbf{k}') d\mathbf{R} = \\
 &= \frac{i}{2\pi} \int d\omega' \epsilon^{\text{im}}(\mathbf{k}, \omega') \int_{-\infty}^{\infty} e^{-i(\omega - \omega')\tau} \operatorname{sgn} \tau d\tau. \quad (32.13)
 \end{aligned}$$

The inner integral can be calculated by making use of formula (III.20) for the sign function (cf. Volume I, Appendix III)

$$\frac{1}{2\pi} \int_{-\infty}^{\infty} \operatorname{sgn} \tau e^{i(\omega - \omega')\tau} d\tau = \frac{i}{\pi} \mathcal{P} \left(\frac{1}{\omega - \omega'} \right).$$

Hence

$$\epsilon^{\text{re}}(\mathbf{k}, \omega) = \frac{1}{\pi} \mathcal{P} \int \frac{\epsilon^{\text{im}}(\mathbf{k}, \omega')}{\omega - \omega'} d\omega'. \quad (32.14)$$

The integral in formula (32.14) is taken in the sense of a principal value. Analogous calculations – the inversion of formula (32.10) and the substitution into (32.11) – give

$$\epsilon^{\text{im}}(\mathbf{k}, \omega) = -\frac{1}{\pi} \mathcal{P} \int \frac{\epsilon^{\text{re}}(\mathbf{k}, \omega')}{\omega - \omega'} d\omega'. \quad (32.15)$$

Formulae (32.14) and (32.15) are called the Kramers–Kronig formulae or dispersion relations. They relate the real and imaginary parts of the dielectric constant, in other words, the characteristics of the processes of dispersion and absorption. All the above calculations can be applied to the constitutive equation of $\mu(\mathbf{k}, \omega)$, and the same relations can be written for the real and imaginary parts of the magnetic permeability. Thus, the general principle according to which the real and imaginary parts of the basic quantities which characterize the properties of a medium – the permittivity $\epsilon(\mathbf{k}, \omega)$ and the

permeability $\mu(\mathbf{k}, \omega)$ — are correlated is established. Since, according to (31.12), the electrical conductivity is connected with the dielectric constant, the result obtained holds equally for electrical conductivity.

The Kramers—Kronig formulae are among the most general relations of electrodynamics. Indeed, in deriving them only two assumptions have been made:

- (1) the existence of the causal relationship: the value of the function \mathbf{D} at an instant t can be determined by polarization processes which occurred only at preceding instants of time,
- (2) the possibility of the expansion of all the functions in a Fourier integral.

The latter assumption is in practice fulfilled for all functions describing physical processes. Thus, the Kramers—Kronig formulae establish the relation between quantities which characterize dispersion processes (the real part of ϵ , μ or σ) and absorption processes (the imaginary part of these quantities) in the most general form. Dispersion processes and absorption processes turn out to be interrelated. Illustrations of this general proposition are encountered in many different branches of physics, in particular in quantum mechanics and the theory of elementary particles (see Part V). Besides the importance of this principle, the Kramers—Kronig formulae are of great practical importance. The imaginary part of the dielectric constant is connected with the absorption of energy in the medium (see (31.13)) and can be found relatively simply by experiment, while the real part ϵ^{re} is found from the Kramers—Kronig formula.

§33. The electromagnetic field in a medium with spatial and time dispersion

The solution of Maxwell's equations which we have already obtained in the form of transverse electromagnetic waves turns out to be not only qualitatively but also quantitatively inapplicable in the case of the propagation of electromagnetic waves in a medium with spatial dispersion.

As we have emphasized in §6, the phenomenon of spatial dispersion proves to be important in the case where the wavelength becomes comparable with the size of the spatial non-uniformities of the medium. Then the value of the induction at a given point \mathbf{r} of space turns out, according to (6.5), to be dependent on the value of the field vector and the properties of the medium in the region of space surrounding it (the whole set of points \mathbf{r}').

In this case one usually speaks of the "non-local connection" between the corresponding quantities \mathbf{D} and \mathbf{E} .

Until recently it was assumed that in macroscopically homogeneous media

the phenomenon of spatial dispersion could be disregarded. However, it turns out that spatial dispersion plays an important role in a very large class of macroscopically homogeneous media called plasma-like media. This class comprises the plasma itself (whose properties will be discussed in ch. 6) as well as conductors (metals) and semi-conductors with a high electric conductivity, when one has to investigate their interaction with high-frequency fields.

In such media there are characteristic non-uniformities of a relatively large scale. As an example one can mention the mean free path of electrons in metals, which will be calculated in Part VI. The mean free path amounts to about 7×10^{-6} cm – 10^{-5} cm.

Another example of spatial non-uniformity in connection with a plasma will be presented in §46.

The important part played by plasma-like media in contemporary physics has made the study of the properties of media with spatial dispersion very relevant.

Let us consider a macroscopically homogeneous, and isotropic, non-magnetizable ($\mu \approx 1$) medium without currents or free charges. We seek a solution of Maxwell's equations in the form of expansions in a Fourier integral. This method has now become one of the most popular and frequently used methods. We write the expansions in the form

$$\mathbf{D}(\mathbf{r}, t) = \frac{1}{(2\pi)^4} \int e^{i(\mathbf{k} \cdot \mathbf{r} - \omega t)} \mathbf{D}(\mathbf{k}, \omega) d\mathbf{k} d\omega, \quad (33.1)$$

$$\mathbf{E}(\mathbf{r}, t) = \frac{1}{(2\pi)^4} \int e^{i(\mathbf{k} \cdot \mathbf{r} - \omega t)} \mathbf{E}(\mathbf{k}, \omega) d\mathbf{k} d\omega, \quad (33.2)$$

$$\mathbf{B}(\mathbf{r}, t) = \frac{1}{(2\pi)^4} \int e^{i(\mathbf{k} \cdot \mathbf{r} - \omega t)} \mathbf{B}(\mathbf{k}, \omega) d\mathbf{k} d\omega, \quad (33.3)$$

$$\mathbf{H}(\mathbf{r}, t) = \frac{1}{(2\pi)^4} \int e^{i(\mathbf{k} \cdot \mathbf{r} - \omega t)} \mathbf{H}(\mathbf{k}, \omega) d\mathbf{k} d\omega. \quad (33.4)$$

Substituting these expansions into Maxwell's equations, we find

$$i [\mathbf{k} \times \mathbf{H}(\mathbf{k}, \omega)] = -i \frac{\omega}{c} \mathbf{D}(\mathbf{k}, \omega), \quad (33.5)$$

$$i [\mathbf{k} \times \mathbf{E}(\mathbf{k}, \omega)] = i \frac{\omega}{c} \mathbf{B}(\mathbf{k}, \omega), \quad (33.6)$$

$$\mathbf{k} \cdot \mathbf{D} = 0, \quad (33.7)$$

$$\mathbf{k} \cdot \mathbf{B} = 0. \quad (33.8)$$

Thus the problem of integration of the system of equations in partial derivatives is reduced to the problem of the solution of a system of algebraic equations and the subsequent inversion of the Fourier transformation formulae.

In order that these relations assume a practical meaning, one has to write constitutive equations for $\mathbf{D}(\mathbf{k}, \omega)$ and $\mathbf{E}(\mathbf{k}, \omega)$, and $\mathbf{B}(\mathbf{k}, \omega)$ and $\mathbf{H}(\mathbf{k}, \omega)$ respectively.

We introduce the dielectric constant connecting $\mathbf{D}(\mathbf{k}, \omega)$ and $\mathbf{E}(\mathbf{k}, \omega)$. We note that, since the dielectric constant depends on \mathbf{k} , even for an isotropic medium it is a tensor and not a scalar.

That is, since it can depend on the vector \mathbf{k} , and the direction of the vector \mathbf{k} is the only direction defined in the isotropic medium, in order to determine the dielectric constant we have to form a symmetric tensor of the second rank containing only the tensor δ_{ij} and the components of the vector \mathbf{k} .

The only second-rank symmetric tensor ϵ_{ij} which can be made up of these quantities has the form

$$\epsilon_{ij}(\mathbf{k}, \omega) = \epsilon_{\perp}(\mathbf{k}, \omega) \left(\delta_{ij} - \frac{k_i k_j}{k^2} \right) + \epsilon_{\parallel} \frac{k_i k_j}{k^2}. \quad (33.9)$$

If the direction of the wave vector is chosen as the z -axis, then one can write for ϵ_{ij} the explicit expression

$$\epsilon_{ij} = \begin{vmatrix} \epsilon_{\perp} & 0 & 0 \\ 0 & \epsilon_{\perp} & 0 \\ 0 & 0 & \epsilon_{\parallel} \end{vmatrix}. \quad (33.10)$$

An isotropic medium with spatial dispersion is characterized by two dielectric constants: the longitudinal one ϵ_{\parallel} and the perpendicular one ϵ_{\perp} . The reason for such a terminology will be clear from what follows. It goes without saying that ϵ_{\parallel} and ϵ_{\perp} are functions of \mathbf{k} and ω .

If spatial dispersion is absent, then the dielectric constant $\epsilon(t-t')$ depends only on the time. Correspondingly, ϵ_{ij} in (33.9) must depend only on ω and not on \mathbf{k} . It can then be assumed that

$$\epsilon_{\perp}(\omega) = \epsilon_{\parallel}(\omega) = \epsilon(\omega). \quad (33.11)$$

Then

$$\epsilon_{ij} = \epsilon(\omega) \delta_{ij}. \quad (33.12)$$

The constitutive equation for the Fourier components will have the form

$$D_i(\mathbf{k}, \omega) = \epsilon_{ij}(\mathbf{k}, \omega) E_j(\mathbf{k}, \omega). \quad (33.13)$$

Forming the vector product of (33.6) and \mathbf{k} , we have

$$\mathbf{k} \times (\mathbf{k} \times \mathbf{E}) = k^2 \mathbf{E} - \mathbf{k}(\mathbf{k} \cdot \mathbf{E}) = -\frac{\omega}{c} (\mathbf{k} \times \mathbf{B}).$$

Substituting into the right-hand side its value from (33.5), we find

$$k^2 \mathbf{E} - \mathbf{k}(\mathbf{k} \cdot \mathbf{E}) = \frac{\omega^2}{c^2} \mathbf{D}, \quad (33.14)$$

or

$$k^2 E_j \delta_{ij} - k_i (k_j E_j) = \frac{\omega^2}{c^2} D_i.$$

Making use of the constitutive equation (33.13), we finally obtain

$$\left\{ k^2 \delta_{ij} - k_i k_j - \frac{\omega^2}{c^2} \epsilon_{ij} \right\} E_j = 0. \quad (33.15)$$

Formula (33.15) determines a system of linear algebraic equations. In order that this system should have a non-trivial solution it is necessary that the following condition be fulfilled:

$$k^2 \delta_{ij} - k_i k_j - \frac{\omega^2}{c^2} \epsilon_{ij} = 0. \quad (33.16)$$

This expression determines the dependence of ϵ_{ij} on \mathbf{k} and ω , i.e. represents a dispersion equation. We note, first of all, that taking into account the definition (33.9) and choosing the direction of the vector \mathbf{k} as the z -axis ($k_x = k_y = 0$, $k_z = k$), one can write the equation in the form of a system of algebraic equations

$$\frac{\omega^2}{c^2} \epsilon_{\perp}(\mathbf{k}, \omega) - k^2 = 0, \quad (33.17)$$

$$\epsilon_{\parallel} = \epsilon_{zz} = 0. \quad (33.18)$$

Eqs. (33.18) and (33.17) are independent dispersion equations for electromagnetic waves which can propagate in a medium with spatial dispersion. We see that in such a medium the existence of two independent wave processes is possible: transverse waves, for which the dispersion law (33.17) is valid, and longitudinal waves, for which the dispersion law is given by formula (33.18). For transverse waves the electric field vector \mathbf{E}_{\perp} has components E_x and E_y which are different from zero; for longitudinal waves the field has only one component: E_z . In order to avoid misunderstanding, we point out that for longitudinal waves the condition (33.7) is fulfilled, so that the vector \mathbf{D} is perpendicular to the vector \mathbf{k} , i.e. to the direction of propagation. However, the vectors \mathbf{D} and \mathbf{E} , by virtue of (33.14), are not parallel to each other. The appearance of longitudinal electromagnetic waves, which are often called polarization waves, appears to be a specific effect associated with the spatial dispersion of a medium. Longitudinal electromagnetic waves in a medium with spatial dispersion have a simple meaning. Consider a medium with an equilibrium but non-uniform charge distribution and assume that such a medium is acted upon by an electromagnetic field with a wavelength which is comparable to the size of the non-uniformity. The field causes a displacement of the charges (i.e. produces a polarization), violating the equilibrium distribution. As a result, charge oscillations which are very similar to elastic sound waves in isotropic media arise in the medium.

A more concrete quantitative description of the propagation of longitudinal waves will be developed in §46 for the case of a plasma. There we shall obtain explicit expressions for ϵ_{\perp} and ϵ_{\parallel} and, by means of eqs. (33.18) and (33.17), the law of dispersion in a plasma, also obtain $\omega_{\perp}(\mathbf{k})$ and $\omega_{\parallel}(\mathbf{k})$ for transverse and longitudinal waves.

In the case of a spatially homogeneous medium the dispersion equation goes over into the equation

$$\frac{\omega^2}{c^2} \epsilon(\omega) - k^2 = 0, \quad (33.19)$$

which is the same as (31.11) and which determines unambiguously the wave frequency $\omega(\mathbf{k})$.

Since, by virtue of (33.11), in such a medium $\epsilon_{||} = \epsilon(\omega) \neq 0$, the only possible solution of eq. (31.6) reads

$$E_{||} \equiv E_z = 0.$$

Thus, in correspondence with the results of §31, only transverse waves can propagate in a medium without spatial dispersion.

We note that we have obtained the dispersion equations and other basic properties of waves without finding the field vectors as functions of the coordinates and time. The latter require the inversion of the Fourier integrals, which, according to (33.1) – (33.4) and (33.13), can actually be carried out if the dispersion law is known in explicit form. In practice it is often just the dispersion law which is of basic interest. The calculation of field vectors according to formulae (33.1) – (33.4), which presents a major difficulty, can often be avoided. This fact represents the major advantage of using the Fourier integral method.

In conclusion we shall find the relation between the tensor ϵ_{ij} and the electrical conductivity tensor σ_{ij} .

Since the relation

$$\frac{\partial \mathbf{D}}{\partial t} = \frac{\partial \mathbf{E}}{\partial t} + \frac{4\pi}{c} \mathbf{j}$$

is of universal character, then, substituting into it the expansions of the corresponding vectors in the Fourier integral and making use of the expression (33.13) and the definition of the electrical conductivity tensor we obtain

$$\epsilon_{ij} = \sigma_{ij} - i \frac{4\pi\sigma_{ij}}{\omega}. \quad (33.20)$$

This formula is a generalization of formula (31.12) which was obtained for the case where spatial dispersion is absent.

§34. The dispersion of light

We have discussed the effect of the scattering of electromagnetic waves by free and bound electrons in §36 of Part I. We shall now consider this effect from a somewhat different point of view. Namely, we shall calculate the

dielectric constant of a medium containing electrons which scatter the radiation.

As the simplest medium we shall consider a rarefied gas in which the polarization \mathbf{P} is equal to

$$\mathbf{P} = N\mathbf{d},$$

where N is the number of charges which produce the scattering, and \mathbf{d} is the dipole moment acquired by each of these. According to (36.2) of Part I, for \mathbf{d} we have

$$\mathbf{d} = \frac{e^2}{m} \frac{\mathbf{E}}{\omega_0^2 - \omega^2 + i\omega\gamma},$$

where ω_0 is the natural frequency of the oscillator.

The field \mathbf{E} in a rarefied gas is equal to the external field. Hence

$$\mathbf{D} = \mathbf{E} + 4\pi\mathbf{P} = \mathbf{E} \left(1 + 4\pi N \frac{e^2}{m} \frac{1}{\omega_0^2 - \omega^2 + i\gamma\omega} \right), \quad (34.1)$$

and, consequently, making use of the definition (31.13), one can write for the dielectric constant

$$\epsilon = (n - i\kappa)^2 = 1 + \frac{4\pi e^2}{m} \frac{N}{\omega_0^2 - \omega^2 + i\gamma\omega}. \quad (34.2)$$

For a sufficiently rarefied gas the second term of (34.2), proportional to the number of electrons per unit volume, is small in absolute value, compared with unity, at all frequencies. Hence one can write approximately

$$n - i\kappa \approx 1 + \frac{2\pi e^2}{m} \frac{N}{\omega_0^2 - \omega^2 + i\gamma\omega}.$$

Separating the real and imaginary parts, we find

$$n = 1 + \frac{2\pi e^2 N}{m} \frac{\omega_0^2 - \omega^2}{(\omega_0^2 - \omega^2)^2 + \gamma^2 \omega^2}, \quad (34.3)$$

$$\kappa = \frac{2\pi e^2 N}{m} \frac{\gamma\omega}{(\omega_0^2 - \omega^2)^2 + \gamma^2 \omega^2}. \quad (34.4)$$

The formulae obtained above determine clearly measurable quantities — the refractive index and the absorption coefficient of the radiation. If we took a system of oscillators with natural frequencies $\omega_{01}, \omega_{02}, \dots, \omega_{0i}, \dots$, as a model of the gas, then in formulae (34.3) and (34.4) we would have to carry out the summation over different kinds of oscillators.

Let us discuss the dependence of n and κ on the frequency of the radiation in more detail. We assume, first of all, that ω differs sufficiently from the natural frequencies ω_{0i} . Then, neglecting $\gamma^2\omega^2$ in the denominator, we obtain

$$n^2 - \kappa^2 = 1 + \frac{4\pi e^2}{m} \sum_i \frac{N_i}{\omega_{0i}^2 - \omega^2}, \quad (34.5)$$

$$2n\kappa = \frac{4\pi e^2}{m} \sum_i \frac{N_i \omega \gamma}{(\omega_{0i}^2 - \omega^2)^2}. \quad (34.6)$$

We see that the absorption coefficient κ in the region $\omega \neq \omega_0$ is very small and that for n one can write

$$n \approx 1 + \frac{2\pi e^2}{m} \sum_i \frac{N_i}{\omega_{0i}^2 - \omega^2}. \quad (34.7)$$

Formula (34.7) expresses the dispersion law in a rarefied gas. The dependence of the refractive index on the frequency is shown in fig. IV.14. As

Fig. IV.14

ω approaches ω_0 , n increases sharply. For values of ω which are greater than ω_0 the index of refraction takes on a very small value (see below) and again increases with frequency. Each substance has its proper set of characteristic frequencies ω_{0i} . As an example we have in fig. IV.14 restricted ourselves to three frequencies.

We have already pointed out in Part I that real microscopic radiators, atoms and molecules, do not obey the laws of classical electrodynamics. Nevertheless, the harmonic oscillator, as a classical model of radiating systems, does yield a number of the basic properties of real emitters. This is seen particularly clearly in the example of dispersion. In quantum mechanics (see §108, Part V) it will be shown that the dispersion law is expressed by the formula

$$n = 1 + \frac{2\pi e^2 N}{m} \sum_r \frac{f_r}{\omega_r^2 - \omega^2}, \quad (34.8)$$

where the ω_r 's are the transition frequencies connected by the relation $\omega_r = (E_r - E_0)/\hbar$ between the r th and the lowest energy levels of the emitter, and the f_r 's are coefficients satisfying the condition $\sum f_r = 1$.

The resemblance between the accurate formula (34.8) and the formula based on the classical model (34.7) is obvious, although the quantities contained in the latter have a completely different meaning.

In the case of high frequencies satisfying the condition $\omega \gg \omega_r$, the quantum formula and the classical formula for the refractive index both assume the form

$$n = 1 - \frac{2\pi e^2}{m} \frac{N}{\omega^2}. \quad (34.9)$$

The refractive index turns out to be smaller than unity and to be independent of the properties of the substance, except for the number of electrons per unit volume. The meaning of this result is very simple: for the scattering of sufficiently hard radiation the binding of electrons in atoms ceases to play a significant part. Atomic electrons scatter the radiation just as free electrons. The refractive index n defined by formula (34.9) appears to be that of a medium which represents a gas of free electrons with density N . Formula (34.9) is applicable in the ultraviolet region to elements which are at the beginning of the periodic system and have a small binding energy for the electrons in the atoms, and it is applicable in the X-ray region to elements of the middle part and end of the periodic system.

A medium with $n < 1$ is optically less dense than vacuum. The phase velocity of electromagnetic waves in it is $v = c/n > c$ (see § 7 of Part II).

When sufficiently short electromagnetic waves are incident on the surface of a body, the phenomenon of total internal reflection (which will be described later, in § 35) can occur.

It is interesting to calculate the group velocity of electromagnetic waves in such a medium

$$v_g = \frac{d\omega}{dk} = \left(\frac{dk}{d\omega} \right)^{-1}.$$

We calculate $dk/d\omega$ making use of (34.9):

$$\frac{dk}{d\omega} = \frac{d}{d\omega} \frac{\omega}{v} = \frac{1}{c} \frac{d}{d\omega} (\omega n) = \frac{1}{c} \left(n + \omega \frac{dn}{d\omega} \right) = \frac{1}{c} \left(1 + \frac{2\pi e^2}{m} \frac{N}{\omega^2} \right).$$

Hence

$$v_g = \frac{c}{1 + \frac{2\pi e^2 N}{m\omega^2}} \approx c \left(1 - \frac{2\pi e^2 N}{m\omega^2} \right) = cn.$$

The group velocity, as is to be expected, turns out to be smaller than the velocity of light.

We now come back to the general case of dispersion and consider the frequency range $\omega \approx \omega_0$. In this case formula (34.5) is inadequate and one has to return to expressions (34.3) and (34.4). For $\omega \approx \omega_0$ one can write that

$$\omega_0^2 - \omega^2 \approx (\omega_0 - \omega) 2\omega_0.$$

We introduce a new variable

$$x = \frac{\omega - \omega_0}{\frac{1}{2}\gamma}.$$

Then

$$n = 1 - \frac{2\pi e^2 N}{m\gamma\omega_0} \frac{x}{1 + x^2},$$

Fig. IV.15

$$\kappa = \frac{2\pi e^2 N}{m\gamma\omega_0} \frac{1}{1+x^2}.$$

The curves $\kappa(x)$ and $n(x) - 1$ are shown in fig. IV.15. We see that maximum absorption occurs for $x = 0$ (i.e. $\omega = \omega_0$). This absorption or, more precisely, attenuation, is associated with a large value of the cross-section for scattering (see §36 of Part I). It decreases sharply with increasing $|x|$, reaching half of its maximum value for $x = \pm 1$. The refractive index in the region $-1 < x < 1$ displays a dependence on x which is completely different from that for $|x| > 1$ (shown in fig. IV.15). For $|x| > 1$, n increases with increasing x , while for $x = \mp 1$ it reaches respectively its maximum and minimum values. In the interval $-1 < x < 1$, $n(x)$ is not an increasing but a decreasing function of x , reaching the value $n = 1$ at $x = 0$. This region, in which the index of refraction decreases with increasing frequency, is called the region of anomalous dispersion. In the region of anomalous dispersion a rarefied gas possesses its highest absorption (minimum transparency).

We shall come back to the problems of dispersion in quantum mechanics where it will be shown that besides scattering without a change in frequency scattering with a change in frequency (so-called Raman scattering) is possible.

§35. Geometrical optics

In the above we have found the law of the propagation of plane electromagnetic waves in homogeneous transparent media. A characteristic of a plane wave is the fact that its equiphase surface is infinitely large and plane.

Plane electromagnetic waves are particularly simple because their amplitude and wave vector remain constant in space and time. It turns out that, under certain conditions and with a certain degree of accuracy, analogous properties are possessed by arbitrary electromagnetic waves. As will be shown below, it is necessary for this that the curvature of the wave surface is sufficiently small over spatial regions which are large compared with the wavelength.

The approximate replacement of the wave surface by a plane is of very great practical importance, since in the case of an arbitrary form of the surface the laws of propagation of the waves turn out to be very complex.

From the aforesaid it is clear that such a substitution is allowed, in any case, if the wavelength is very small. Therefore the limiting case of electromagnetic waves whose wavelength $\lambda \rightarrow 0$ deserves particular consideration.

In practice the region of visible light already corresponds to this case. Indeed, the wavelength of visible light is about 5×10^{-5} cm. It is always very small in comparison with the size of macroscopic bodies and optical devices. For this reason the study of the laws of propagation of electromagnetic waves in the limiting case $\lambda \rightarrow 0$ is called geometrical optics.

We shall below, for the same reason, sometimes call an electromagnetic wave a light wave, and we shall speak of the propagation of light. This should not lead to misunderstanding.

In a transparent medium each of the components of the field vectors \mathbf{E} and \mathbf{H} satisfies the wave equation

$$\nabla^2 F - \frac{\epsilon}{c^2} \frac{\partial^2 F}{\partial t^2} = 0.$$

Here F denotes an arbitrary component of the field.

In a bounded medium, in addition to the wave equation the components of the field vectors must also satisfy the boundary conditions. Therefore the

components of the vectors \mathbf{E} and \mathbf{H} are connected with each other by certain relations and are not quite independent. However, at a sufficiently large distance from the interface of media this fact can be disregarded and all the components of \mathbf{E} and \mathbf{H} can be considered as independent. Then the wave field can be characterized by the scalar quantity F .

Considering a monochromatic wave, we can write

$$F = f(x, y, z) e^{-i\omega t}.$$

The function f obviously satisfies the equation

$$\nabla^2 f + \frac{\epsilon\omega^2}{c^2} f = 0.$$

Introducing the wave number $k = \omega/c$ and the refraction index $n = \epsilon^{1/2}$, one can rewrite the above equation in the form

$$\nabla^2 f + n^2 k^2 f = 0. \quad (35.1)$$

To a plane wave there corresponds the solution of eq. (35.1)

$$f = a e^{in(\mathbf{k} \cdot \mathbf{r})} a e^{ik(n\mathbf{k}_0 \cdot \mathbf{r})} = a e^{ikl}, \quad (35.2)$$

where a is a constant amplitude, and $l = n(\mathbf{k}_0 \cdot \mathbf{r})$ is a quantity which is usually called the optical path length and is a linear function of coordinates. It differs from the geometrical path by the factor n .

We have to find the solutions of eq. (35.1) in a general form, without confining ourselves to a plane wave. However, we shall consider the limiting case $\lambda \rightarrow 0$ or $k \rightarrow \infty$. We shall try to write the solution of eq. (35.1) in the limiting case of very large k as

$$f = a e^{i\psi(x, y, z)}. \quad (35.3)$$

Here the quantity ψ , called the eikonal, has a form which approaches as closely as possible that of the phase of the plane wave

$$\psi = k\mathcal{L}(x, y, z),$$

where $\mathcal{L}(x, y, z)$ is a function of the coordinates which is sufficiently close to a linear function. Thus, we shall try to find the solution of (35.1) in the form

$$f = a e^{ik\mathcal{L}(x,y,z)} . \quad (35.4)$$

We calculate the derivatives of the function f :

$$\nabla f = a \nabla e^{ik\mathcal{L}} = ika e^{ik\mathcal{L}} \nabla \mathcal{L}$$

$$\nabla^2 f = \nabla \cdot \nabla a e^{ik\mathcal{L}} = ika e^{ik\mathcal{L}} \nabla^2 \mathcal{L} - k^2 a e^{ik\mathcal{L}} (\nabla \mathcal{L})^2 .$$

Hence eq. (35.1) assumes the form

$$ika e^{ik\mathcal{L}} \nabla^2 \mathcal{L} - k^2 a e^{ik\mathcal{L}} (\nabla \mathcal{L})^2 + n^2 k^2 a e^{ik\mathcal{L}} = 0 ,$$

or

$$(\nabla \mathcal{L})^2 - (i/k) \nabla^2 \mathcal{L} = n^2 . \quad (35.5)$$

The quantity \mathcal{L} does not depend on k . Therefore, if for $k \rightarrow \infty$ the inequality

$$|\nabla \mathcal{L}|^2 \gg k^{-1} \nabla^2 \mathcal{L} , \quad (35.6)$$

is fulfilled, then one can pass to the limit $k \rightarrow \infty$ in eq. (35.5) and drop the second term. Then eq. (35.5) assumes the form

$$|\nabla \mathcal{L}|^2 = n^2 ,$$

or

$$(\nabla \psi)^2 = n^2 k^2 . \quad (35.7)$$

In the coordinate representation this last equation has the form

$$\left(\frac{\partial \psi}{\partial x} \right)^2 + \left(\frac{\partial \psi}{\partial y} \right)^2 + \left(\frac{\partial \psi}{\partial z} \right)^2 = n^2 k^2 . \quad (35.7')$$

Eq. (35.7) is called the eikonal equation. In deriving it we have not made any assumptions about the values of the refractive index n , which can be an arbitrary function of the coordinates.

Knowing the solutions of eq. (35.7), we find an approximate solution of the wave equation (35.1) with the assumption that k is a sufficiently large number. In the limit $k \rightarrow \infty$ this solution is the same as a plane wave propagat-

ing in the direction of n . The condition of applicability of eq. (35.7) is (35.6). Later we shall discuss the question of the physical conditions to which this inequality corresponds and when it may not be satisfied.

If ψ is a solution of the eikonal equation, then

$$\psi = k\mathcal{L}(x, y, z) = \text{const}$$

is the equation of an equiphase surface. The propagation of electromagnetic waves takes place in the direction of the normal to the constant-eikonal surface, i.e. in the direction of the vector $\nabla\mathcal{L}$. This direction of propagation of waves is called the light ray direction.

Over a small region of space the eikonal ψ can be expanded in a series, writing

$$\psi \approx \frac{\partial\psi}{\partial\mathbf{r}} \cdot \mathbf{r} = k \frac{\partial\mathcal{L}}{\partial\mathbf{r}} \cdot \mathbf{r} = k(\nabla\mathcal{L}) \cdot \mathbf{r}. \quad (35.8)$$

For f , according to (35.3), we have

$$f = a e^{ik(\nabla\mathcal{L}) \cdot \mathbf{r}} = a e^{ikl}, \quad (35.9)$$

The optical path l turns out to be equal to $(\nabla\mathcal{L}) \cdot \mathbf{r}$.

Comparing (35.9) with (35.2), we see that, within the framework of the applicability of geometrical optics, over a small region of space each wave can be considered as a plane wave with its wave vector directed along the normal to the constant-eikonal surface. In particular, for a homogeneous medium with a constant refractive index, it follows from (35.7) that

$$\nabla\psi = \text{const}.$$

This means that adjacent equi-eikonal surfaces are at equal distances from each other. The normals to these surfaces are straight lines. This statement has a simple meaning: in a homogeneous medium light rays are propagated rectilinearly.

We shall not dwell on the application of geometrical optics to optical and electro-optical systems*. We shall discuss only the question of the meaning

* See, for example, L.D.Landau and E.M.Lifshitz, *The classical theory of fields* (Pergamon Press, London, 1962) §55–57; M.Born and E.Wolf, *Principles of optics* (Pergamon Press, London, 1959, 1965).

of the inequality (35.6) which serves as the condition of applicability of the approximation of geometrical optics.

As is known from geometry, the quantity $\nabla^2\psi$ determines the mean radius of curvature of a slightly curved surface $\psi = \text{const}$. Thus, the inequality (35.6) has a simple geometrical meaning: it means that the mean radius of curvature of the constant-eikonal surface must be large in comparison with the wavelength λ . In other words, the light perturbation must vary smoothly from point to point. The conditions of applicability of the approximation of geometrical optics are undoubtedly violated in the immediate vicinity of the emitter. Here the variation of the wave field from point to point is very rapid. The quantity $\nabla^2\psi$ can be of the same order of magnitude as the wavelength.

Consider a second important case where it turns out that it is impossible to make use of the concepts of geometrical optics.

Let a completely non-transparent body, or screen, be placed in the path of light rays. In the approximation of geometrical optics the light rays do not penetrate the region behind the screen (fig. IV.16). Behind the opaque screen there is a region of shadow.

Let us consider the boundary separating the illuminated region and the shadow (straight lines AB and CD in fig. IV.16). Here a discontinuous change in the amplitude from the value a to zero occurs. Hence the derivatives of f with respect to the coordinates become infinite at the boundary between light and shadow. Here the conditions for applicability of geometrical optics are again violated. In the next paragraph we shall discuss physical phenomena which arise in this case.

Fig. IV.16

§36. Diffraction

As we have just shown, at the boundary separating the illuminated and the shaded regions the approximation of geometrical optics and the concept of rectilinear light rays becomes inadmissible.

Naturally, there cannot exist a sharp boundary between these regions. Near the edge of the non-transparent screen the propagation of light cannot in reality be described by a simplified wave equation. The solution of the correct equation, taking into account the boundary conditions at the surface of the screen, leads to an intensity distribution corresponding to a gradual transition from the region of total illumination to that of shadow. At the boundary between the illuminated and shaded regions departure from the rectilinear propagation of light occurs, as if the rays were bent. This is called diffraction.

The solution of the boundary value problem of diffraction turns out to be very complicated. Therefore special methods for a simplified calculation of diffraction phenomena have been developed. We shall restrict ourselves to the discussion of the most important and at the same time simplest case.

Let a plane parallel beam of light be incident on a screen having an opening of arbitrary shape. The light beam comes from a source of intensity I_0 which is distant from the screen. At the edge of the screen diffraction of the light occurs. We are interested in the light intensity distribution at a large distance from the opening (large compared with the size of the opening). Diffraction in the case where both the light source and the point of observation are located at infinitely large distances from the aperture which produces the diffraction, or from the screen, is called Fraunhofer diffraction.

For Fraunhofer diffraction the waves which fall on the screen and those which pass through the opening at a large distance from its edge can be assumed to be plane waves. We shall call the wave incident on the screen the primary wave. This wave, falling on the opaque screen, is completely absorbed. However, part of it passes through the opening in the screen. The opening in the screen becomes an emitter of electromagnetic waves into the space behind the screen.

Each point of the area of the opening is a source of secondary spherical waves which reach the point of observation with a certain retardation.

If the value of any component of the field at a point \mathbf{r}_0 located in the area of the opening is $f_0 = \text{const } e^{-i\omega t}$, then the perturbation coming from this point to the point of observation N will be of the order of magnitude of $R^{-1} f_0(\tau) = \text{const } e^{-i\omega\tau}$, where $\tau = t - R/c$ is the delay time (see §23 of Part I).

The total field at the point of observation is obtained on the basis of the principle of superposition by summing over all the emitters, i.e. over all points of the opening in the screen.

Thus, at the point of observation N we have

$$\begin{aligned} f_N &= \text{const} \cdot \int \frac{e^{-i\omega(t-R/c)}}{R} dS = \text{const} \cdot e^{-i\omega t} \int \frac{e^{i\omega R/c}}{R} dS = \\ &= \text{const} \cdot e^{-i\omega t} \int \frac{e^{ikR}}{R} dS. \end{aligned} \quad (36.1)$$

Here f denotes any component of the electric or magnetic field. In the same approximation as in the preceding section we ignore polarization phenomena and assume all components of the field to be independent.

Formula (36.1) is of a general character. In calculating the integral (36.1) we shall bear in mind that the distance to the point of observation is large in comparison with the size of the opening (Fraunhofer diffraction!).

We introduce an origin, locating it at a point of the opening (fig. IV.17). Then one can, as usual (see, for example, §15 or §26 of Part I), write

Fig. IV.17

$$R = |\mathbf{r}_0 - \mathbf{r}| \approx r_0 - \mathbf{n}_0 \cdot \mathbf{r},$$

where $\mathbf{n}_0 = \mathbf{r}_0/r_0$ is the unit vector in the direction of \mathbf{r}_0 .

The quantity $|\mathbf{r}|$, which varies within the limits of the opening, is small in comparison with $|\mathbf{r}_0|$, but may be large compared with the wavelength. Therefore the term $\mathbf{n}_0 \cdot \mathbf{r}$ can be dropped in the denominator of formula (36.1) but must be retained in the exponent. Hence we have

$$f \approx \frac{\text{const}}{r_0} \exp[-i\omega t] \exp[ikr_0] \int \exp[-ik\mathbf{n}_0 \cdot \mathbf{r}] dS = A \int \exp[-i\mathbf{q} \cdot \mathbf{r}] dS, \quad (36.2)$$

where $\mathbf{q} = k\mathbf{n}_0$, and A denotes the whole set of factors in front of the integral. The value of this constant will be expressed in terms of the intensity of the incident wave.

Choosing the plane of the opening to be the plane $z = 0$, one can write the quantity $\mathbf{q} \cdot \mathbf{r}$ in the form

$$\mathbf{q} \cdot \mathbf{r} = q_1 x + q_2 y = k \frac{x_0}{r_0} x + k \frac{y_0}{r_0} y = kx \cos \alpha + ky \cos \beta. \quad (36.3)$$

Here $\cos \alpha$ and $\cos \beta$ are the direction cosines of the vector \mathbf{n}_0 .

If the wave vector of the incident wave is normal to the plane of the opening and the angle of deflection is small, then it is easily seen that

$$\cos \alpha \approx \sin \theta_1 \approx \theta_1,$$

$$\cos \beta \approx \sin \theta_2 \approx \theta_2,$$

where θ_1 and θ_2 are the angles of diffraction in the xz -plane and yz -plane. In this case

$$q_1 \approx k\theta_1, \quad q_2 \approx k\theta_2. \quad (36.4)$$

The integration in (36.2) is carried out over the area of the opening. If one introduces the function

$$\xi(x, y) = \begin{cases} 1 & \text{for } (x, y) \text{ within the limits of the opening} \\ 0 & \text{for } (x, y) \text{ outside the limits of the opening,} \end{cases}$$

then one can write (36.2) in the form

$$f = A \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \xi(x, y) \exp [-i(q_1 x + q_2 y)] dx dy \quad (36.5)$$

where the integration is carried out over the entire area of the screen (including the opening).

In order to determine the constant A we note that (36.5) represents the Fourier integral of the function $\xi(x, y)$. Hence

$$\xi(x, y) = \frac{1}{(2\pi)^2 A} \int \exp [i(q_1 x + q_2 y)] f(q_1, q_2) dq_1 dq_2 .$$

From formula (II.9) it follows that

$$\int |\xi(x, y)|^2 dx dy = \frac{1}{(2\pi)^2 A^2} \int |f(q_1, q_2)|^2 dq_1 dq_2 .$$

By the definition of ξ the integral on the left is equal to unity multiplied by the area S of the opening. The integral $\int |f(q_1, q_2)|^2 dq_1 dq_2$ by definition represents the total intensity behind the screen. The latter is equal, obviously, to the total intensity of light passing through the opening in the screen, i.e. to

$$\int |f|^2 dq_1 dq_2 = I_0 S ,$$

where I_0 is the intensity of the incident light. Hence we find the value of A :

$$A = I_0^{1/2} / 2\pi \quad (36.6)$$

and, finally, we have

$$f(q_1, q_2) = (I_0^{1/2} / 2\pi) \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \exp [-i(q_1 x + q_2 y)] \xi(x, y) dx dy . \quad (36.7)$$

Formula (36.7) gives the general solution of the problem posed; the distribution of the wave field behind a screen having an aperture at a large distance from it.

The intensity distribution is given by the quantity

$$dI = |f(q_1, q_2)|^2 dq_1 dq_2. \quad (36.8)$$

From the meaning of the quantities q_1 and q_2 it is clear that $|f|^2 dq_1 dq_2$ represents the intensity of the diffracted light for given values of the diffraction angles θ_1 and θ_2 :

$$dI = |f(q_1, q_2)|^2 k^2 d\Omega. \quad (36.8')$$

Up to now we have considered diffraction from a small opening in a screen. We now assume that light falls on a small screen whose size and form are the same as those of the opening in the screen previously considered. Such a screen is called a complementary screen with respect to the opening. The diffraction at the edge of the complementary screen is easily found from the following considerations. We match the complementary screen with the opening. Then behind the new screen, which is continuous, there will be no field of light. This latter fact can be expressed as follows: as a result of the superposition of the fields diffracted from the opening and from the complementary screen the total field is reduced to zero. Hence it follows that the field behind the complementary screen can be connected with the field behind the opening by the relation

$$f_{\text{compl}} = -f,$$

or

$$|f_{\text{compl}}|^2 dq_1 dq_2 = |f|^2 dq_1 dq_2. \quad (36.9)$$

The opening and its complementary screen give identical intensity distributions of the diffracted light. This proposition is called Babinet's principle.

We shall apply the general expression for the intensity distribution to three cases which are of great practical importance.

The first of these is the diffraction at an infinitely long slit in an opaque screen. Let the width of the slit be a . We locate the origin in the middle of the slit, and direct the y -axis parallel to its edge. The direction of the incident light coincides with the direction of the z -axis. It is obvious that the diffraction comes only from the two edges of the slit, i.e. in the integral (36.7) one has to integrate only with respect to the coordinate x . For an infinitely long slit, no diffraction of rays falling on the screen occurs in the direction of y . Hence we shall refer all quantities to unit length of the slit. In the one-dimensional case a calculation analogous to that which has been carried

out before gives the value $A = (I_0/2\pi)^{\frac{1}{2}}$. Formula (36.7) in the one-dimensional case has the form

$$f = (I_0/2\pi)^{\frac{1}{2}} \int_{-\frac{1}{2}a}^{\frac{1}{2}a} e^{-iqx} dx = (2I_0/\pi)^{\frac{1}{2}} \frac{\sin \frac{1}{2}aq}{q} = (2I_0/\pi)^{\frac{1}{2}} \frac{\sin \frac{1}{2}ka\theta}{k\theta}. \quad (36.10)$$

The intensity of light diffracted at an angle between θ and $\theta + d\theta$ is equal to

$$dI = I_0 \frac{2 \sin^2 \frac{1}{2}ka\theta}{\pi(k\theta)^2} dq = \frac{I_0 ka^2}{2\pi} \frac{\sin^2 \frac{1}{2}ka\theta}{(\frac{1}{2}ka\theta)^2} d\theta. \quad (36.11)$$

The quantity $I_0 a$ represents the total intensity of light incident on unit length of the slit.

As a result of diffraction, a system of light and dark bands arises parallel to the slit.

The intensity distribution as a function of $x = \frac{1}{2}ka\theta$ is shown in fig. IV.18. In the direction $\theta = 0$ there is a principal maximum of the intensity. At points

Fig. IV.18

$\frac{1}{2}ka\theta = \frac{1}{2}(n+1)\pi$ ($n=1,2,\dots$) the intensity has a number of secondary maxima. In these maxima the intensity is considerably lower than in the principal maximum, and decreases with increasing order of the maximum (the number n).

One can in an analogous way find the diffraction from a circular opening of radius a in the screen. We locate the origin at the centre of the circle. Then

$$\begin{aligned} f &= (I_0^{\frac{1}{2}}/2\pi) \int_0^a \int_0^{2\pi} e^{-i\mathbf{q}\cdot\mathbf{r}} r \, dr d\varphi = \\ &= (I_0^{\frac{1}{2}}/2\pi) \int_0^a \int_0^{2\pi} e^{-iqr \cos \varphi} r \, dr d\varphi = (I_0^{\frac{1}{2}}/2\pi) \int_0^a r \, dr \int_0^{2\pi} e^{-iqr \cos \varphi} d\varphi. \end{aligned}$$

From the theory of Bessel functions it is known that

$$\int_0^{2\pi} e^{-iqr \cos \varphi} d\varphi = 2\pi J_0(qr),$$

where J_0 is the Bessel function of zero order *. Hence

$$f = I_0^{\frac{1}{2}} \int_0^a J_0(qr) r \, dr.$$

In the theory of Bessel functions it is proved that

$$\int_0^a J_0(qr) r \, dr = \frac{a}{q} J_1(qa).$$

Hence, finally,

$$f = I_0^{\frac{1}{2}} \frac{a}{q} J_1(aq). \quad (36.12)$$

* This formula is most simply obtained by expanding the exponent in a series and integrating term by term. See V.I. Smirnov, *Course of higher mathematics*, Vol. III, Part 2 (Pergamon Press, Oxford, 1964).

The intensity of radiation diffracted into a solid angle $d\Omega$ is equal to

$$dI = |f|^2 k^2 d\Omega = I_0 a^2 \frac{J_1^2(ka\theta)}{\theta^2} d\Omega = (I_0 a^2 \pi) \frac{J_1^2(ka\theta)}{\pi\theta^2} d\Omega, \quad (36.13)$$

where $I_0 \pi a^2$ is the total intensity of radiation incident on the opening.

As a result of diffraction at a circular opening, a system of concentric circles of illumination arises.

The angular distribution of the diffracted radiation given by the function $[J_1^2(ka\theta)]/\pi\theta^2$ is very similar to the distribution shown in fig. IV.18. The height of the principal maximum is relatively greater, but the spacings between secondary maxima are close to those which are shown in fig. IV.18.

It should be recalled that identical formulae give the intensity distribution for diffraction from the complementary screens. Naturally there correspond to the intensity maxima for the diffraction from the aperture the maxima for the diffraction from the complementary opaque screen.

In conclusion we shall dwell on the diffraction which occurs when light is passing through a set of N infinitely long thin slits which are located at equal distances from each other (a diffraction grating).

Let the distance between the centres of neighbouring slits be d , and let the grating be oriented along the x -axis. The coordinates of the centres of the slits are $x_n = nd$, where the n are integers $n = 0, 1, 2, \dots, N$. Then (36.7) gives

$$f = (I_0/2\pi)^{\frac{1}{2}} \sum_{n=0}^N e^{-iqx_n} \int_{-\frac{1}{2}a}^{\frac{1}{2}a} e^{-iqx} dx = f_1 \sum_{n=0}^N e^{-iqnd} = f_1 \frac{1 - e^{-iNdq}}{1 - e^{-idq}},$$

where f_1 is defined by formula (36.10).

The intensity of radiation diffracted from the system of slits is given by the formula

$$dI = |f|^2 dq \sim I_0 \left(\frac{\sin \frac{1}{2} Nqd}{\sin \frac{1}{2} qd} \right)^2 \left(\frac{\sin \frac{1}{2} qa}{\frac{1}{2} qa} \right)^2 dq. \quad (36.14)$$

The interference pattern which arises corresponds to the superposition of the diffraction from different slits, but not to a simple sum of intensities.

An important part is played in modern physics by the phenomenon of diffraction of X-rays (as well as electrons, neutrons etc.) by crystals (see Part V).

We shall discuss below the simplest theory of X-ray diffraction by crystals.

Let a crystal lattice be formed by a set of atoms of the same kind (i.e. atoms which are identical in their properties). We assume that absorption in the lattice is absent.

We further assume that an X-ray beam propagating in the direction \mathbf{n}_1 falls on the lattice. The coordinate of the point of the crystal at which the m th atom of the lattice is located can be written in the form

$$\mathbf{r}_m = l\mathbf{a} + n\mathbf{b} + p\mathbf{c}, \quad (36.15)$$

where l, n, p are integers (positive and negative), and the vectors $\mathbf{a}, \mathbf{b}, \mathbf{c}$ are the unit vectors of the lattice (for more detail see §109 of Part V; we restrict ourselves here to the case of the so-called primitive lattice).

A wave with amplitude

$$f = f_0 \exp \left[-i \left(\omega t - \frac{\omega \mathbf{r}_m \cdot \mathbf{n}_1}{c} \right) \right],$$

where f is an arbitrary component of the field vectors and f_0 is a constant, arrives at the point \mathbf{r}_m . The atom which is located at the point \mathbf{r}_m scatters the wave, and a wave with an amplitude

$$f_N = \frac{f_0}{R_m} \exp \left[-i \left(\omega t - \frac{\omega \mathbf{r}_m \cdot \mathbf{n}_1}{c} - \frac{\omega R_m}{c} \right) \right]$$

arrives at the point of observation N which is located at a distance R_m from the m th atom.

Assuming that

$$R_m \approx r_0 - \mathbf{n} \cdot \mathbf{r}_m,$$

where r_0 is the distance from the point N to the origin, we find for the amplitude of the wave scattered by the m th atom

$$f_N = f_0 r_0^{-1} \exp [-i\omega t] \exp [ikr_0] \exp [-ik\{\mathbf{r}_m \cdot (\mathbf{n} - \mathbf{n}_1)\}].$$

If one disregards the secondary action of the wave scattered by the m th atom on other atoms of the lattice, then one can write the total intensity at the point of observation in the form

$$I \sim I_0 \left| \sum \exp [-ik\{\mathbf{r}_m \cdot (\mathbf{n} - \mathbf{n}_1)\}] \right|^2, \quad (36.16)$$

where the summation is carried out over all the atoms of the crystal (the numbers l, n, p).

Taking into account the expression (36.15), one can write

$$\begin{aligned} k[\mathbf{r}_m \cdot (\mathbf{n} - \mathbf{n}_1)] &= kl[\mathbf{a} \cdot (\mathbf{n} - \mathbf{n}_1)] + kn[\mathbf{b} \cdot (\mathbf{n} - \mathbf{n}_1)] + kp[\mathbf{c} \cdot (\mathbf{n} - \mathbf{n}_1)] = \\ &= l[\mathbf{a} \cdot (\mathbf{k} - \mathbf{k}_1)] + n[\mathbf{b} \cdot (\mathbf{k} - \mathbf{k}_1)] + p[\mathbf{c} \cdot (\mathbf{k} - \mathbf{k}_1)]. \end{aligned}$$

Then each of the sums can be calculated directly. For example,

$$\sum_{l=0}^{N_1} \exp [-il\{\mathbf{a} \cdot (\mathbf{k} - \mathbf{k}_1)\}] = \frac{1 - \exp [-iN_1\{\mathbf{a} \cdot (\mathbf{k} - \mathbf{k}_1)\}]}{1 - \exp [-i\{\mathbf{a} \cdot (\mathbf{k} - \mathbf{k}_1)\}]} ,$$

where N_1 is the number of lattice points along the first rib of the crystal. Hence it follows immediately that

$$I \sim I_0 \frac{\sin^2 \frac{1}{2} N_1 [\mathbf{a} \cdot (\mathbf{k} - \mathbf{k}_1)]}{\sin^2 \frac{1}{2} [\mathbf{a} \cdot (\mathbf{k} - \mathbf{k}_1)]} \frac{\sin^2 \frac{1}{2} N_2 [\mathbf{b} \cdot (\mathbf{k} - \mathbf{k}_1)]}{\sin^2 \frac{1}{2} [\mathbf{b} \cdot (\mathbf{k} - \mathbf{k}_1)]} \frac{\sin^2 \frac{1}{2} N_3 [\mathbf{c} \cdot (\mathbf{k} - \mathbf{k}_1)]}{\sin^2 \frac{1}{2} [\mathbf{c} \cdot (\mathbf{k} - \mathbf{k}_1)]} . \quad (36.17)$$

Formula (36.7) is called the Laue formula. It is a generalization of the formula of the diffraction grating to the case of three dimensions with unequal spacings.

The principal maxima lie in directions determined by a set of equations which are called Bragg's conditions:

$$\begin{aligned} \mathbf{a} \cdot (\mathbf{n} - \mathbf{n}_1) &= 2\pi h_1/k = h_1 \lambda, \\ \mathbf{b} \cdot (\mathbf{n} - \mathbf{n}_1) &= 2\pi h_2/k = h_2 \lambda, \\ \mathbf{c} \cdot (\mathbf{n} - \mathbf{n}_1) &= 2\pi h_3/k = h_3 \lambda, \end{aligned} \quad (36.18)$$

where h_1, h_2, h_3 are integers.

Each of these expressions is the condition for the reduction to zero of the corresponding factor in the denominator of formula (36.17).

It should be emphasized that for given wavelength λ and direction of the

incident beam n_1 the set of three equations (36.18) allows the determination of two independent components of the unit vector \mathbf{n} . The system of eqs. (36.18) has a solution only for a definite wavelength. The reflection of X-rays from the crystal is said to have a selective character. The difference between one-dimensional and two-dimensional diffraction gratings and crystals lies in this fact.

In practice, when the wavelength which can be selectively reflected from the lattice is unknown, then the crystal is either irradiated by a continuous X-ray spectrum or the orientation of the diffraction crystal (the direction of n_1) is changed. In both cases the crystal itself "selects" conditions (the wavelength or orientation) under which the selective reflection is possible, i.e. under which the equations (36.18) are simultaneously fulfilled.

§37. The reflection and refraction of electromagnetic waves at the boundary between media

Up to now we have studied the propagation of electromagnetic waves in a homogeneous medium. We shall now consider the electromagnetic wave incident on the boundary between two dielectric media which differ from each other in the values of their dielectric constants. For simplicity of calculation we shall assume that the magnetic permeabilities of the two media are equal to unity.

We assume the boundary to be plane. It is clear that near the boundary the physical properties of the media may differ from those within their volumes, so that a thin transition layer exists at the boundary. However, if the thickness of the latter is small compared with the wavelength, its effect can be neglected and the boundary can be considered as a mathematical interface having no thickness.

We assume that a monochromatic plane wave is incident on this surface, which we choose as the plane $z = 0$. For simplicity we assume that the vector \mathbf{k} characterizing the direction of propagation of the incident wave lies in the xz -plane. We shall call the medium in which the incident wave is propagating the first medium.

We write the vectors of the electric and magnetic fields of the incident wave in the first medium in the form

$$\mathbf{E}^{\text{inc}} = A \exp [i(\omega t - \mathbf{k} \cdot \mathbf{r})] = A \exp [i(\omega t - kx \cos \alpha - kz \cos \gamma)] ,$$

$$\mathbf{H}^{\text{inc}} = C \exp [i(\omega t - \mathbf{k} \cdot \mathbf{r})] = C \exp [i(\omega t - kx \cos \alpha - kz \cos \gamma)] ,$$

where $\cos \alpha$ and $\cos \gamma$ are the direction cosines of the wave vector. Since the wave is lying in the xz -plane, $\cos \beta = 0$. The wave number k is connected with the frequency by the relation

$$k = \omega \epsilon_1^{\frac{1}{2}} / c .$$

At the interface the vectors \mathbf{E}^{inc} and \mathbf{H}^{inc} must satisfy the boundary conditions (5.2) and (5.4). The quantities \mathbf{E} and \mathbf{H} are not independent but are perpendicular to each other, and their absolute values are related by the expression (31.31). Hence two independent boundary conditions can be satisfied simultaneously only by assuming that the incident wave is partially transmitted into the second medium and partially reflected from the interface. We shall call the wave transmitted into the second medium the refracted wave, because its direction of propagation does not, as a rule, coincide with the direction of propagation of the incident wave. Let

$$\mathbf{E}^{\text{refl}} = \mathbf{A}^{\text{refl}} \exp [i(\omega^{\text{refl}} t - \mathbf{k}^{\text{refl}} \cdot \mathbf{r})] ,$$

$$\mathbf{E}^{\text{refr}} = \mathbf{A}^{\text{refr}} \exp [i(\omega^{\text{refr}} t - \mathbf{k}^{\text{refr}} \cdot \mathbf{r})] .$$

denote the electric vectors of the reflected and refracted waves. The total field in the first medium is characterized by the vector

$$\mathbf{E}_1 = \mathbf{E} + \mathbf{E}^{\text{refl}} = \mathbf{A} \exp [i(\omega t - \mathbf{k} \cdot \mathbf{r})] + \mathbf{A}^{\text{refl}} \exp [i(\omega^{\text{refl}} t - \mathbf{k}^{\text{refl}} \cdot \mathbf{r})] .$$

The boundary condition (5.2) at the interface of two media gives

$$\begin{aligned} \mathbf{A}_{\text{tg}}^{\text{inc}} \exp [i(\omega t - kx \cos \alpha)] + \mathbf{A}_{\text{tg}}^{\text{refl}} \exp [i(\omega^{\text{refl}} t - k^{\text{refl}} x \cos \alpha^{\text{refl}} - k^{\text{refl}} y \cos \beta^{\text{refl}})] \\ = \mathbf{A}_{\text{tg}}^{\text{refr}} \exp [i(\omega^{\text{refr}} t - k^{\text{refr}} x \cos \alpha^{\text{refr}} - k^{\text{refr}} y \cos \beta^{\text{refr}})] . \end{aligned}$$

This equation must hold for arbitrary values of time t and coordinates x and y . This is possible only if

$$\omega = \omega^{\text{refl}} = \omega^{\text{refr}} , \quad (37.1)$$

$$k \cos \alpha = k^{\text{refl}} \cos \alpha^{\text{refl}} = k^{\text{refr}} \cos \alpha^{\text{refr}} ,$$

$$\cos \beta^{\text{refl}} = \cos \beta^{\text{refr}} = 0 .$$

The first condition means that the reflection and refraction occur without any change in the frequency. The third equality shows that the reflected and refracted waves lie in the same plane as the incident wave. Finally, taking into account that $k = \omega/v = \epsilon^{1/2} \omega/c$, one can rewrite the second relation in the form

$$(\epsilon^{1/2} \omega/c) \cos \alpha = (\epsilon^{1/2} \omega/c) \cos \alpha^{\text{refl}},$$

$$(\epsilon^{1/2} \omega/c) \cos \alpha = (\epsilon^{1/2} \omega/c) \cos \alpha^{\text{refr}},$$

whence we find that

$$\alpha = \alpha^{\text{refl}}, \quad (37.2)$$

i.e. that the angle of incidence is equal to the angle of reflection, and

$$\frac{\cos \alpha}{\cos \alpha^{\text{refr}}} = \left(\frac{\epsilon_2}{\epsilon_1} \right)^{1/2}. \quad (37.3)$$

Instead of the direction cosines $\cos \alpha$ and $\cos \alpha^{\text{refr}}$ one usually introduces $\sin \theta$ and $\sin \theta^{\text{refr}}$, where θ and θ^{refr} are the angles formed by the incident and refracted waves with the normal to the plane $z = 0$, and which are called the angle of incidence (θ) and the angle of refraction (θ^{refr}). For the latter we find

$$\frac{\sin \theta}{\sin \theta^{\text{refr}}} = n_{12} = \left(\frac{\epsilon_2}{\epsilon_1} \right)^{1/2}. \quad (37.4)$$

Here n_{12} denotes the refractive index of the boundary of the second medium with respect to the first medium.

We arrive at the laws of reflection and refraction of light. However, the value of the refractive index turns out to be related to the dielectric constants of the media. In particular, if the first medium is vacuum so that $\epsilon_1 = 1$, then

$$n = \epsilon_0^{1/2}$$

is called the refractive index of the given medium.

The expression for the refractive index justifies the terminology which we have introduced in §33.

In considering the phenomena of reflection and refraction of electromagnetic waves, which had been extensively investigated for light even before the

establishment of its electromagnetic nature, the optical terminology is adopted. A medium with a higher refractive index is said to be optically more dense than a medium with a lower refractive index.

Having established the directions of propagation of the reflected and refracted waves, we go on to the calculation of their amplitudes. Taking into account eqs. (37.1) we obtain, using the boundary condition (5.2), for the amplitudes of the reflected and refracted waves

$$A_{tg} + A_{tg}^{refl} = A_{tg}^{refr}.$$

In order to find the two quantities A^{refl} and A^{refr} , it is necessary to have a second equation. This is given by the boundary condition for the magnetic field. We restrict ourselves to the case of normal incidence in the xz -plane, which requires no cumbersome calculations. For normal incidence we have

$$E_x = A \exp [i(\omega t - kz)] , \quad E_y = E_z = 0 ;$$

$$H_y = -\epsilon_1^{\frac{1}{2}} A \exp [i(\omega t - kz)] , \quad H_x = H_z = 0 .$$

For the reflected wave we have, analogously,

$$E_x^{refl} = A^{refl} \exp [i(\omega t + kz)] , \quad E_y = E_z = 0 ,$$

$$H_y^{refl} = \epsilon_1^{\frac{1}{2}} A^{refl} \exp [i(\omega t + kz)] , \quad H_z = H_x = 0 .$$

H_y^{refl} differs from H_y in sign, since the reflected wave propagates in the opposite direction and the projection H_y^{refl} is oriented in the positive direction of the y -axis. For the refracted wave

$$E_x^{refr} = A^{refr} \exp [i(\omega t - k^{refr} z)] , \quad E_y = E_z = 0 ,$$

$$H_y^{refr} = -\epsilon_2^{\frac{1}{2}} A^{refr} \exp [i(\omega t - k^{refr} z)] , \quad H_z = H_x = 0 .$$

The conditions of the continuity of the tangential components of the vectors \mathbf{E} and \mathbf{H} for $z = 0$ are written in the form

$$A + A^{refl} = A^{refr} ,$$

$$\epsilon_1^{\frac{1}{2}} (A - A^{refl}) = \epsilon_2^{\frac{1}{2}} A^{refr} .$$

Expressing the quantities A^{refl} and A^{refr} in terms of A , we find

$$A^{\text{refl}} = \frac{1 - (\epsilon_2/\epsilon_1)^{\frac{1}{2}}}{1 + (\epsilon_2/\epsilon_1)^{\frac{1}{2}}} A = \frac{\epsilon_1^{\frac{1}{2}} - \epsilon_2^{\frac{1}{2}}}{\epsilon_1^{\frac{1}{2}} + \epsilon_2^{\frac{1}{2}}} A, \quad (37.5)$$

$$A^{\text{refr}} = \frac{2}{1 + (\epsilon_2/\epsilon_1)^{\frac{1}{2}}} A = \frac{2\epsilon_1^{\frac{1}{2}}}{\epsilon_1^{\frac{1}{2}} + \epsilon_2^{\frac{1}{2}}} A. \quad (37.6)$$

Formulae (37.5) and (37.6) represent a particular case (normal incidence) of the well-known Fresnel formulae derived by Fresnel in 1820 from the general concept of light as a wave motion.

Knowing the amplitudes of the reflected and refracted waves, one can find the time averages of the energy fluxes reflected from the interface and transmitted into the second medium. They are given by the quantities

$$|\sigma^{\text{refl}}| = \frac{c\epsilon_1^{\frac{1}{2}}}{4\pi} \overline{[\mathbf{E}^{\text{refl}} \mathbf{H}^{\text{refl}}]} = \frac{c}{8\pi} \epsilon_1^{\frac{1}{2}} \left(\frac{\epsilon_1^{\frac{1}{2}} - \epsilon_2^{\frac{1}{2}}}{\epsilon_1^{\frac{1}{2}} + \epsilon_2^{\frac{1}{2}}} \right)^2 A^2 = \left(\frac{\epsilon_1^{\frac{1}{2}} - \epsilon_2^{\frac{1}{2}}}{\epsilon_1^{\frac{1}{2}} + \epsilon_2^{\frac{1}{2}}} \right)^2 |\sigma|,$$

$$|\sigma^{\text{refr}}| = \frac{c\epsilon_2^{\frac{1}{2}}}{4\pi} \overline{[\mathbf{E}^{\text{refr}} \mathbf{H}^{\text{refr}}]} = \frac{c}{8\pi} \epsilon_2^{\frac{1}{2}} \left(\frac{2\epsilon_1^{\frac{1}{2}}}{\epsilon_1^{\frac{1}{2}} + \epsilon_2^{\frac{1}{2}}} \right)^2 A^2 = \left(\frac{\epsilon_2}{\epsilon_1} \right)^{\frac{1}{2}} \left(\frac{2\epsilon_1^{\frac{1}{2}}}{\epsilon_1^{\frac{1}{2}} + \epsilon_2^{\frac{1}{2}}} \right)^2 |\sigma|,$$

where σ is the Poynting vector of the incident waves.

The ratio

$$R = \frac{|\sigma^{\text{refl}}|}{|\sigma|} = \left(\frac{\epsilon_1^{\frac{1}{2}} - \epsilon_2^{\frac{1}{2}}}{\epsilon_1^{\frac{1}{2}} + \epsilon_2^{\frac{1}{2}}} \right)^2 = \left(\frac{1 - n_{12}}{1 + n_{12}} \right)^2 \quad (37.7)$$

is called the reflectivity, while the ratio

$$D = \frac{|\sigma^{\text{refr}}|}{|\sigma|} = \left(\frac{\epsilon_2}{\epsilon_1} \right)^{\frac{1}{2}} \left(\frac{2\epsilon_1^{\frac{1}{2}}}{\epsilon_1^{\frac{1}{2}} + \epsilon_2^{\frac{1}{2}}} \right)^2 = 1 - R \quad (37.8)$$

is called the transmissivity.

Formula (37.7) shows that for $\epsilon_2 \approx \epsilon_1$ the effect of reflection of the wave from the interface is small. On the contrary, for $\epsilon_2 \gg \epsilon_1$ or $\epsilon_1 \gg \epsilon_2$ (i.e. for $n_{12} \gg 1$ or $n_{12} \ll 1$), $R \approx 1$ and the wave is almost completely reflected. The considerable reflection of the wave from a dielectric with a large dielectric constant is associated with the fact that in such a dielectric the incident wave excites a large displacement current. Because of this, screening of the external

electric field takes place, and its strength turns out to be close to zero. In the limit, as $\epsilon_2 \rightarrow \infty$, the electric field vector has a node at the interface, while the magnetic field vector has an antinode. However, for any finite value of ϵ_2 the transmissivity D for normal incidence has a small but finite value.

In the case of incidence of the electromagnetic wave at an angle to the normal of the plane of the interface the expressions for the amplitudes (Fresnel formulae) become more complex. However, the general picture is not changed, with the exception of the case $n_{12} < 1$ which calls for special consideration.

If a plane wave falls at an angle θ on the surface of an optically less dense medium, then for a sufficiently small value of n_{12} eq. (37.4) can only be valid for an imaginary value of the angle θ^{refr} . The limiting value of the angle of incidence θ for which θ^{refr} can still have a real value is determined by the condition

$$\frac{\sin \theta_0}{n_{12}} = 1. \quad (37.9)$$

The angle θ_0 is called the critical angle for total reflection. In this case $\theta^{\text{refr}} = \frac{1}{2}\pi$, i.e. the refracted ray slides along the plane of the interface of the media.

For $\theta > \theta_0$ the angle θ^{refr} and, consequently, the value of $\sin \theta^{\text{refr}}$ turn out to be imaginary. In the exponent of the exponential term of the refracted wave the following term arises:

$$i(k^{\text{refr}} \cos \theta^{\text{refr}})z = i \left(\frac{\omega \epsilon_2^{\frac{1}{2}}}{c} (1 - \sin^2 \theta^{\text{refr}})^{\frac{1}{2}} \right) z = \left[- \frac{\omega \epsilon_2^{\frac{1}{2}}}{c} \left(\frac{\sin^2 \theta^{\text{refr}}}{n_{12}^2} - 1 \right)^{\frac{1}{2}} \right] z.$$

This means that in the optically less dense medium damping takes place according to the exponential law

$$|E^{\text{refr}}| \sim \exp \left[- \frac{\omega \epsilon_2^{\frac{1}{2}}}{c} \left(\frac{\sin^2 \theta^{\text{refr}}}{n_{12}^2} - 1 \right)^{\frac{1}{2}} z \right]. \quad (37.10)$$

The effective penetration distance of the electromagnetic field into the optically less dense medium is of the order of magnitude of δ , where

$$\delta \sim \lambda \left(\frac{\sin^2 \theta^{\text{refr}}}{n_{12}^2} - 1 \right)^{-\frac{1}{2}} \quad (37.11)$$

where $\lambda = (\omega \epsilon_2^{1/2} / c)^{-1}$ is the wavelength divided by 2π .

Since there is no absorption in the ideal dielectric considered, the weakening of the field in the optically less dense medium can be associated only with the release of electromagnetic waves backward into the first medium. A direct calculation confirms this. The reflectivity R for $\theta > \theta_0$ turns out to be unity. The effect described is called the phenomenon of total internal reflection.

We cannot, within the framework of this book, dwell on the problem of the appearance of polarization under certain conditions of the reflection of unpolarized waves *.

In conclusion we shall consider briefly the reflection of electromagnetic waves from the surface of conductors. An electromagnetic wave incident on the surface of a conductor induces in it a considerable conduction current. Free charges in the field scatter the wave strongly. Inside the conductor the field is rapidly attenuated. Therefore it is natural to expect the surface of the conductor to possess appreciable reflecting properties. However, part of the energy of the electromagnetic field will be dissipated in the conductor in such a way that the coefficient of reflection will have a value which is somewhat less than unity. If in the formula for R we formally replace the refractive index by its value as given by formula (31.13), then we easily find, taking into account that $\epsilon_1 = 1$ and $\epsilon_2^{1/2} = \epsilon_{\text{met}}^{1/2} = n - i\kappa$; $n \approx \kappa \gg 1$:

$$R = \left| \frac{1-n+i\kappa}{1+n-i\kappa} \right|^2 = \frac{1-2n+n^2+\kappa^2}{1+2n+n^2+\kappa^2} \approx$$

$$\approx \frac{1-2n+2n^2}{1+2n+2n^2} \approx 1 - \frac{2}{n} = 1 - 2 \left(\frac{\omega}{2\pi\sigma} \right)^{\frac{1}{2}}. \quad (37.12)$$

This formula, which is called the Hagen–Rubens formula, is in good agreement with experimental data on the reflection from metal conductors of electromagnetic waves lying in the range of radio and infrared frequencies of the spectrum. For higher frequencies the relations of classical macroscopic electrodynamics turn out to be inapplicable.

The characteristic metallic glitter is due to the high value of the coefficient of reflection in the optical range. In the limiting case of a conductor with an infinitely large conductivity the coefficient of reflection is $R = 1$. This means that a high-frequency electromagnetic field does not penetrate at all

* See, for example, J.A.Stratton, *Electromagnetic theory* (McGraw-Hill, New York, 1941); L.D.Landau and E.M.Lifshitz, *Electrodynamics of continuous media* (Pergamon Press, Oxford, 1960).

into a conductor with an infinitely large conductivity. We shall call such a conductor an ideal conductor. In the range of high frequency fields the ideal conductor is an analogue of the conductor in electrostatics.

Let us write the boundary conditions for the field vectors at the surface of an ideal conductor. Since electric and magnetic fields are absent inside an ideal conductor, it follows from (5.2) – (5.6) that

$$\left. \begin{aligned} E_{tg} &= 0, \\ H_n &= 0, \\ H_{tg} &= \frac{4\pi}{c} i_S, \\ E_n &= \frac{4\pi\omega S}{\epsilon} \end{aligned} \right\} \begin{array}{l} \text{at the surface of} \\ \text{an ideal conductor} \end{array} \quad (37.13)$$

where the vectors **E** and **H** refer to the field in vacuum, and i_S and ω_S are respectively the densities of the surface current and charge. Thus, at the dielectric–ideal conductor interface the electric field vector is directed normally to the surface, whereas the magnetic field vector is directed parallel to the surface. Although in nature there are no ideal conductors, the approximation of an ideal conductor often yields adequately the character of the behaviour of the electromagnetic field at the surface of bodies with a high conductivity.

§38. Wave-guides

The transmission of electromagnetic energy over relatively small distances plays an important role in present day communication engineering. It is brought about by means of the excitation of the electromagnetic field in tubes with metallic walls of various forms and cross-sections, called wave-guides. In this book we cannot dwell on methods for the excitation of fields, and shall confine ourselves only to the study of the process of propagation of electromagnetic waves in wave-guides.

As will be clear from what follows, the propagation of electromagnetic waves in wave-guides differs essentially from the propagation of plane electromagnetic waves which are not limited in space. Therefore the problem of propagation of waves in wave-guides is not only of practical but also of theoretical interest.

To avoid complicated calculations, we shall restrict ourselves to considering a wave-guide of rectangular cross-section with walls made of an ideal conductor. Let the sides of the rectangle be equal to a and b ; for definiteness we assume that $a > b$. We assume that a monochromatic plane electromagnetic wave moves in the wave-guide (in the plane $z = 0$). It is natural to assume that field vectors inside the wave-guide depend on time and the coordinate along the wave-guide according to the law

$$\mathbf{E}, \mathbf{H} \sim \exp [i(\omega t - k_z z)] . \quad (38.1)$$

Substituting (38.1) into the wave equations, we find

$$\frac{\partial^2 \mathbf{E}}{\partial x^2} + \frac{\partial^2 \mathbf{E}}{\partial y^2} = \left(k_z^2 - \frac{\omega^2}{v^2} \right) \mathbf{E} , \quad (38.2)$$

$$\frac{\partial^2 \mathbf{H}}{\partial x^2} + \frac{\partial^2 \mathbf{H}}{\partial y^2} = \left(k_z^2 - \frac{\omega^2}{v^2} \right) \mathbf{H} . \quad (38.3)$$

Here and below \mathbf{E} and \mathbf{H} are unknown functions of the coordinates x and y , since their dependence on z is already taken into account. The connection between the vectors \mathbf{E} and \mathbf{H} is determined by the equations for $\nabla \times \mathbf{E}$ and $\nabla \times \mathbf{H}$. Substituting (38.1) into these equations, we find

$$\frac{\partial E_z}{\partial y} + ik_z E_y = -\frac{i\mu\omega}{c} H_x , \quad (38.4)$$

$$-ik_z E_x - \frac{\partial E_z}{\partial x} = -\frac{i\mu\omega}{c} H_y , \quad (38.5)$$

$$\frac{\partial E_y}{\partial x} - \frac{\partial E_x}{\partial y} = -\frac{i\mu\omega}{c} H_z , \quad (38.6)$$

$$\frac{\partial H_z}{\partial y} + ik_z H_y = \frac{i\epsilon\omega}{c} E_x , \quad (38.7)$$

$$-ik_z H_x - \frac{\partial H_z}{\partial x} = \frac{i\epsilon\omega}{c} E_y , \quad (38.8)$$

$$\frac{\partial H_y}{\partial x} - \frac{\partial H_x}{\partial y} = \frac{i\epsilon\omega}{c} E_z . \quad (38.9)$$

Formulae (38.4)–(38.9) allow the vector components E_x, E_y, H_x and H_y to be expressed in terms of E_z and H_z . A simple calculation gives

$$E_x = \frac{1}{c^2 k_z^2 - \epsilon \mu \omega^2} \left(i c^2 k_z \frac{\partial E_z}{\partial x} + i \omega \mu c \frac{\partial H_z}{\partial y} \right), \quad (38.10)$$

$$E_y = \frac{1}{-\omega^2 \epsilon \mu + c^2 k_z^2} \left(i c^2 k_z \frac{\partial E_z}{\partial y} - i \omega \mu c \frac{\partial H_z}{\partial x} \right), \quad (38.11)$$

$$H_x = \frac{1}{-\epsilon \mu \omega^2 + c^2 k_z^2} \left(-i \epsilon \omega c \frac{\partial E_z}{\partial y} + i c^2 k_z \frac{\partial H_z}{\partial x} \right), \quad (38.12)$$

$$H_y = \frac{1}{c^2 k_z^2 - \epsilon \mu \omega^2} \left(i \epsilon \omega c \frac{\partial E_z}{\partial x} + i c^2 k_z \frac{\partial H_z}{\partial y} \right). \quad (38.13)$$

At the surface of the wave-guide the boundary conditions for an ideal conductor (see §37) must be fulfilled.

We first try to find the solution of eqs. (38.2) and (38.3) in the form of transverse plane waves, i.e. we assume

$$E_z = H_z = 0.$$

Then from formulae (38.10)–(38.13) it is clear that all components of the field are equal to zero, provided $c^2 k_z^2 - \epsilon \mu \omega^2 \neq 0$. If, on the contrary, $c^2 k_z^2 = \epsilon \mu \omega^2$, as is the case of a monochromatic plane wave in a non-limited medium propagating with a velocity $c/(\epsilon \mu)^{1/2}$, then (38.2) gives

$$\frac{\partial^2 H(x, y)}{\partial x^2} + \frac{\partial^2 H(x, y)}{\partial y^2} = 0,$$

i.e. the magnetic field satisfies the two-dimensional Laplace equation, and over the entire closed boundary of the region (at the edges of the rectangle $x = 0, a; y = 0, b$) the magnetic field by virtue of (37.13) is directed along a tangent to the boundary. In the mathematical theory it is shown* that the only solution of such a boundary value problem is $H = 0$. If there is no

* See, for example, V.I. Smirnov, *A course of higher mathematics* (Pergamon Press, Oxford, 1964).

magnetic field in the wave, then, obviously, the electric field is also equal to zero.

Thus we see that transverse electromagnetic waves cannot propagate in a rectangular wave-guide with ideally conducting walls. It should be stressed that this conclusion is not associated with the form of the wave-guide, but refers to any wave-guide made in the form of a simple tube of any cross-section whose walls are ideally conducting. In the case where the boundaries of the region are open, for example, in the case of the gap between two infinite ideally conducting plane surfaces, or in the case of multiply connected space, for example a wave-guide formed by two concentric cylinders, this conclusion is no longer valid. In such systems the propagation of transverse electromagnetic waves is in principle possible.

The meaning of this result is very simple. In a transverse wave in a wave-guide the lines of the magnetic field must be directed along a tangent to the walls and must have the character of closed curves. In this case the lines of the field do not enter into the ideal conductor and therefore do not enclose any tubes of conduction current. A longitudinal component of displacement current is absent, so that the lines of the magnetic field do not enclose any tubes of displacement current either. However, from general considerations it is clear that the lines of a magnetic field which do not enclose any current tubes cannot exist.

This kind of reasoning also allows one to understand why the existence of transverse waves is possible in the open wave-guide or in a wave-guide formed by concentric cylinders. In an unbounded space the lines of the magnetic field can be open and go off to infinity. In a wave-guide formed by concentric cylinders they can enclose the tubes of current flowing on the surface of the internal cylinder. In both cases the existence of magnetic and electric fields travelling along the wave-guide in the form of transverse waves is possible.

It turns out, however, that the absence of transverse waves in a wave-guide does not mean that the propagation of an electromagnetic field in it is impossible. As will now be shown, the formation of longitudinal waves, which cannot exist in unbounded space, is possible in a wave-guide. By longitudinal waves we understand waves which have a non-zero field component in the direction of propagation of the wave. From formulae (38.10) – (38.13) it is clear that two independent possibilities must be considered:

$$1) \quad E_z \neq 0, \quad H_z = 0,$$

$$2) \quad H_z \neq 0, \quad E_z = 0.$$

In the first case the magnetic field in the wave has two components, H_x and H_y , and is purely transverse. Such waves are usually called transverse magnetic waves or, briefly, TM-waves. The electric field has a longitudinal component and two transverse components.

In the second case the electric field of the wave has a transverse character and the wave is called correspondingly a transverse electric wave or, briefly, TE-wave.

In the case of TM-waves, on the basis of (38.2) we have

$$\frac{\partial^2 E_z}{\partial x^2} + \frac{\partial^2 E_z}{\partial y^2} = \left(k_z^2 - \frac{\omega^2}{v^2} \right) E_z \quad (38.14)$$

and

$$E_z = 0 \quad \text{for} \quad x = 0, a; \quad y = 0, b, \quad (38.15)$$

by virtue of (37.13). Below we shall show that it is sufficient to satisfy only these boundary conditions. In order to satisfy eq. (38.14) and the boundary conditions (38.15), one must write for E_z

$$E_z = A \sin(k_x x) \sin(k_y y) \exp[i(\omega t - k_z z)] , \quad (38.16)$$

where

$$k_x^2 + k_y^2 + k_z^2 = \omega^2/v^2 \quad (38.17)$$

and, moreover,

$$k_x = \pi m/a; \quad k_y = \pi n/b, \quad (38.18)$$

where m and n are integers which are not equal to zero. This solution has the form of waves travelling in the positive direction of the z -axis and standing waves in the planes $z = \text{const}$.

The transverse magnetic wave corresponding to the numbers m and n is usually denoted by TM_{mn} . If the value of E_z is known, then from (38.10) – (38.13) one can easily find the remaining components of the field. We shall not write down the corresponding formulae, and shall only point out the following fact. It is easily understood that the boundary conditions for all components of the electric and magnetic fields are automatically fulfilled. For example, in the plane $y = 0$ the normal component of the magnetic field is

$$H_n = H_y \sim \frac{\partial E_z}{\partial x} \sim \sin \frac{\pi n}{b} y \Big|_{y=0} = 0 ;$$

analogously,

$$E_{tg} = E_x = E_z = 0 .$$

Hence, as we have already pointed out, it is sufficient to satisfy the boundary conditions (38.15). Thus, at the walls of the wave-guide the lines of the magnetic field are tangential to the surface. They form closed curves embracing the longitudinal lines of the electric field.

Let us discuss formula (38.17) in more detail. We rewrite it in the form

$$k_z = \left(\frac{\omega^2}{v^2} - \frac{\pi^2 m^2}{a^2} - \frac{\pi^2 n^2}{b^2} \right)^{\frac{1}{2}} . \quad (38.19)$$

For given values of m and n the quantity k_z has a real value only for

$$\frac{1}{\lambda^2} = \frac{\omega^2}{4\pi^2 v^2} \geq \frac{(\omega_{crit}^{m,n})^2}{4\pi^2 v^2} = \left(\frac{\pi^2 m^2}{a^2} + \frac{\pi^2 n^2}{b^2} \right) \frac{1}{4\pi^2} = \frac{1}{\lambda_{crit}^2} , \quad (38.20)$$

where $\omega_{crit}^{m,n}$ is a certain critical frequency, and λ_{crit} is the corresponding wavelength.

If k_z turns out to be imaginary, which corresponds to $\omega < \omega_{crit}$, then we arrive at an exponentially decreasing expression for E_z and the other field components instead of a wave travelling along the z -axis. Thus, only waves with $\omega > \omega_{crit}^{m,n}$ or $\lambda < \lambda_{crit}$ can propagate through the wave-guide.

The largest value of the wavelength of the propagating wave, λ_{crit}^{max} , is obtained for the TM_{11} -wave ($m = 1$ and $n = 1$) which is the wave of TM-type of lowest order. Namely,

$$\lambda_{TM_{11}} = \frac{2ab}{(a^2 + b^2)^{\frac{1}{2}}} .$$

The phase velocity of the TM_{mn} -wave is obviously equal to

$$\begin{aligned} v_{phase} &= \frac{\omega}{k_z} = \frac{c}{(\epsilon\mu)^{\frac{1}{2}} (1 - \lambda^2 [(m/2a)^2 + (n/2b)^2])^{\frac{1}{2}}} = \\ &= \frac{c}{(\epsilon\mu)^{\frac{1}{2}} [1 - (\lambda^2/\lambda_{crit}^2)]^{\frac{1}{2}}} = \frac{v}{[1 - (\lambda^2/\lambda_{crit}^2)]^{\frac{1}{2}}} . \end{aligned} \quad (38.21)$$

Since $\lambda < \lambda_{\text{crit}}$ always, the phase velocity of waves in a wave-guide is always larger than the velocity of light v in a corresponding medium, and for $\lambda \rightarrow \lambda_{\text{crit}}$ it increases indefinitely. In particular, if no dielectric is introduced inside the wave-guide (i.e. $\epsilon = \mu = 1$), v_{phase} is always larger than the velocity of light in vacuum c .

The group velocity can easily be found from formula (38.17):

$$v_{\text{group}} = \frac{d\omega}{dk_z} = \frac{c}{(\epsilon\mu)^{\frac{1}{2}}} \left(1 - \frac{\lambda^2}{\lambda_{\text{crit}}^2} \right)^{\frac{1}{2}}. \quad (38.22)$$

The group velocity is always smaller than the velocity $v = c/(\epsilon\mu)^{\frac{1}{2}}$ and tends to zero as λ approaches λ_{crit} .

From (38.21) and (38.22) it is clear that v_{phase} and v_{group} satisfy the general relation $v_{\text{phase}} v_{\text{group}} = v^2$.

Let us now consider TE-waves. For such waves we have

$$\frac{\partial^2 H_z}{\partial x^2} + \frac{\partial^2 H_z}{\partial y^2} = \left(k_z^2 - \frac{\omega^2}{v^2} \right) H_z. \quad (38.23)$$

By means of (38.10) and (38.11) the boundary conditions for the tangential component of the electric field can be expressed in terms of the derivatives of H_z . Then instead of

$$E_x = 0 \quad \text{for } y = 0, b$$

we have

$$\partial H_z / \partial y = 0 \quad \text{for } y = 0, b. \quad (38.24)$$

Analogously, instead of

$$E_y = 0 \quad \text{for } x = 0, a$$

we have

$$\partial H_z / \partial x = 0 \quad \text{for } x = 0, a. \quad (38.25)$$

The solution of eq. (38.23) for the boundary conditions (38.24) and (38.25) can be written in the form of a TE-wave:

$$H_z = B \cos(k_x x) \cos(k_y y) \exp [i(\omega t - k_z z)] , \quad (38.26)$$

where

$$k_x = \pi m/a ; \quad k_y = \pi n/b .$$

Here m and n are integers. In contrast to the case of TM-waves, each of these numbers (but not both of them simultaneously) can take on the value zero. Formulae (38.19) – (38.22) remain valid for TE-waves. In them, however, one of the numbers m or n can be set equal to zero. The TE_{10} -wave is the TE-wave of lowest order. For the TE_{10} -wave the critical wavelength is

$$\lambda_{\text{crit}}^{\text{max}} = 2a .$$

The most important conclusion which can be drawn from the theory described is that the transverse character of plane waves is closely associated with the unlimited dimensions of the medium in which they are propagating. When waves are propagating in a limited region, purely transverse waves can exist only under particular conditions (multiply connected regions). Under usual conditions the waves do have a longitudinal component of the electric or magnetic field. We recall also, that in an unlimited space, but near the emitter, the electromagnetic wave has non-zero longitudinal (radial) field components E_r and H_r (see §25 and §26 of Part I).

In the calculations for a wave-guide of the simplest form which we have presented above we have not taken into account effects which in practice play an important part. Such an effect is, first of all, the power loss associated with the non-ideal character of the walls of the wave-guide and the dielectric which fills it. Also we have not considered the theory of wave-guides of a more complex form and wave-guides which are inhomogeneous over their length.

Neither have we touched upon numerous problems associated with various applications of wave-guides, including their use in linear accelerators for charged particles. For all these problems we refer the reader to the comprehensive specific literature *.

* See, for example, L.A.Vainshtein, *Elektromagnitnye volny (Electromagnetic waves)*, Sov. Radio, 1957; S.Ramo, J.R.Whinnery and Th.Van Duzer, *Fields and waves in communication electronics* (Wiley, New York, 1965).

§39. The passage of fast particles through matter

The problem of the energy loss and radiation by fast particles moving in matter is of great importance in contemporary physics.

As we shall see below, there are several different mechanisms of energy loss by particles moving in matter.

First of all it should be recalled that, as we have seen in §43 of Part I and §26 of Part II, particles which undergo collisions with atoms and are deflected by the nuclear field emit bremsstrahlung. According to eq. (26.15) of Part II the bremsstrahlung of ultra-relativistic particles is inversely proportional to the mass of the particle and plays an important part for light particles (electrons). When heavy charged particles (protons, ions) pass through matter, other sources of energy loss usually play a greater part. The charged particle moving in matter interacts with the atoms of the substance and polarizes them. In other words, the moving particle produces a field in the substance. This field induces a reaction on the particle itself which decelerates it. The energy loss of the particle associated with this deceleration is obviously equal to the work done by the decelerating force. This is called the polarization energy loss, since the decelerating field is the polarization field produced by the moving particle. The medium which is polarized by the particle can however emit transverse electromagnetic waves. To do this it is necessary that the polarization caused by the particle moving in the medium does not follow the particle. The moving particle leaves the medium in a polarized state and the medium emits the excess energy in the form of transverse electromagnetic waves. This source of energy loss is the Cerenkov-Vavilov radiation or briefly the Cerenkov radiation.

We stress that Cerenkov-Vavilov radiation is not associated with any acceleration, since it is radiation emitted by the medium and not by the moving charge. On the other hand, as will be shown in the following, Cerenkov radiation is possible only in the case of motion of a particle with a velocity v which is larger than the velocity of propagation of the field in the medium c/n . This restriction expresses the above-mentioned condition of the lag of the polarization field behind the moving particle. We now go on to the simultaneous calculation of the polarization losses and Cerenkov losses of one particle moving in a macroscopically homogeneous and isotropic medium. Our purpose is to find the field produced in the medium by a single charge moving with a velocity v .

We disregard the decrease in velocity during the motion and consider the velocity to be constant in magnitude and direction. We assume the medium to be transparent, so that the imaginary part of the dielectric constant is $\epsilon^i \rightarrow 0$. The magnetic permeability μ is assumed to be equal to unity.

The current density in the medium corresponding to a uniform motion of one particle can be written in the form

$$\mathbf{j} = ev\delta(\mathbf{r}-\mathbf{v}t). \quad (39.1)$$

Hence Maxwell's equations will have the form

$$\nabla \times \mathbf{E} = -\frac{1}{c} \frac{\partial \mathbf{B}}{\partial t}, \quad (39.2)$$

$$\nabla \times \mathbf{H} = \frac{1}{c} \frac{\partial \mathbf{D}}{\partial t} + \frac{4\pi e}{c} \mathbf{v}\delta(\mathbf{r}-\mathbf{v}t). \quad (39.3)$$

We shall discuss below the conditions under which one can assume a medium to be continuous and disregard its atomic structure describing it by macroscopic quantities.

We seek the solution of Maxwell's equations by means of expansion in a Fourier integral. Writing formulae (33.1) – (33.4) for the field vectors and for the vector \mathbf{j} the expression

$$\mathbf{j}(\mathbf{r}, t) = \frac{1}{(2\pi)^4} \int \exp[i(\mathbf{k} \cdot \mathbf{r} - \omega t)] \mathbf{j}(\mathbf{k}, \omega) d\mathbf{k} d\omega, \quad (39.4)$$

we write the system (39.2) – (39.3) in the form

$$i[\mathbf{k} \times \mathbf{E}(\mathbf{k}, \omega)] = i \frac{\omega}{c} \mathbf{B}(\mathbf{k}, \omega), \quad (39.5)$$

$$i[\mathbf{k} \times \mathbf{H}(\mathbf{k}, \omega)] = -i \frac{\omega}{c} \mathbf{D}(\mathbf{k}, \omega) + \frac{4\pi}{c} \mathbf{j}(\mathbf{k}, \omega). \quad (39.6)$$

Forming the vector product of (39.5) and \mathbf{k} , thereupon eliminating $\mathbf{k} \times \mathbf{H}$ from (39.6), and making use of the constitutive equation (33.4), we arrive at the equation

$$\left\{ k^2 \delta_{ij} - k_i k_j - \frac{\omega^2}{c^2} \epsilon_{ij} \right\} E_j = i \frac{4\pi\omega}{c^2} j_i, \quad (39.7)$$

which differs from (33.15) only in the presence of the right-hand side. The quantity j_i in (39.7) denotes the Fourier component of the current density

$\mathbf{j}(\mathbf{k}, \omega)$. For the isotropic medium we substitute for ϵ_{ij} its value from formula (33.9). We then find

$$\{k^2 \delta_{ij} - k_i k_j\} E_j - \frac{\omega^2 \epsilon_{\perp}}{c^2} \left\{ \delta_{ij} - \frac{k_i k_j}{k^2} \right\} E_j - \frac{\omega^2 \epsilon_{\parallel}}{c^2} \frac{k_i k_j}{k^2} E_j = i \frac{4\pi\omega}{c^2} j_i,$$

or, in the vector form

$$\left(k^2 - \frac{\omega^2 \epsilon_{\perp}}{c^2} \right) \left(\mathbf{E} - \frac{\mathbf{k}(\mathbf{k} \cdot \mathbf{E})}{k^2} \right) - \frac{\omega^2 \epsilon_{\parallel}}{c^2} \frac{\mathbf{k}(\mathbf{k} \cdot \mathbf{E})}{k^2} = i \frac{4\pi\omega}{c^2} \mathbf{j}. \quad (39.8)$$

Forming the scalar product of (39.8) and the vector \mathbf{k} , we obtain

$$\mathbf{k} \cdot \mathbf{E} = -i \frac{4\pi}{\omega \epsilon_{\parallel}} (\mathbf{k} \cdot \mathbf{j}). \quad (39.9)$$

Substituting (39.9) into (39.8), we find

$$\left(k^2 - \frac{\omega^2 \epsilon_{\perp}}{c^2} \right) \mathbf{E} = -i \frac{4\pi\omega}{k^2} \left\{ \left(k^2 - \frac{\omega^2 \epsilon_{\perp}}{c^2} \right) \frac{(\mathbf{k} \cdot \mathbf{j})\mathbf{k}}{\omega^2 \epsilon_{\parallel}} + \frac{\mathbf{k}(\mathbf{k} \cdot \mathbf{j})}{c^2} - \frac{k^2}{c^2} \mathbf{j} \right\}.$$

Hence

$$\mathbf{E}(\omega, \mathbf{k}) = -\frac{4\pi\omega i}{k^2} \left\{ \frac{(\mathbf{k} \cdot \mathbf{j}(\omega, \mathbf{k}))\mathbf{k}}{\omega^2 \epsilon_{\parallel}} + \frac{\mathbf{k}(\mathbf{k} \cdot \mathbf{j}(\omega, \mathbf{k})) - k^2 \mathbf{j}(\omega, \mathbf{k})}{c^2(k^2 - \omega^2 \epsilon_{\perp})} \right\}. \quad (39.10)$$

Going from the Fourier component to the electric field, we have

$$\mathbf{E}(\mathbf{r}, t) = \int \mathbf{E}(\omega, \mathbf{k}) \exp [i(\mathbf{k} \cdot \mathbf{r} - \omega t)] d\mathbf{k} d\omega = \mathbf{E}_1(\mathbf{r}, t) + \mathbf{E}_2(\mathbf{r}, t). \quad (39.11)$$

The first term $\mathbf{E}_1(\mathbf{r}, t)$ has the form

$$\mathbf{E}_1 = -4i\pi \int \frac{d\mathbf{k} d\omega}{k^2} \frac{(\mathbf{k} \cdot \mathbf{j})\mathbf{k}}{\omega \epsilon_{\parallel}}. \quad (39.12)$$

We now substitute the value of $\mathbf{j}(\omega, \mathbf{k})$, making use of formula (III.8'). We have, obviously,

$$\mathbf{j}(\omega, \mathbf{k}) = \frac{e\mathbf{v}}{(2\pi)^3} \delta(\omega - \mathbf{k} \cdot \mathbf{v}). \quad (39.13)$$

Then E_1 assumes the form

$$\begin{aligned} E_1 &= -i \frac{4\pi e}{(2\pi)^3} \int d\omega \frac{dk}{k^2} \frac{k(k \cdot v)}{\omega \epsilon_{||}} \delta(\omega - k \cdot v) \exp [i(k \cdot r - \omega t)] = \\ &= -\frac{ie}{2\pi^2} \int dk \exp [i(k \cdot r - k \cdot vt)] \frac{k}{k^2 \epsilon_{||}(k \cdot v, k)}, \end{aligned} \quad (39.14)$$

where $\epsilon_{||}(k \cdot v, k)$ is the value of $\epsilon_{||}(\omega, k)$ for $\omega = k \cdot v$.

The field E_1 produced by the moving charged particle in the medium induces a reaction on it. The particle is acted upon by a force

$$F = e(E_1)_{r=vt} + \frac{e}{c} (v \times H)_{r=vt},$$

where the index shows that the value of the field at each instant of time must be taken at the point $r = vt$ at which the particle is found. The energy loss of the particle (we shall relate it to unit path in matter) is equal to the work done by this force per unit path. Since the magnetic part of the Lorentz force $ec^{-1}(v \times H)$ does no work the work done by the force F per unit path is equal to

$$\begin{aligned} W_1 &= e \left(\frac{v}{v} \cdot E_1 \right) = -\Delta E_1 = \\ &= \text{Re} \left\{ -\frac{ie^2}{2\pi^2 v} \int dk \exp [i(k \cdot r - k \cdot vt)] \frac{k \cdot v}{k^2} \frac{1}{\epsilon_{||}(k \cdot v, k)} \right\}_{r=vt} = \\ &= \text{Re} \left\{ -\frac{ie^2}{4\pi^2 v} \iint dk d\omega \frac{\omega \delta(\omega - k \cdot v)}{k^2 \epsilon_{||}(\omega, k)} \right\}. \end{aligned} \quad (39.15)$$

The notation Re is introduced in order to show that the expression for the work W_1 is real. This work has a clear physical meaning. It is determined by the value of $\epsilon_{||}$ and represents the work done on the particle by the longitudinal polarization produced by the particle. Thus, dW_1/dr is a measure of the energy loss ΔE_1 of the particle per unit path. This energy goes into the production of the longitudinal polarization. Later, in calculating ΔE_1 , we shall discuss the question as to what processes actually occur in a medium when a moving particles produces a longitudinal polarization in it.

We now come back to the second term of (39.11). According to formulae (39.11) and (39.8), we have

$$\begin{aligned}
 E_2(\mathbf{r}, t) &= i \frac{4\pi e}{(2\pi)^3} \int d\mathbf{k} d\omega \exp [i(\mathbf{k} \cdot \mathbf{r} - \omega t)] \frac{k^2 \mathbf{v} - \mathbf{k}(\mathbf{k} \cdot \mathbf{v})}{c^2(k^2 - \omega^2 c^{-2} \epsilon_{\perp})} \delta(\omega - \mathbf{k} \cdot \mathbf{v}) \frac{\omega}{k^2} = \\
 &= \frac{ie}{2\pi^2 c^2} \int d\mathbf{k} \exp [i(\mathbf{k} \cdot \mathbf{r} - \mathbf{k} \cdot \mathbf{v} t)] \frac{(\mathbf{k} \cdot \mathbf{v})}{k^2} \frac{k^2 \mathbf{v} - \mathbf{k}(\mathbf{k} \cdot \mathbf{v})}{k^2 - (\mathbf{k} \cdot \mathbf{v})^2 c^{-2} \epsilon_{\perp}(\mathbf{k} \cdot \mathbf{v}, \mathbf{k})}.
 \end{aligned} \quad (39.16)$$

Correspondingly, the work done on the charge due to the field E_2 and the energy loss ΔE_2 of the particle per unit path are equal to

$$\begin{aligned}
 W_2 = -\Delta E_2 &= \operatorname{Re} \left\{ \frac{ie^2}{2\pi^2 v c^2} \int d\mathbf{k} \frac{(\mathbf{k} \cdot \mathbf{v}) [v^2 - (\mathbf{k} \cdot \mathbf{v})^2 k^{-2}]}{k^2 - (\mathbf{k} \cdot \mathbf{v})^2 c^{-2} \epsilon_{\perp}(\mathbf{k} \cdot \mathbf{v}, \mathbf{k})} \right\} \bigg|_{\mathbf{r} = \mathbf{v} t} = \\
 &= \operatorname{Re} \left\{ \frac{ie^2}{2\pi^2 v c^2} \int d\mathbf{k} d\omega \frac{\omega (v^2 - \omega^2 k^{-2}) \delta(\omega - \mathbf{k} \cdot \mathbf{v})}{k^2 - \omega^2 c^{-2} \epsilon_{\perp}(\omega, \mathbf{k})} \right\}.
 \end{aligned} \quad (39.17)$$

The energy loss ΔE_2 determines the Cerenkov loss of the particle. This is associated with the excitation of a transverse electromagnetic field in the medium, i.e. with the radiation of the polarized medium.

Taking account of spatial dispersion allows us to separate clearly the two types of energy loss: polarization loss and Cerenkov loss.

In what follows we shall restrict ourselves to the calculation of losses in a medium without spatial dispersion*. For this, according to (33.11), we have to set in the formulae obtained

$$\epsilon_{\parallel}(\omega, \mathbf{k}) = \epsilon_{\perp}(\omega, \mathbf{k}) = \epsilon(\omega) \big|_{\omega = \mathbf{k} \cdot \mathbf{v}}. \quad (39.18)$$

We pass on to the calculation of the integrals in formulae (39.15) and (39.17). We have, taking into account (39.18),

$$\Delta E_1 = -\operatorname{Re} \left\{ \frac{ie^2}{2\pi^2 v} \int d\mathbf{k} \frac{\omega}{k^2 \epsilon(\omega)} \right\}. \quad (39.19)$$

* For losses taking into account spatial dispersion see, for example, V.P.Silin and A.A.Rukhadze, *Elektromagnitnye svoistva plazmy i plazmopodobnykh sred* (Electromagnetic properties of plasma and plasma-like media), Moscow, 1961; V.D.Shafranov, *Elektromagnitnye volny v plazme* (Electromagnetic waves in plasma), collected papers *Voprosy fiziki plazmy* (Problems of plasma physics), Vol. II, Moscow, 1963. V.L.Ginzburg, *Propagation of electromagnetic waves in plasma* (North-Holland Publ. Co., Amsterdam, 1961).

We have already pointed out above that all our considerations will refer to transparent media, more precisely to media with a negligibly small absorption. This means that in the expression for the dielectric constant $\epsilon(\omega) = \epsilon^r(\omega) + i\epsilon^i(\omega)$ we have to go to the limit $\epsilon^i(\omega) \rightarrow 0$. This allows us to greatly simplify all subsequent calculations. That is, we can write

$$\operatorname{Re} \frac{i}{\epsilon(\omega)} = \operatorname{Re} \frac{i}{\epsilon^r(\omega) + i\epsilon^i(\omega)} = \operatorname{Re} \frac{i(\epsilon^r + i\epsilon^i)}{(\epsilon^r)^2 + (\epsilon^i)^2} = \frac{(-\epsilon^i)}{(\epsilon^r)^2 + (\epsilon^i)^2}.$$

In the limit $\epsilon^i \rightarrow 0$, we can make use of formula (III.4'), Vol. 1, and write

$$\lim_{\epsilon^i \rightarrow 0} \operatorname{Re} \frac{i}{\epsilon(\omega)} = - \lim_{\epsilon^i \rightarrow 0} \left[\frac{i}{(\epsilon^r)^2 + (\epsilon^i)^2} \right] = - \pi \delta[\epsilon(\omega)]. \quad (39.20)$$

Then the formula for polarization loss assumes the form

$$\Delta E_1 = \frac{e^2}{2\pi v} \int \frac{\omega}{k^2} \delta[\epsilon(\omega)] dk = \frac{e^2}{2\pi v} \int \frac{(\mathbf{k} \cdot \mathbf{v})}{k^2} \delta[\epsilon(\mathbf{k} \cdot \mathbf{v})] dk, \quad (39.21)$$

where we have made use of the fact that only the frequency $\omega = \mathbf{k} \cdot \mathbf{v}$ gives a contribution to the loss. If the explicit form of $\epsilon(\omega)$ is known, then the integral in (39.21) can easily be calculated. In §46 such a calculation will be carried out for the case of a plasma.

We note that formula (39.21) does not contain the mass of the particle. This is quite natural, since the energy losses are associated with the polarization of the medium. Polarization losses are therefore the main source of energy loss for heavy particles moving in matter for a wide energy range. Light particles, for example electrons of relatively high energies, lose most of their energy due to bremsstrahlung.

We now go on to the calculation of the Cerenkov losses, which can be carried out by the same method. We have

$$\Delta E_2 = - \frac{e^2}{2\pi^2 v c^2} \operatorname{Re} \left\{ i \int dk \frac{v^2 - (\mathbf{k} \cdot \mathbf{v})^2 k^{-2}}{k^2 - (\mathbf{k} \cdot \mathbf{v})^2 c^{-2} \epsilon(\omega)} \right\}. \quad (39.22)$$

We choose the direction of motion of the particles as the z -axis and introduce new variables

$$\omega = \mathbf{k} \cdot \mathbf{v} = k_z v,$$

$$q^2 = k_x^2 + k_y^2 = k^2 - \omega^2 v^{-2}.$$

Then

$$dk = dk_x dk_y dk_z = q dq d\varphi \frac{d\omega}{v}.$$

In the new variables we have

$$\begin{aligned} \Delta E_2 &= -\frac{e^2}{2\pi^2 v^2 c^2} \operatorname{Re} \left\{ i \int_{-\infty}^{\infty} \omega d\omega \int_0^{\infty} \frac{q dq}{q^2 + \omega^2 v^{-2}} \right. \\ &\quad \left. \int_0^{2\pi} d\varphi \frac{q^2 v^2}{q^2 + \omega^2 [v^{-2} - \epsilon(\omega) c^{-2}]} \right\} = \\ &= -\frac{e^2}{\pi c^2} \operatorname{Re} \left\{ i \int_{-\infty}^{\infty} \omega d\omega \int_0^{\infty} \frac{q^3 dq}{q^2 + \omega^2 c^{-2}} \frac{1}{q^2 + \omega^2 v^{-2} - \omega^2 c^{-2} \epsilon(\omega)} \right\}. \end{aligned}$$

For a non-absorbing medium we can write, analogously to (39.20),

$$\lim_{\epsilon \rightarrow 0} \operatorname{Re} \left\{ \frac{i}{q^2 + \omega^2 v^{-2} - c^{-2} \epsilon(\omega)} \right\} = -\pi \delta \left[q^2 + \omega^2 \left(\frac{1}{v^2} - \frac{\epsilon(\omega)}{c^2} \right) \right].$$

Hence

$$\Delta E_2 = \frac{e^2}{\pi c^2} \int_{-\infty}^{\infty} \omega d\omega \int_0^{\infty} \frac{q^3 dq}{q^2 + \omega^2 v^{-2}} \delta \left[q^2 + \omega^2 \left(\frac{1}{v^2} - \frac{\epsilon(\omega)}{c^2} \right) \right].$$

Introducing the new variable $u = q^2$, we have

$$\begin{aligned} &\int_0^{\infty} \frac{q^3 dq}{q^2 + \omega^2 v^{-2}} \delta \left[q^2 + \omega^2 \left(\frac{1}{v^2} - \frac{\epsilon(\omega)}{c^2} \right) \right] = \\ &= \frac{1}{2} \int_0^{\infty} \frac{u du}{u + \omega^2 v^{-2}} \delta \left[u - \left(\frac{\epsilon(\omega)}{c^2} \omega^2 - \frac{\omega^2}{v^2} \right) \right] = \\ &= \begin{cases} \frac{1}{2} \left(1 - \frac{c^2}{v^2 \epsilon(\omega)} \right), & v > c/n \\ 0, & v < c/n, \end{cases} \end{aligned}$$

where $n = \epsilon^{\frac{1}{2}}(\omega)$.

Hence we arrive finally at the following expression for the energy loss per unit path due to the Cerenkov–Vavilov transverse electromagnetic radiation:

$$\Delta E_2 = \frac{e^2}{2c^2} \int_{-\infty}^{\infty} \omega \, d\omega \left(1 - \frac{c^2}{v^2 \epsilon(\omega)} \right) = \frac{e^2}{c^2} \int_0^{\infty} \left(1 - \frac{c^2}{v^2 \epsilon(\omega)} \right) \omega \, d\omega, \quad (39.23)$$

since $\epsilon(\omega)$ is an even function of its argument (see (32.9)).

Thus we obtain the following basic properties of the Cerenkov–Vavilov radiation:

- (1) it arises only for particles moving with a velocity which is larger than $v_{\text{cut-off}} = c/n$ (cut-off of radiation),
- (2) it depends on the charge of the particles, but not on their mass,
- (3) the radiation lies in the visible spectrum and in part of the ultraviolet spectrum. For shorter waves $n < 1$ (see §34) and the radiation is no longer possible,
- (4) the energy emitted per unit path in unit frequency interval has a characteristic spectral distribution (39.23),
- (5) the radiation arising at a given point of the trajectory propagates over the surface of a cone with the vertex at this point and the axis coinciding with the direction of motion of the particle. The angle θ of the cone is determined by the condition

$$\cos \theta = \frac{c}{nv}. \quad (39.24)$$

In conclusion we stress that the energy loss due to Cerenkov–Vavilov radiation is very small and amounts to only about 0.1% of the energy loss of very fast particles in matter. The rest is determined by bremsstrahlung and a number of other phenomena. The importance of Cerenkov radiation lies in the fact that new detectors of fast particles are based on the use of it. These detectors, which are called Cerenkov counters, have now become one of the chief working instruments in the field of high-energy particle physics. By observing the Cerenkov radiation one can not only record the passage of particles but also according to (39.24) determine directly the magnitude and direction of their velocity, according to (39.23) determine their charge, and separate particles with the same momentum but a different mass (making use of the existence of the cut-off $v_{\text{cut-off}} = p_{\text{cut-off}}/m$), and so on.

In conclusion we shall discuss the problem of the limits of applicability of the macroscopic treatment. Fast particles actually interact with individual

atoms or, more precisely, with atomic electrons. For the macroscopic description of the process to be valid it is necessary that during the time of flight of the particle past the atom the intra-atomic electrons do not undergo an appreciable displacement. The particle in flight is moving in the quasi-stationary field of many atoms.

Thus the velocity of the particle must be large compared with the characteristic velocity of atomic electrons.

An interesting source of energy loss due to radiation by a uniformly moving particle is the so-called transitional radiation. It arises when a particle passes from one medium to another. In order to simplify the formulae we assume that a particle which is moving uniformly in vacuum with a velocity $v \sim c$ falls on the boundary of a medium with a dielectric constant $\epsilon(\omega)$. We assume the boundary of the medium to be the plane $z = 0$, and the incident direction of the particle to be normal to the boundary. We choose the instant of impact of the particle on the boundary to be the time $t = 0$, and find the vector potential of the field of the particle according to formula (32.10) of Part I.

Obviously, for the Fourier component A_ω at a large distance from the charge we have

$$\begin{aligned} A_\omega &= \frac{e}{2\pi cr} e^{ikr} \int_{-\infty}^{\infty} v(t) \exp [i(k \cdot r(t) - \omega t)] dt = \\ &= \frac{ev}{2\pi cr} e^{ikr} \left\{ \int_{-\infty}^0 \exp [it(k \cdot v \epsilon^{\frac{1}{2}} - \omega)] dt + \int_0^{\infty} \exp [it(k \cdot v - \omega)] dt \right\} = \\ &= \frac{ev}{2\pi cr} e^{ikr} \left\{ \int_{-\infty}^0 \exp \left[i\omega t \left(\frac{v \epsilon^{\frac{1}{2}} \cos \theta}{c} - 1 \right) \right] dt + \int_0^{\infty} \exp \left[i\omega t \left(\frac{v \cos \theta}{c} - 1 \right) \right] dt \right\}. \end{aligned}$$

Making use of the definition of δ_+ and δ_- functions (see Appendix III, Vol. 1), we find

$$A_\omega = \frac{ev}{2\pi c\omega r} \frac{1}{i} \left\{ \frac{\delta_-}{1 - v\epsilon^{-1} \epsilon^{\frac{1}{2}} \cos \theta} - \frac{\delta_+}{1 - v\epsilon^{-1} \cos \theta} \right\}. \quad (39.25)$$

The intensity emitted according to formula (32.14) of Part I is equal to

$$\Delta E = \frac{e^2 \omega^2}{4\pi^2 c^2} \left[\frac{1}{1 - v c^{-1} \epsilon^{\frac{1}{2}} \cos \theta} - \frac{1}{1 - v c^{-1} \cos \theta} \right]^2 \sin^2 \theta \, d\Omega. \quad (39.26)$$

The meaning of this result is quite simple. In motion in a medium the role of the relative velocity v/c is played by the quantity $v\epsilon^{\frac{1}{2}}/c$, which determines the optical path in the medium. When the particle passes from one medium to another (or to vacuum) the quantity $v\epsilon^{\frac{1}{2}}/c$ changes discontinuously. This change is equivalent to an abrupt change in the velocity, i.e. to an acceleration of the particle. Formulae (39.25) and (39.26) show that the radiation is directed mainly forward ($\theta \approx 0$) and that it contains very high frequencies (high harmonics). We shall not dwell on the calculation of the total intensity, which can be accomplished by integrating over all angles. We note only that the total intensity turns out to be proportional to the energy of the particle. The analogous calculation for $v \ll c$ turns out to be more complicated, since in this case it is necessary to take into account the phenomena of reflection and refraction of electromagnetic waves at the interface.

Matter in the Plasma State

§40. The general characteristics of plasma

The problem of the passage of current through gases and the behaviour of gases conducting current in electric and magnetic fields is of great interest in present day physics.

As is well known, gases are normally non-conductors. If, however, a sufficiently large ionization is produced in the gas, i.e. if a sufficiently large number of free electrons and ions (positive and negative) are produced, the gas will become conducting. The process of the passage of current through the gas is called gaseous discharge. Depending on the mechanism causing the ionization of the gas the gaseous discharge is called non-self-maintained or self-maintained.

In the first case the basic ionization is produced by external sources (for example by γ -radiation or by a high temperature maintained by an external source).

In the self-maintained discharge the initial ionization is caused by electrons emerging from a cold cathode (the Townsend discharge and glow discharge).

The density of the current which can flow through the gas depends, in the first place, on the number of ions produced per cm^3 of the gas. In particular, if the entire gas is completely ionized current densities can be very large.

The self-maintained discharge displays a great diversity of properties. However, it possesses one outstanding feature: the space in which the gas discharge takes place can be divided into three regions — the cathode region, the anode region and the plasma region.

The properties of the cathode region and anode region depend on the mechanism of the discharge. In the cathode region the ionization of the atoms of the gas by electrons emerging from the cathode occurs. The greatest charge is concentrated in the cathode and anode regions and the major fall of the potential difference applied to the electrodes also takes place there. The size of these regions is, as a rule, not large, and they occupy only a small part of the space between the electrodes. The largest part of the interelectrode space is occupied by an ionized gas which is on the average electrically neutral. This region of the discharge is called a plasma. In a plasma the number of positive ions is on the average equal to the number of electrons and negative ions per unit volume. Besides ions and electrons, a plasma can also contain a larger or smaller number of neutral atoms or molecules.

The properties of a plasma in which we shall be interested in what follows do not depend on the detailed properties of the discharge nor on its character. The behaviour of a plasma plays an important part in the phenomena of gaseous discharge, a process which finds a wide variety of applications in modern engineering. A special interest in high-temperature plasmas has recently arisen in association with studies on controlled thermonuclear reactions as well as in connection with a number of astrophysical problems.

As is well known, in order to obtain thermonuclear reactions it is necessary to reach such high temperatures (higher than 10^8 degrees) that the energy of thermal motion of nuclear particles is sufficiently large to overcome the energy barriers which hinder the penetration of nuclei into each other. At such temperatures atoms are completely ionized and matter consists of a stripped plasma. Temperatures which are necessary for thermonuclear reactions to take place exist in the interiors of stars.

Under laboratory conditions it has not up to now been possible to prepare a plasma of the necessary temperature. However, intense investigations on high-temperature plasmas, which have already yielded a number of important results, are being carried out.

In astrophysical conditions matter is found in the plasma state not only in the interior of stars but also in stellar atmospheres and in clouds of interstellar matter.

§41. Equilibrium plasma

We naturally begin the study of the properties of a plasma with consideration of the theory of an equilibrium plasma.

We assume for simplicity that the plasma contains charges of only two kinds: positive ions with charge p_1 and electrons. In order to give a general character to the relations to be obtained we shall also call the latter ions and shall assign them the charge $p_2 = 1$. Then the condition of electrical neutrality for the plasma can be written in the form

$$\bar{n}_1 p_1 + \bar{n}_2 p_2 = 0, \quad (41.1)$$

where \bar{n}_1 and \bar{n}_2 are the mean numbers of ions and electrons respectively per unit volume.

In considering the equilibrium properties of a plasma we shall confine ourselves to the approximation of an ideal gas. In this approximation the Coulomb interaction between charged particles can be assumed to be small in comparison with the thermal energy:

$$p_1 p_2 e^2 / \bar{l} \ll kT, \quad (41.2)$$

where \bar{l} is the mean distance between the ions. The latter is connected with the number of ions per unit volume (the concentration of the plasma) N by the relation

$$\bar{l} \approx N^{-1/3}, \quad (41.3)$$

so that the condition of ideality of a gaseous plasma can be written in the form

$$N \ll \frac{kT}{p_1^3 p_2^3 e^6}. \quad (41.4)$$

The concentration of the plasma N is connected with the numbers \bar{n}_1 and \bar{n}_2 by the relation

$$N = \bar{n}_1 + \bar{n}_2. \quad (41.5)$$

If the inequality (41.4) is satisfied, then the plasma, in the zeroth order approximation, can be considered as an ordinary gas characterized by a temperature T .

The particles of the plasma will have a Maxwell velocity distribution and a uniform distribution in space. The Coulomb interaction between charged particles gives rise to a certain mean electric field in the volume of the plasma characterized by a potential $\bar{\varphi}$. In our approximation the change of the properties of the gas caused by this field can be assumed to be small.

In order to find the value of $\bar{\varphi}$ the following reasoning can be applied. We mentally single out a certain arbitrary ion in the plasma located at a point O which is chosen as the origin, and find the total mean potential of the electric field $\bar{\varphi}$ in the neighbourhood of the point O. The potential $\bar{\varphi}$ is produced by all ions (including the ion located at the point O). The averaging is carried out over all times of observation, during which the ions assume all possible positions in the plasma.

We consider a volume element dV located at a distance r from the origin O. Let the potential of the electric field in this volume be equal to $\bar{\varphi}(r)$. In view of the isotropy of the field, the potential $\bar{\varphi}$ depends only on the absolute value of r but not on the direction of the radius vector. For a low concentration of plasma one can apply the Boltzmann distribution law to the ions in the field, writing for the number of particles in the volume dV the expressions

$$n_1 dV = A \exp [-p_1 e \bar{\varphi} / kT] dV, \quad (41.6)$$

$$n_2 dV = B \exp [-p_2 e \bar{\varphi} / kT] dV, \quad (41.7)$$

where \bar{n}_1 and \bar{n}_2 are the numbers of positive and negative ions in unit volume.

The constants A and B can be found in the following way. At an arbitrarily high temperature $T \rightarrow \infty$ the field produced by the ions in the plasma cannot affect their spatial distribution, because their potential energy will be negligibly small. Hence as $T \rightarrow \infty$ both distributions must go over into a uniform distribution of the particles in space, i.e.

$$n_1 dV = \bar{n}_1 dV, \quad (41.8)$$

$$n_2 dV = \bar{n}_2 dV, \quad (41.9)$$

where n_1 and n_2 are the mean numbers of positive and negative ions per unit volume.

Comparing (41.8) and (41.9) with (41.6) and (41.7), we find

$$n_1 dV = \bar{n}_1 \exp [-p_1 e \bar{\varphi} / kT] dV, \quad (41.10)$$

$$n_2 dV = \bar{n}_2 \exp [-p_2 e \bar{\varphi} / kT] dV, \quad (41.11)$$

According to formulae (41.10) and (41.11), in the volume near the point O, where the ion which we have singled out is located, there is a charge

$$de = (\bar{n}_1 p_1 e \exp [-p_1 e \bar{\varphi} / kT] + \bar{n}_2 p_2 e \exp [-p_2 e \bar{\varphi} / kT]) dV. \quad (41.12)$$

This charge is determined by the fact that the probability of finding an ion in dV of the same sign as the ion at point O is somewhat lowered, whereas that of finding an ion of the opposite sign is somewhat increased, in comparison with the probability where we do not take into account the inter-ion interaction. In this sense it is said that a non-uniformly charged ion cloud arises around the ion located at point O.

It goes without saying that in practice there is no cloud around each of the ions, because we have singled out the ion at point O only for convenience of the argument, and all the ions in the plasma are equivalent. There is only a certain correlation probable between the positions of any pair of ions in space. This can be expressed in other words: it can be said that each ion produces around it an ion cloud and, at the same time, is a part of ion clouds of all the other ions in the plasma.

By means of (41.12) one can obtain the mean charge density at the point r :

$$\bar{\rho}(r) = de/dV = e(\bar{n}_1 p_1 \exp [-p_1 e \bar{\varphi} / kT] + \bar{n}_2 p_2 \exp [-p_2 e \bar{\varphi} / kT]). \quad (41.13)$$

Since by our assumption the energy of the inter-ion interaction is small in comparison with kT , one can expand the exponential expressions $\exp [-p_1 e \bar{\varphi} / kT]$ and $\exp [-p_2 e \bar{\varphi} / kT]$ in a series, writing

$$\bar{\rho}(r) \approx - \frac{e^2 (p_1^2 \bar{n}_1 + p_2^2 \bar{n}_2)}{kT} \bar{\varphi}(r). \quad (41.14)$$

The mean potential of the field $\bar{\varphi}$ at a given point of the plasma is connected with the mean charge density $\bar{\rho}$ at this point by the equation of electrostatics

$$\nabla^2 \bar{\varphi} = -4\pi \bar{\rho} / \epsilon. \quad (41.15)$$

Hence for $\bar{\varphi}$ we find the equation

$$\nabla^2 \bar{\varphi} = \kappa^2 \bar{\varphi}, \quad (41.16)$$

where κ^2 denotes the essentially positive quantity

$$\kappa^2 = \frac{4\pi e^2(p_1^2 \bar{n}_1 + p_2^2 \bar{n}_2)}{\epsilon k T}. \quad (41.17)$$

Eq. (41.16) or eq. (41.15), in which $\bar{\rho}$ is defined by (41.13), is called the Poisson-Boltzmann equation and represents the basis of the theory of an equilibrium plasma.

The solution of eq. (41.16) satisfying the requirement of isotropy in space can easily be obtained in polar coordinates. In polar coordinates, taking into account that $\bar{\varphi}$ does not depend on the polar angles θ and ψ , eq. (41.16) has the form

$$\frac{1}{r} \frac{d^2}{dr^2} (r\bar{\varphi}) = \kappa^2 \bar{\varphi}.$$

Introducing a new unknown function $f = r\bar{\varphi}$ we obtain

$$\frac{d^2 f}{dr^2} = \kappa^2 f.$$

The solution of the last equation has the form

$$f = C_1 e^{-\kappa r} + C_2 e^{\kappa r},$$

whence it follows that

$$\bar{\varphi} = C_1 r^{-1} e^{-\kappa r} + C_2 r^{-1} e^{\kappa r}. \quad (41.18)$$

The constant $C_2 = 0$, because the exponentially increasing solution leading to an infinitely large potential for $r \rightarrow \infty$ must be discarded. Hence

$$\bar{\varphi} = C_1 r^{-1} e^{-\kappa r}. \quad (41.19)$$

The constant C_1 can be found from the requirement that near the charge which is singled out the potential of the field should coincide with the Coulomb field of the charge. Hence it follows that

$$\varphi_{r \rightarrow 0} = C_1 r^{-1} \rightarrow p_1 e / \epsilon r,$$

so that

$$C_1 = p_1 e / \epsilon$$

and, finally,

$$\bar{\varphi} = \frac{p_1 e e^{-\kappa r}}{\epsilon r} . \quad (41.20)$$

Formula (41.20) shows that the potential of the field near the ion decreases, basically, according to an exponential law. At a distance $r > \kappa^{-1}$ from the ion the potential turns out to be small. The quantity κ^{-1} characterizing the rate of decrease of the potential is called the Debye length.

In order to elucidate the meaning of the solution obtained, we resolve the potential into the Coulomb potential of the ion which is singled out and the potential $\bar{\varphi}'$ of the field produced by all the other ions:

$$\bar{\varphi} = \frac{p_1 e}{\epsilon r} + \bar{\varphi}' .$$

From (41.20) we find

$$\bar{\varphi}' = \frac{p_1 e}{\epsilon} \frac{e^{-\kappa r} - 1}{r} . \quad (41.21)$$

Let us find the charge density corresponding to the potential $\bar{\varphi}'$. By virtue of (41.15) we have

$$\bar{\rho}' = -\frac{\epsilon}{4\pi} \nabla^2 \bar{\varphi}' = -\frac{p_1 e \kappa^2}{4\pi} \frac{e^{-\kappa r}}{r} .$$

This formula shows that near the ion with charge $p_1 e$ an ion cloud having the opposite sign of charge is formed. The charge density in the cloud decreases exponentially with the distance from the central ion. The total charge of the cloud is equal to

$$\int_0^\infty \bar{\rho}' dV = -p_1 e .$$

The meaning of this result is quite clear: around a given ion there are

grouped with a larger probability ions of the opposite sign. The total charge of the ion cloud surrounding any given ion is exactly equal to the charge of the given ion. The presence around an ion of a cloud of ions of the opposite sign leads to a weakening or, as is usually said, a screening of the field of the ion. Hence the potential of the screened field near the ion decreases more rapidly than the Coulomb potential. The quantity κ^{-1} represents the mean radius of the ion cloud surrounding a given ion.

Introducing the value of the Debye length $\kappa \sim e^2 N/kT$ into the condition of the applicability of the theory (41.4), we can rewrite it in the form

$$N\kappa^{-3} \gg 1,$$

i.e. in the form of the requirement that the mean number of ions confined in the volume of a sphere with a Debye radius must be large enough compared with unity.

The phenomenon of screening is of very great importance in the behaviour of a plasma. It is clear that any charge introduced into the plasma is screened at a distance of κ^{-1} .

Let, for example, the plasma be confined in a container with solid walls. If there is a surface charge on the walls then the field produced by it will be screened and will penetrate into the plasma only up to a depth κ^{-1} . The distance κ^{-1} is thus the thickness of the shielding layer which is formed at the boundary of an equilibrium plasma and which insulates it from external influences.

The same result can be obtained much more quickly by means of the method of correlation functions. That is, we make use of the smallness of the concentration of the plasma to close eq. (48.4) of Part III at the binary function. The latter contains the ternary function ρ_{123} . For small concentrations one can write approximately

$$\rho_{12}(r) = 1 + \psi_{12}(r), \quad (41.22)$$

where $\psi_{12}(r) \ll 1$. Formula (41.22) means that the interaction of particles in the plasma leads to a weak correlation. Further, if the probability of triple collisions between particles in the plasma is disregarded, then the ternary function ρ_{12j} can be written in the form of the product

$$\rho_{12j} = \rho_{12}\rho_{2j}\rho_{1j} \approx 1 + \psi_{12} + \psi_{2j} + \psi_{1j}. \quad (41.23)$$

Substituting this into (48.4) of Part III, we find,

$$\frac{\partial \psi_{12}}{\partial \mathbf{r}_1} = -\frac{1}{kT} \frac{\partial U_{12}(|\mathbf{r}_1 - \mathbf{r}_2|)}{\partial \mathbf{r}_1} - \frac{N}{VkT} \int \frac{\partial U_{1j}}{\partial \mathbf{r}_1} (1 + \psi_{12} + \psi_{2j} + \psi_{1j}) d\mathbf{r}_j. \quad (41.24)$$

We recall that the summation with respect to the index j is carried out over all (in our case two) kinds of particles.

We drop, as small, the term $\psi_{12}(\partial U_{12}/\partial \mathbf{r}_1)$. It is obvious that two integrals on the right-hand side reduce to zero:

$$\int \frac{\partial U_{12}(|\mathbf{r}_1 - \mathbf{r}_2|)}{\partial \mathbf{r}_1} d\mathbf{r}_j = 0,$$

$$\int \frac{\partial U_{1j}(|\mathbf{r}_1 - \mathbf{r}_j|)}{\partial \mathbf{r}_1} \psi_{2j}(|\mathbf{r}_2 - \mathbf{r}_j|) d\mathbf{r}_j = 0.$$

Indeed, they involve integration with respect to the angles of the vector $\partial U/\partial \mathbf{r}_1$, where U is an isotropic function of the corresponding variables. Hence, finally

$$\frac{\partial \psi_{12}}{\partial \mathbf{r}_1} = -\frac{1}{kT} \frac{\partial U_{12}(|\mathbf{r}_1 - \mathbf{r}_2|)}{\partial \mathbf{r}_1} - \frac{N}{VkT} \int \frac{\partial U_{1j}}{\partial \mathbf{r}_1} \psi_{2j} d\mathbf{r}_j. \quad (41.25)$$

We take the divergence of eq. (41.25) with respect to the coordinates \mathbf{r}_1 and take into account that the interaction is the Coulomb interaction, so that

$$\nabla \cdot \frac{\partial U_{12}}{\partial \mathbf{r}_1} = \nabla^2 U_{12}(|\mathbf{r}_1 - \mathbf{r}_2|) = 4p_1 p_2 \pi e^2 \delta(|\mathbf{r}_1 - \mathbf{r}_2|).$$

Then we find

$$\nabla^2 \psi_{12}(r) = \frac{4\pi p_1 p_2 e^2}{kT} \delta(r) + \frac{4\pi e^2}{VkT} p_1 N \sum p_j \psi_{1j}.$$

Setting

$$\psi_{12} = p_1 p_2 \psi(r),$$

we find finally

$$\nabla^2 \psi - \kappa^2 \psi = \frac{4\pi e^2}{kT} \delta(r), \quad (41.26)$$

which is the same as the equation for the mean potential (41.16). The term with the δ -function allows one to take the boundary condition (41.19) into account automatically.

It is easily seen that the correlation function satisfying (41.26) has the form

$$\psi_{12} = p_1 p_2 (1 - r^{-1} e^{-\kappa r}). \quad (41.27)$$

We shall now find the thermodynamic characteristics of an equilibrium plasma. The presence of the Coulomb interaction between the ions and electrons is responsible for the additional energy possessed by the plasma as compared to a neutral gas at the same pressure. This energy is obviously equal to $E' = \frac{1}{2} V \sum e n_i p_i \bar{\varphi}_i$, where n_i is the mean number of particles of the i th kind per unit volume, V is the total volume of the plasma, and $\bar{\varphi}_i$ is the mean potential produced by all ions at the locus of the i th ion.

The mean value of the potential of the electric field at distances $r < \kappa$ (for such distances the formulae derived above have a quantitative meaning) can be written in the form

$$\bar{\varphi}_i = -e p_i \kappa.$$

Hence

$$E' = -\frac{1}{2} e^2 V \kappa \sum n_i p_i^2 = -e^2 \left(\frac{\pi}{kTV} \right)^{\frac{1}{2}} \left(\sum n_i p_i^2 \right)^{\frac{3}{2}}.$$

Consequently, the total energy of the plasma is equal to

$$E = \sum n_i kTV - e^2 \left(\frac{\pi}{kTV} \right)^{\frac{1}{2}} \left(\sum n_i p_i^2 \right)^{\frac{3}{2}}.$$

Making use of the Gibbs-Helmholtz formula (30.11) of Part III, we find the free energy of the plasma

$$F = -T \int \frac{E}{T^2} dT = -V \sum n_i kT - \frac{2}{3} \left(\frac{\pi}{kTV} \right)^{\frac{1}{2}} \left(\sum n_i p_i^2 \right)^{\frac{3}{2}}.$$

The pressure of the plasma is equal to

$$p = - \left(\frac{\partial F}{\partial V} \right)_T = \sum n_i kT - \frac{e^2}{3V^{\frac{3}{2}}} \left(\frac{\pi}{kT} \right)^{\frac{1}{2}} \left(\sum n_i p_i^2 \right)^{\frac{3}{2}}.$$

The pressure of the plasma turns out to be lower than that of an ideal gas of the same density. This result has the following simple meaning: the attraction between charges of opposite signs, which are distributed closer to each other, predominates over the repulsion between charges of the same region.

In conclusion, we stress that although a plasma is a macroscopically homogeneous medium, on the scale $r < \kappa^{-1}$ it is inhomogeneous. This fact is of very great importance for electromagnetic processes in a plasma.

Up to now we have considered the plasma to be a completely equilibrium plasma. However, very often one has to study a plasma which is in incomplete equilibrium*. Namely, since the mass of the heavy ions is very large in comparison with the mass of the electrons, the energy exchange between them in elastic collisions proceeds very slowly. On the contrary, the energy exchange between electrons or between ions proceeds much more rapidly.

If at a certain initial instant of time the plasma was in a non-equilibrium state, then after the lapse of the relaxation time τ an equilibrium (Maxwell) distribution will be established for electrons and ions separately. Each set of particles can be characterized by the proper temperature T_e and T_i respectively. However, for the equalization of the temperatures and the establishment of a common temperature T of the plasma corresponding to equilibrium between the electrons and the ions, a relaxation time $\tau_T \gg \tau$ is necessary.

The presence of incomplete equilibrium in the plasma, which is characterized by two temperatures, does not have a very strong effect on the property of screening which we have described above.

§42. Plasma in static electric and magnetic fields

If a plasma is placed in an external static electric field E , then an electric current will arise in it.

In the absence of an external electric field the Maxwell velocity distribution is established for the ions and electrons in the plasma. When an external electric field is applied, the electrons and ions begin to move preferentially in different directions. A current arises in the plasma in the direction of the applied electric field. The density of this current is

* For more details on incomplete equilibrium see, for example, B.G. Levich, *Vvedenie v statisticheskuyu fiziku (Introduction to statistical physics)* (Gostekhizdat, Moscow, 1954).

$$\mathbf{j} = \sigma \mathbf{E}. \quad (42.1)$$

Up to now we have not tried to elucidate the meaning of the electric conductivity σ , assuming it to be a macroscopic characteristic of the medium. Here, however, it is necessary, if only on the basis of a very rough model, to estimate the value of σ . We proceed from the assumption that ions and electrons form an ideal gas. Let the mean velocities, masses and mean free paths of the ions and electrons be denoted by v_i , m_i , λ_i respectively. In the presence of an external electric field ions and electrons in the plasma undergo an acceleration between collisions in contrast to a neutral gas.

The mean velocity acquired by a particle under the action of the field \mathbf{E} is equal, in order of magnitude, to

$$\bar{u} \sim \frac{e_i}{m_i} E \tau_i,$$

where the mean time of flight between two successive collisions $\tau_i \sim \lambda_i/v_i$.

The systematic motion with velocity \bar{u} leads to a transport of charge in the direction of the field. The current density can be written in the form

$$\mathbf{j} = \sum n_i e_i \bar{u}_i \sim \left(\sum \frac{n_i e_i^2}{m_i} \tau_i \right) \mathbf{E}.$$

Thus, to within a numerical factor,

$$\sigma \sim \sum \frac{n_i e_i^2 \tau_i}{m_i}. \quad (42.2)$$

The values of τ_i will be found in Part VI of this book.

We assume that the value of τ is calculated or known from measurements. In weak fields and at relatively high pressures the electrical conductivity of a system consisting of electrons and randomly distributed ions has a constant value and does not depend on the applied field. The equilibrium velocity distribution of the electrons is disturbed only to a small degree by the external field.

For strong fields and low pressures the situation is different. Under the action of the applied field the electrons are accelerated (since the mean free path in a rarefied gas is sufficiently large) and acquire an energy which is considerably larger than the energy of thermal motion.

On the other hand, in collisions with ions the electrons lose energy. A calculation shows that a velocity distribution of the electrons can be estab-

lished, for which the increase in the energy of the electrons as they are accelerated in the field is compensated for by energy losses in collisions. Such a distribution is not an equilibrium distribution. Nevertheless, since it does not change in time (i.e. is stationary), one can speak of an effective temperature of the electrons which is equal to their mean energy. It turns out to be of the order of magnitude of

$$T_{\text{el}} \sim \frac{1}{k} \left(\frac{M_{\text{ion}}}{m_{\text{el}}} \right)^{\frac{1}{2}} \lambda_{\text{el}} eE, \quad (42.3)$$

(where M_{ion} and m_{el} are the masses of the ion and electron) and very large in comparison with the temperature of the ions and neutral molecules. The electrical conductivity is

$$\sigma \sim E^{-\frac{1}{2}}. \quad (42.4)$$

Let us now consider a plasma in constant electric and magnetic fields. As we shall see below, the magnetic field has a very important effect on the behaviour of the plasma.

The reasoning of §23 can be applied to a system of electrons moving with a velocity \mathbf{v} . Namely, when electrons are moving with respect to the magnetic field an electric field of strength

$$\mathbf{E}_{\text{ind}} = \frac{\mu}{c} (\mathbf{v} \times \mathbf{H}) \quad (42.5)$$

is induced, where μ is the magnetic permeability of the medium (the plasma). In the presence of an electric field \mathbf{E} a current

$$\mathbf{j} = \sigma(\mathbf{E} + \mathbf{E}_{\text{ind}}) = \sigma \left(\mathbf{E} + \frac{\mu}{c} (\mathbf{v} \times \mathbf{H}) \right) = \sigma \mathbf{E} + \frac{\sigma \mu}{c} (\mathbf{v} \times \mathbf{H}) \quad (42.6)$$

arises in the system of electrons. Expressing σ in terms of the quantities involved in it and noting that $\mathbf{j} = n_{\text{el}} e \mathbf{v}$, we can rewrite this last formula in another form:

$$\mathbf{j} = \sigma \mathbf{E} + \alpha (\mathbf{j} \times \mathbf{H}), \quad (42.7)$$

where

$$\alpha = \frac{e\mu\tau_{el}}{m_{el}c} = \frac{\omega_H\mu\tau_{el}}{H} \quad (42.8)$$

and ω_H is the cyclotron frequency for the electrons.

It should be noted that formula (42.7) also remains valid when one takes into account the velocity distribution of the electrons since this has an effect only on the numerical coefficient α .

Let us consider two cases:

- (1) the electric field parallel to the magnetic field, $\mathbf{E} \parallel \mathbf{H}$,
- (2) the electric field perpendicular to the magnetic field, $\mathbf{E} \perp \mathbf{H}$.

In the first case the magnetic field does not directly affect the current density $\mathbf{j} = \sigma\mathbf{E}$ so that $\mathbf{j} \times \mathbf{H} = 0$.

The second case is of great interest. To find the vector \mathbf{j} from (42.7) we first form the scalar product of (42.7) and \mathbf{H} and then the vector product of (42.7) and \mathbf{H} . We then have

$$\mathbf{j} \cdot \mathbf{H} = \sigma(\mathbf{E} \cdot \mathbf{H}) + \alpha[(\mathbf{j} \times \mathbf{H}) \cdot \mathbf{H}] = + \alpha[(\mathbf{j} \times \mathbf{H}) \cdot \mathbf{H}] ,$$

or, since $(\mathbf{j} \times \mathbf{H}) \cdot \mathbf{H} = \mathbf{j} \cdot (\mathbf{H} \times \mathbf{H}) = 0$, we obtain

$$\mathbf{j} \cdot \mathbf{H} = 0 . \quad (42.9)$$

Further,

$$\begin{aligned} \mathbf{j} \times \mathbf{H} &= \sigma(\mathbf{E} \times \mathbf{H}) + \alpha[(\mathbf{j} \times \mathbf{H}) \times \mathbf{H}] = \\ &= \sigma(\mathbf{E} \times \mathbf{H}) + \alpha\mathbf{H}(\mathbf{j} \cdot \mathbf{H}) - \alpha\mathbf{j}H^2 = \sigma(\mathbf{E} \times \mathbf{H}) - \alpha\mathbf{j}H^2 . \end{aligned} \quad (42.10)$$

Whence, substituting (42.10) into (42.7), we find

$$\mathbf{j} = \sigma\mathbf{E} + \alpha\sigma(\mathbf{E} \times \mathbf{H}) - \alpha^2H^2\mathbf{j}$$

or

$$\mathbf{j} = \frac{\sigma}{1 + \alpha^2H^2} \mathbf{E} + \frac{\sigma\alpha}{1 + \alpha^2H^2} (\mathbf{E} \times \mathbf{H}) . \quad (42.11)$$
